RESIDENT PHYSICIAN TO THE JOHNS HOPKINS HOSPITAL, BALTIMORE, MD.

In The Medical News for January 27, 1894, Dr. Da Costa publishes some interesting clinical remarks on the use of guaiacol externally in reducing high temperatures in typhoid fever and other febrile diseases. Following the observations of Sciolla, Bard, Lannois and others, concerning the powerful antipyretic action of guaiacol applied in this manner, Dr. Da Costa states that he was induced to try its effect in the "systemic fevers." The guaiacol was applied with a camel's-hair brush, and then rubbed in for fifteen minutes with the hand, or covered immediately with an impermeable bandage. Thirty to sixty drops at a time were applied, thirty being about the average dose. A very marked effect on the temperature was noticed, a fall of several degrees occurring through two to three to four hours. The effect was so marked in cases where large quantities were used that Da Costa advises small doses in the beginning—not more than twenty minims, for in-

stance, is advised as an initial dose in a temperature of 103°. During the fall in temperature no ill effects were noted on the pulse or the respiration. In one case, after the temperature had reached its lowest point, there were chills on three occasions, but in the other cases no particular reference was made to excessive sweating or to chills. Dr. Da Costa suggests the possible value of this method of treatment in cases of typhoid fever, in which, for one reason or another, baths are inadvisable.

On the appearance of Dr. Da Costa's note we proceeded to test the action of guaiacol in various cases in Professor Osler's wards at the Johns Hopkins Hospital, with results which are perhaps of sufficient interest to note. Guaiacol has been used in all in eight cases. The skin, generally of the abdomen, was washed carefully with soap and water, and dried. The guaiacol was then painted on with a camel's-hair brush and immediately covered with an impermeable dressing, or else rubbed in for fifteen minutes with the hand, the area being afterward covered with a similar dressing. The results, in brief, are as follows:

Case I.—*Acute pneumonia; fall of 3½° in temperature, with profuse sweating in two hours and a half after the application of guaiacol, gtt. xx; chilliness between three and four hours after the application, with rapid return of fever.*

The patient was a male, eighteen years of age, at the fourth day of the disease (January 30, 1894). The temperature, at 8 A.M., was 102.8°; at 10 A.M., 103°; at 12 M., 104.2°; at 2 P.M., 103.6°; at 4 P.M., 102.8°; at 6 P.M., 99.8°; at 8 P.M., 103.4°; at 10 P.M., 103.6°; at 12 midnight, 104°. At 3.30 P.M., guaiacol, gtt. xx, was rubbed into the abdomen. Between 4 and 6 o'clock there was profuse sweating; between 6 and 8 o'clock chilliness. The pulse fell from 92 to 72 at 6 P.M.; at 8 P.M. it was 112. The crisis occurred on the following day.

Case II.—*Typhoid fever; applications of guaiacol, gtt. xxx (1 c.c.), followed by falls in temperature varying from 3° to 4.5°; profuse sweating; chills or chilly sensations with the reaction.*

The patient was a woman, twenty-four years old. On the ninth day of a mild attack of typhoid fever, the temperature being at about 103°, twenty drops of guaiacol were applied to the outer side of the thigh, without previously washing the skin; no effect was noted. On the two ensuing days six applications of guaiacol, each of thirty drops (1 c.c), were made; the skin was washed and the guaiacol rubbed in with the hand. The falls of temperature varied between 3° and 4½°, the lowest point being reached in from two to four hours. In all instances, shortly after the lowest point was reached there were either chilly sensations or a distinct chill, with a rapid rise of temperature. An example of one of these falls after the application is as follows:

On February 1st, the temperature at 4 A.M. was 102°; at 6 A.M., 103.2°; at 8 A.M., 99.8°; at 10 A.M., 100.4°; at 11 A.M., 103.4°. Thirty drops of guaiacol were applied at 6 A.M.; profuse sweating followed between 6 and 8 o'clock; at 10 A.M. there was a chill. The patient was much relieved by the applications, and expressed a desire that they should be continued. The profuse sweating and the chills or chilliness following the applications had had, however, a visibly weakening effect, and the applications were discontinued. Tub-baths and cold sponge-baths were renewed, and there was an uninterrupted recovery.

Case III.—*Pneumonia; application of guaiacol, ℥ss (2 c.c.), followed by a fall of only, 0.8°; further application of gtt xx followed by a fall of 0.2°.*

A male, aged fifty-four, had acute pneumonia. On February 3d, the third day, the temperature at 8 P.M. was 102°; at 10 P.M., 101°; at 12, midnight, 100.2°; at 2 A.M., 101°; at 4 A.M., 101.2°; at 6 A.M., 102.4°. Guaiacol, ℥ss, was applied at 10 P.M.

At 1.30 P.M., on the following day, guaiacol, gtt. xx, was applied, when the temperature was 103°, with no visible effect. Several counts of the leukocytes, before and after the application of the guaiacol, showed no particular change.

Case IV.—*Typhoid fever; application of guaiacol, ℥j (3.75 c.c.), followed by a fall of temperature of about five degrees in three and a half hours; profuse sweating; chill, with rapid rise of temperature, in about four hours.*

The patient was a woman, nineteen years of age. On February 6th, in the third week of the disease, the temperature at 4 P.M. was 103.8°; at 6 P.M., 103.5°; at 8 P.M., 103 4°; at 9 P.M., 102 3°; at 10 P.M., 99.8°; at 12 midnight, 97.6°; at 2 A.M., 104.2°; at 4 A.M., 103.2°. Guaiacol, ℥j (3.75 c.c.), was applied at 8.30 P.M.; this was followed by profuse sweating between 9 and 12 o'clock, and a chill between 12 and 2. The dose in this case was (accidentally) larger than those used previously, and the effect was correspondingly more marked. The chill was quite severe.

Case V.—*Pulmonary tuberculosis; five applications of guaiacol, ♏xxx; falls in temperature varying from 1.2° to 5.8°, occurring in from one to two and a half hours, with profuse sweating and chilliness.*

The patient was a man, thirty-three years of age, with bilateral pulmonary tuberculosis, with excavations. The fever was remittent, with evening exacerbations. The applications in this case were on each occasion thirty minims (2 c.c.) The sweating was so profuse, and the patient complained so bitterly of weakness and exhaustion after the applications, that they were omitted. An example of a moderate fall is the following:

On February 15th the temperature at 2 P.M. was 101°; at 2 45 P.M., 102.2°; at 3.45 P.M, 100.8°; at 4.45 P.M., 99.8°; at 6 P.M., 101°; at 8 P.M., 102°. Guaiacol, ♏xxx, was applied at 2.30 P.M.; there was profuse sweating during the fall in temperature, and chilliness later on.

Case VI.—*Pulmonary tuberculosis; applications of guaiacol, gtt. xx and ℥ss respectively ineffectual; fall of 4.8° in three hours after ℥j (3.75 c.c.); chill in about four hours, with rapid return of fever.*

The patient was a colored woman, thirty years of age, with evidences of infiltration at both apices.

She had had a steady, continuous fever, varying for three days from 100.6° to 103.4°.

On February 10th, guaiacol, gtt. xx, was applied at 5.30 P.M.; this was followed by a slight chill at 10 P.M.; there was no effect on the temperature.

On February 19th, guaiacol, ʒss (2 c.c.), was applied at 9.20 A.M., the temperature being about 101°, without any effect.

On February 19th, the temperature at 2 P.M. was 102.2°; at 3.50 P.M., 102.8°; at 4.50 P.M., 103°; at 5 50 P.M, 98.8°; at 6.50 P.M., 98°, at 8 P.M., 98°; at 9.30 P.M., 103 6°; at 10.30 P.M, 103°. Guaiacol, ʒj (3.75), was applied at 3.50, followed by sweating and a slight chill between 8 and 9.30 o'clock. This patient was a colored woman, with thick skin, hence, possibly, the inefficacy of smaller doses.

Case VII.—*Acute rheumatism; application of* ♏xxx *(2 c.c.) of guaiacol followed by a fall of 3.4° in four hours, with profuse sweating.*

The patient was a woman, thirty-two years of age, with acute rheumatism. On February 19th the temperature at 2 P.M. was 101°; at 3.50 P.M., 101.4°; at 4.50 P.M., 100.4°; at 5 50 P.M., 99.6°; at 6.50 P.M., 99.2°; at 8 P.M., 98°; at 10 P.M., 101°. Guaiacol, ♏xxx, was applied at 3.50 o'clock; there was profuse sweating during the fall in temperature.

Case VIII.—*Typhoid fever; fall of temperature of six degrees in three and a half hours after the application of 2 c.c.* (ʒss) *of guaiacol; profuse sweating; chill lasting an hour, with a return of the temperature in two hours to a point higher than before the application.*

The patient was a man, twenty-one years of age. On February 3d, the ninth day of the disease, the temperature at 8 P.M. was 104 5°; at 10 P.M., 103 5°; at 12 midnight, 103 8°; at 1 A.M., 104°; at 2 A.M., 103°; at 3 A.M., 100°; at 4 A.M., 98°; at 5 A.M., 103.2°; at 6 A.M., 105°; at 7 A.M., 104 6°. Guaiacol, 2 c.c., was applied at 1 A.M; profuse sweating began at 1.45 A.M.; a chill, lasting an hour, occurred between three and four hours after the application.

In almost all of these eight cases the cutaneous application of guaiacol was followed by a marked fall in temperature. In Case II the first application of only twenty drops had no effect. The dose, however, was very small and was applied to the outer side of the thigh without previous preparation of the part. In Case III the results, with twenty drops and with half a dram, were either negative or very slight. This was a case of pneumonia in a fat man. In Case VII twenty drops and half a dram were followed by slight effect, while a dram (3.75 c.c.) showed a marked result. This case was that of a colored woman, in whom the skin was possibly thicker than in the other patients. The lowest point of the temperature was reached generally in from two to four hours, the average time being between three and four hours. In almost all of the cases there was very profuse sweating, of which in one instance the patient complained bitterly. In the majority of the cases after the lowest point in the temperature was reached there was a rather rapid rise, associated in almost all instances with chilly sensations, in several instances with severe shaking chills, the temperature within two hours generally reaching a point as high or higher than at the time of the application. In none of the instances was there any marked effect upon the pulse or respiration During the fall of temperature there was generally some slowing of the pulse; in the cases in which there were marked chilly sensations with the reaction, the pulse was somewhat quickened. In none of our cases were there symptoms of collapse. The urine showed no marked changes. The breath shortly after the application of guaiacol gave a distinct odor of the drug.

Hence, while the antipyretic action of guaiacol was certainly very striking in these cases, the profuse sweating, the marked chills, in some instances even with small doses, and the decidedly weakening effect which was noted in those cases in which it was frequently repeated, have led us to take a somewhat less hopeful view of its possible value than Dr. Da Costa's experience would suggest; and these conclusions would on the whole seem to agree with those which have been reached by the majority of observers who have recently experimented with this drug. Sciolla (quoted by Stolzenburg, *Berliner klin. Wochenschr.*, 1894, No. 5) used guaiacol in a variety of different febrile affections. He applied the drug with a camel's hair brush to different parts of the body, covering it immediately with a protective dressing. The doses used varied between 2 c.c. and 10 c.c.

In all cases there was a fall in temperature lasting between three and four hours, amounting to several degrees C. This fall was generally associated with profuse sweating. After six or eight hours there generally occurred a rapid rise in temperature associated with a chill or chilly sensations. Shortly after the application of guaiacol the characteristic taste was noticed.

Sciolla determined that the drug was excreted in the urine and in the respiration in from five to six hours without deleterious effects. He concluded that, used in this manner, guaiacol is a prompt and harmless antipyretic.

Bard (*Lyon Medical*, June 4, 1893) used the drug by this method in cases of tuberculosis, erysipelas, and pneumonia. At first he used doses of 3 c.c., but soon diminished the doses to 2 c.c. or 1 c.c., or even 0.5 c.c. He noted the profuse sweating in almost all of the cases, and frequently the following chills. He believes that the drug, applied in this manner, may be of value in some cases of tuberculosis, though he recommends special care in the dose with weak patients.

Lannois (*Lyon Médical*, August 6, 1893) obtained exactly similar results in a number of obser-

vations. He notes, however, that in some instances the local effects upon the skin may be unpleasant. In one case, for instance, in which the drug was applied on an area on which tincture of iodin had been recently painted, there was marked exfoliation of the skin, while in another, in which the sweating was profuse, the skin over the seat of application was raised in quite large bullæ.

Stolzenburg (*Berliner klinische Wochenschrift*, 1894, No. 5) made an extensive series of observations in Senator's clinic with similar results, excepting that he notes the falls in temperature as lasting rather longer—between five and eight hours. At the time when the lowest point was reached there was, in a majority of instances, chilliness, or a definite chill, with a rise in temperature to a point even higher than before. There was almost always profuse sweating. In weak patients he has seen symptoms of collapse. While in most instances no ill effects on the respiration and pulse were noticed, the patients often complained of the weakening effect of the sweating. In a few instances a dark color of the urine was noted, similar to that seen in carbolic-acid poisoning. In his conclusions Stolzenburg states that the initial dose should not be above 2 c.c., and that it should probably never be above 4 c.c. on account of the danger of collapse. On account of the weakening sweats and chills, with the reactive fever, he concludes that the continued use of guaiacol is not to be recommended.

It will be noted that all observers agree as to the efficacy of guaiacol applied externally. Its employment has been so far limited to the fever of infectious diseases of various sorts, but in all it has been efficacious. There can be no doubt also that it is *absorbed* directly through the skin. Lannois (*loc. cit.*) tested in three cases the inhalation of guaiacol in considerable quantities for a considerable time, but without effect. Stolzenburg (*loc. cit.*) tried similar experiments with Curschmann's mask. More recently Linossier and Lannois (*Comp. rend. hebd. de la Soc. de Biol.*, February 9, 1894) have shown that while a small amount was actually absorbed by inhalation, as proved by its appearance later in the urine, this quantity was insufficient to affect the temperature. Its *elimination* has been shown by Sciolla and Lannois to take place by the urine and the respiration. The early appearance of the taste suggests that it appears in the saliva. The elimination, according to Sciolla (*loc. cit.*), is accomplished in from five to six hours. Lannois and Linossier have shown that in most instances traces appear in the urine a quarter of an hour after the beginning of the application. The part to which the guaiacol is applied would appear to have some influence upon the rapidity and thoroughness of the action. This would be suggested by the result in Case II of our series, in which the first application on the external part of the thigh showed no result, while afterward doses but slightly larger applied to the abdomen were so efficacious.

There is, of course, no difference in the effect of guaiacol absorbed through the skin from that which follows its introduction into the system in other manner. Lannois, for instance, showed that its action in enemata was exactly the same, the effects appearing in almost the same time. In one instance we have made a similar experiment, the patient being the same colored woman who figures in Case VI in the earlier part of this note.

On March 4th the temperature at 8 A.M. was 100.7°; at 12 M., 100 2°; at 4 P.M., 99.8°; at 5 P.M., (?); at 6.30 P.M., 100 8°; at 7.30 P.M., 98.8°; at 8.30 P.M., 97°; at 9.30 P.M., 95.2°; at 10.30 P.M., 96 8°; at 11.30, 97.2°; at 12 30, 97.3°; at 4 A.M., 104.2°; at 5.30 P.M. guaiacol, 2 c.c., was given by enema. At about 12.30 there were well marked chilly sensations; there was, however, no very marked sweating. The urine after the application showed a well-marked, smoky, greenish-brown color.

Interesting as may be these results concerning the antipyretic action of guaiacol, there is really little that is new, excepting in so far as they prove the readiness of its absorption through the skin. Exactly similar effects have been shown from the hypodermatic and rectal use of creosote, of which drug guaiacol forms the most important part.

Lépine, who used creosote hypodermatically (*Semaine Médicale*, 1890, No. 20, page 221), noted marked sweating after the injections.

Gimbert (*Gaz. hebd.*, Paris, 1891) also noted similar results from the subcutaneous introduction of creosote—*i. e.*, the sweating, the fall of temperature, the chill with reactive rise in temperature.

Revillet (*Semaine Médicale*, 1891, page 266) used creosote by enemata in doses of from 2 c.c. to 4 c.c. He noted the almost immediate taste of the drug in the mouth, the elimination by the respiration, by the urine, by the saliva, the well-marked antipyretic action, with the profuse sweating, and the subsequent disagreeable chilly sensations. Though the creosote was free from carbolic acid, he noted in one instance, two hours after a dose of 3 c.c., a well-marked dark color in the urine. The exact similarity of all these results with those formerly obtained by the administration of carbolic acid may be noted. Lannois (*Lyon Méd.*, 1882, No. 30), for instance, in speaking of the results of the treatment of typhoid fever by carbolic acid, notes the same train of symptoms—the fall in temperature with profuse sweating, the reactive chill and rise in temperature, the discoloration of the urine. This similarity is, of course, not remarkable when one considers the close chemic relation between guaiacol and carbolic acid.

In *conclusion*, then, from the few experiments which we have made here, and from a consideration of the results obtained by other observers, we are perhaps justified in asserting that guaiacol applied to the skin is readily absorbed into the economy; that its application is followed in most instances of fever by a gradual reduction in temperature, which reaches its lowest point generally between three and four hours after the application; that this fall of temperature is almost always associated with disagreeably profuse sweating; at a variable period, usually a short time after the lowest point is reached, the temperature rises rapidly, generally in association with marked chilly sensations, if not with an actual chill; that a dose of more than 2 cc. is rarely advisable; that exactly similar results are produced by the absorption of guaiacol through any other channel (the rectum, or the subcutaneous tissues); that the antipyretic action is exactly similar to that which has been previously observed to follow a corresponding use of creosote and carbolic acid; that owing to the disagreeable effects of the immediate application of guaiacol (sweating and chilliness) and the weakening effects of the continued use, its employment as an antipyretic, as in the case of carbolic acid and creosote, will probably have but a limited application.

CLINICAL LECTURE.

A COINCIDENT INTRA-UTERINE AND EXTRA-UTERINE PREGNANCY—TWO CASES OF OBLIQUELY-CONTRACTED PELVIS—THE PRIMARY REPAIR OF A LACERATED PERINEUM—STRICTURE OF THE RECTUM FOLLOWING A WHITE-HEAD OPERATION FOR HEMORRHOIDS.[1]

By BARTON COOKE HIRST, M.D.
PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF PENNSYLVANIA; OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL AND TO THE MATERNITY HOSPITAL.

COINCIDENT INTRA-UTERINE AND EXTRA-UTERINE PREGNANCY.

Gentlemen: The specimen of a tubal pregnancy that I here present to you was removed a few weeks ago, by abdominal section, from a young woman with a peculiar history. Just four weeks before I saw her she had induced abortion on herself at the fourth month of gestation, by passing into the womb this rubber catheter and its steel stylet that she had bought at a drug-store. Profuse hemorrhage followed, and a few hours later the fetus was discharged. She saw it plainly, distinguished its limbs, trunk, head and face, and from her unprompted description of its development and length it corresponded with the date that she believed pregnancy had reached. She threw the fetus and its placenta down a water-closet. Shortly after the delivery the woman was seized with abdominal pains that increased steadily in severity until she was forced to go to bed. When I first saw her I found the temperature 103°, the pulse rapid and feeble, the abdomen tympanitic and exquisitely sensitive. On vaginal examination, large, tender masses were felt behind and to the right side of the uterus. I concluded, naturally enough, that I had to deal with a case of a common kind in this hospital—septic infection of pelvic tissues from criminally induced abortion. The abdomen was opened the following day, when, to my surprise, I found the conditions characteristic of tubal pregnancy and no sign whatever of septic inflammation. Old clots and a quantity of black blood welled out as soon as the peritoneum was incised, and on removing the right tube a gestation-sac of from six to eight weeks' development was found in it, without an embryo, but with the chorial villi so well developed and so evident that, as you see, there is no mistaking the character of the mass within the tube. Here is an extra-uterine pregnancy that never could have been diagnosticated or even suspected before operation. The intra-uterine pregnancy that must have coexisted with it and the induced abortion completely masked its symptoms. The patient has made a perfect recovery.

OBLIQUELY CONTRACTED PELVIS.

I cannot present to you the next two patients in the flesh, for they are inmates of other hospitals, but I show

Fig. 1.

An obliquely deformed pelvis. (The lines follow the crests of the ilia; the central dot corresponds with the depression below the spinous process of the last lumbar vertebra.)

you their photographs, which are quite as instructive. Figs. 1 and 2 show the pelvis of a young primigravida recently delivered in the Maternity Hospital,

[1] Abstracts from clinical lectures at the Philadelphia Hospital.

under the charge of my friend Dr. Robert H. Hamill, who kindly permitted me to examine her. The girl had developed tuberculous disease of the right knee-joint at the early age of three months. Ankylosis of the joint

Fig. 2.

The same as Fig. 1, but in profile, showing the backward displacement of the left innominate bone.

and atrophy of the limb followed, so that from the time of the first attempts to walk the greater part of the weight of the trunk has been supported by the sound leg. As always happens in such cases, the corresponding innominate bone is displaced backward, upward, and inward, encroaching to some degree upon the area of intra-pelvic space and distorting the shape of the pelvic inlet and canal. The direction of the pelvic canal, too, is altered. The inlet is directed to the unsound side; the outlet toward the sound side. The best known example of this deformity is the unique case described by Mme. LaChapelle, of a young woman who had always borne the weight of the trunk entirely upon one leg, the other being absent. The pelvis was so distorted in consequence that labor was very difficult. I have learned from experience, however, that ordinarily simple, oblique distortion of the pelvis, without atrophy of the sacral ala and ankylosis of the sacro-iliac joint, as in a true Naegele pelvis, is not to be feared. On the other hand, even a slight oblique distortion, along with other pelvic deformity, such as antero-posterior or lateral contraction, is to be dreaded. Cases in the former category may exhibit some slight abnormality in pregnancy or some unimportant anomaly in the mechanism of labor, but the result is usually fortunate. The history of my case bears out this statement. The woman had backward displacement of the womb, and symptoms of incarceration and dysuria suddenly appeared in the fifth month. Eighty-eight ounces of urine were drawn off one morning, although until the night before there had been no difficulty in urination. In labor there was a rather curious anomaly of mechanism —the vertex presented, the occiput was turned forward and to the right, the anterior parietal bone caught on the ramus of the pubis, and the head was laterally inclined, so that the posterior parietal bone descended first into the pelvic inlet and canal. The common Naegele obliquity was reversed. Aside from these two minor complications, there were no difficulties in pregnancy or labor.

The second patient, from the University Maternity, shows a minor grade of the scoliotic obliquely-distorted pelvis. She had congenital syphilis, with some intracranial lesion that determined atrophy and diminished power on the left side. The difference in power between the two sets of spinal muscles has caused a lateral curvature, with the convexity toward the left side. (Fig. 3.) The distortion of the spine necessarily throws the greater weight of the trunk on the left leg, with the same result noted in the preceding case—a displacement of the corresponding innominate bone upward, backward, and inward. This woman is not yet delivered, but I anticipate no special difficulty in labor. A peculiar abnormality at present is a marked lateral tilting of the womb to the left instead of the common inclination to the right side. It was interesting in both of these cases to observe the relation between the spine of the ischium on the affected side and the nearest edge of the sacrum. In the first case it is one finger's breadth nearer on the deformed than on the normal side; in the second there is about half the distance on the deformed that there is on the sound side.

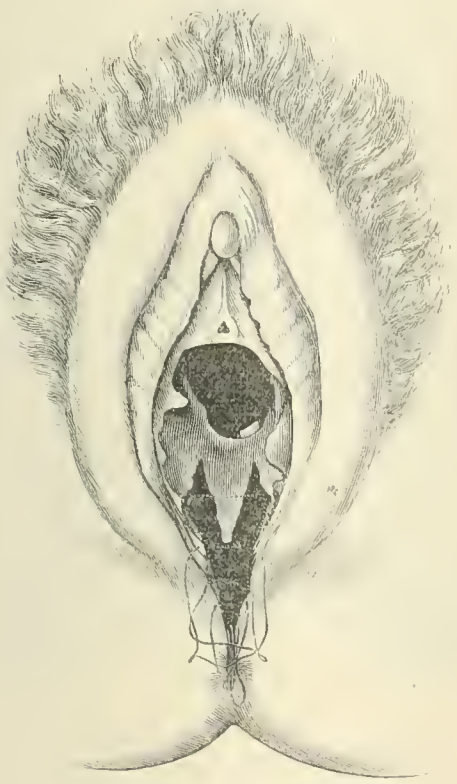
Fig. 3.

A scoliotic pelvis.

PRIMARY REPAIR OF LACERATED PERINEUM.

My next patient has a common condition, but one that should interest you. There has been here a laceration of the pelvic floor in labor at some remote period. There is now a large retrocele as the result of the injury to the levator ani muscles and of the stripping off of the vaginal mucous membrane from its subjacent attachments by the passage of the child's head through the vagina. The method of repairing this old injury must now be familiar to you, for we have had already in this clinic a number of modified Emmet operations. I would prefer, if I could, showing you the method of immediately repairing a primary tear. Were this always done properly there would be few opportunities for the secondary operation. In default of cases of primary

FIG. 4.



Primary repair of lacerated perineum.

tears for clinical demonstration, I have had constructed a gigantic model for class teaching (Fig. 4) that is, perhaps, more instructive than a living woman would be. You observe in this model the perineal tear dividing at the base of the posterior column of the vagina and running up both lateral sulci. It is in these sulcal tears that the levator ani muscle is injured. To restore the pelvic floor satisfactorily and permanently it is necessary to bring the fibers of this torn muscle in firm and accurate apposition. To do this it is very rarely necessary to sew up the sulci separately, as is done in the secondary operation, and this is fortunate for several reasons. In the first place, the operation is tedious and painful, requiring an anesthetic and demanding more skill in plastic surgery than is commonly possessed by the general physician. Further, if one places his stitches in the vagina they must be removed after the vaginal and perineal tears are healed—a troublesome and painful procedure. Catgut stitches would obviate this difficulty, but catgut is not to be depended upon, exposed, as it must be, to the decomposing action of the lochial discharge. The advantages, on the other hand, of the method illustrated on the model are manifold. The stitches are few in number; they can be introduced rapidly and easily, and, tied or shotted on the external perineum, they are easy to remove; an anesthetic is not required in this primary operation, and the ultimate result is perfect if the stitches are inserted deeply enough and with sufficient lateral curve to include a thick bunch of muscle on each side. On this point I can speak with assurance, for I have tested the method thoroughly in hospital and private practice. In the living woman it is necessary to insert, as a rule, two more sutures than are shown in the model, one above and one below the highest stitch. These I have omitted, so as to avoid a multiplicity of sutures that might be confusing. The needle used must be large and well curved. It is convenient to have one set upon a handle, with the eye at the point. This is driven through the tissues threaded with silk wormgut and withdrawn.

UNUSUAL STRICTURE OF THE RECTUM.

The next patient is a woman on whom I operated two weeks ago for a stricture of the rectum. I bring her before you to remove the stitches and to observe the success of the operation. This case interested me much and puzzled me not a little. She informed us that she had been operated upon eight weeks before in another hospital, but for what the operation had been done she could not say. Ever since, she had had great and constant pain in the back, increasing difficulty in defecation, so that she was compelled to take large doses of a laxative every day, and suffered excruciating agony when the bowels did move. On examination, I found a firm, broad annular stricture of the rectum just within the anus, barely admitting the tip of my little finger. There were two angry fissures in ano, and the whole circumference of the stricture was badly ulcerated. The slightest attempt at dilatation caused unbearable pain, and the results of this treatment did not seem to be promising, in view of the deep ulceration and the possibility of carcinoma, an idea that I then entertained. Consequently, I determined on a radical treatment. The recto-vaginal septum was cut with one blade of a scissors in the rectum and the other in the vagina, until the stricture was well exposed to view. This stricture was then completely excised. The end of the rectum was then brought down and stitched to the anus and the wound closed by rectal and perineal stitches, as though there had been a complete tear of the perineum after labor. I am happy to report to you a complete cure. The wound is firmly united, and in perfect apposition; there is entire control over the sphincter, and no difficulty in defecation. From the time the girl left the clinic-room after the operation she suffered none of her former pain. I have recently had the nature of this case satisfactorily explained to me by the surgeon who first had charge of it. He had performed a Whitehead operation for hemorrhoids while his patient was suffering from acute gonorrhea with a

profuse discharge. The area of his operation had been infected and a virulent rectal gonorrhea was the result.

CLINICAL MEMORANDA.

A SUCCESSFUL SIMULTANEOUS TRIPLE AMPUTATION.[1]

By HENRY R. WHARTON, M.D.,
OF PHILADELPHIA;
SURGEON TO THE CHILDREN'S HOSPITAL, THE PRESBYTERIAN HOSPITAL, AND THE METHODIST EPISCOPAL HOSPITAL; ASSISTANT SURGEON TO THE UNIVERSITY HOSPITAL; DEMONSTRATOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

L. J., twenty-one years of age, was admitted to the University Hospital on the night of October 20, 1893, having a short time before been run over by a train on the Philadelphia, Wilmington, and Baltimore Railroad. Upon examination after his admission, it was found that he had sustained a crush of the right leg extending to the knee-joint; the left leg was crushed and torn off in its middle third; and the right hand and lower part of the right forearm were completely crushed. At the time of his admission there was little bleeding from the injured parts, although it was stated that he had lost a large amount of blood before he was brought to the hospital. He exhibited marked symptoms of shock, his surface being cold and his temperature being a little over 96° F. Esmarch's elastic straps were wrapped around the lacerated tissues of the limbs to control any bleeding which was present, and the patient was placed upon the operating-table and surrounded by hot-water cans and covered with blankets; his clothing was only removed so far as to expose freely the injured parts. He was given one thirtieth of a grain of strychnin hypodermatically, and this dose was repeated in half an hour. When I saw him for Prof. Ashhurst, into whose service he came, about an hour after his admission to the hospital, I found that he was reacting from the shock, his temperature was 98° F., and although his pulse was rapid it had some volume. Dr. Girvin, the resident surgeon in charge of the patient, stated that his condition had markedly improved since his admission. Under the circumstances I considered that an attempt to remove the crushed limbs was justifiable. The patient was again given one-thirtieth of a grain of strychnin hypodermatically and carefully etherized, and Esmarch straps were applied to each of the injured limbs some distance above the proposed points of amputation. The right limb was first prepared for operation by washing with soap and water and bichlorid solution, and I amputated this limb just above the knee, making antero-posterior flaps; the vessels were secured by ligatures. While the first limb was being removed the other limbs were prepared for operation by my assistants, so that little time was lost, and I amputated next the left leg a short distance below the knee-joint, making lateral flaps, and the right forearm in its middle third. Having secured the vessels, the stumps were closed and dressed with a bichlorid-gauze dressing.

The patient lost very little blood during the operation, and his condition after its completion seemed to me to be almost as good as before it was begun.

[1] Read before the College of Physicians, February 7, 1894.

He was given strychnin, one-thirtieth of a grain, several times during the operation, receiving in all from the time of his admission five injections hypodermatically of one-thirtieth of a grain each. The time consumed in amputating the limbs and dressing the stumps was about an hour and twenty minutes. The patient was placed on his bed after the operation and was kept surrounded with hot-water cans for twelve hours, was given liquid diet and about four ounces of whiskey in twenty-four hours, and five grains of ammonium carbonate every two hours. His recovery was uninterrupted, and I have the pleasure of showing him to you this evening with his stumps perfectly healed.

A few cases of successful simultaneous triple amputations have been reported by Prof. Ashhurst, and Drs. Jackson, Wallace, Lowman, and others, but the majority of patients that have suffered from injuries requiring this procedure perish promptly from hemorrhage and shock, or are in such a condition when they come under the surgeon's care that no operative treatment can be instituted. Although the mortality following multiple amputations is high, there is no reason why recoveries should not be more numerous under modern methods of wound-treatment if the element of shock could be eliminated. When, however, a case comes under the care of the surgeon, and the condition is such that it seems justifiable to amputate a number of limbs at the same time, I think there are certain details which should be carefully carried out.

In the first place, such cases usually present a condition of marked shock; this is to be overcome by the application of external heat, and by the use of strychnin hypo-

dermatically, the value of this drug as a heat-stimulant in such cases being unquestionable. Stimulants administered by the mouth are usually vomited promptly, and have little effect. Strong black coffee, as hot as the patient can comfortably swallow, is often retained, and in my experience is one of the most useful stimulants that can be taken by the mouth.

The practice of stripping the patient immediately and putting clean clothing upon him, by which means his surface is exposed and chilled, is to be condemned. If the clothing is dry I do not have it removed, but cut away such portions as are necessary to get a free exposure of the injured parts, and often allow the clothing which he wears at the time of the accident to remain upon him until he has thoroughly reacted, often for some days after the operation. As regards the method of amputating, some surgeons consider it advisable to have the limbs amputated at the same time by different operators, so that the patient need be under the influence of the anesthetic for the shortest possible time.

I fail to see the advantage of this method of procedure, for it seems to me that the shock of the operations when thus done synchronously must be greater than when the parts are removed one at a time, as was done in the case I have shown.

I make it a rule to amputate first the limb which has received the greatest injury, and whose removal would most likely be accompanied by the most shock, and, if the patient's condition is not markedly affected by its removal, I then operate upon the second or third, as the case may be. If, however, I find that the patient's condition becomes decidedly worse after the first limb has been removed, and that he would not possibly survive the removal of the other member or members at the same time, I desist from further operative interference, and wrap the other injured parts in an antiseptic gauze dressing and wait until he reacts, which may be in twelve or twenty-four hours; and when reaction has been established, I undertake the further amputation or amputations that may be required. I can possibly illustrate this better by reporting a case in which I adopted this procedure. During my service at the Presbyterian Hospital, in the summer of 1892, there was admitted a switchman who had been thrown from the top of a car and run over, sustaining a crush of both legs below the knee, and an extensive compound comminuted fracture of the shaft of the left femur. As the patient had reacted when I saw him, I amputated his left leg and removed a number of large fragments from the fractured femur, and drained and closed the wounds. Upon examining the patient, before operating upon the other leg, I found that his condition was so unfavorable that I did not think he would survive the removal of the second limb; his temperature, which had been nearly normal before the removal of the first limb, had fallen to 96° F., his pulse was very feeble, and his skin was covered with a cold sweat. I therefore had the other injured limb wrapped in towels which had been wrung out in bichlorid solution, and the patient was treated actively to bring about reaction from the shock. He reacted fully, and when I saw him about eight hours afterward his temperature was 99° F., his skin was dry, and he had a good pulse. He was then etherized and I amputated the second limb, and he made an uneventful recovery.

PUERPERAL FEVER, COMPLICATED WITH EMBOLIC PNEUMONIA AND PHLEGMASIA DOLENS; RECOVERY.

By W. D. JONES, M.D.,
OF RISING CITY, NEB.

Mrs. R., twenty-four years old, a woman of good general health and the mother of two children, fell in labor on November 13, 1893, giving birth to a nine-pound boy in about three hours from the initiatory pains. Labor was normal in every respect. The placenta was delivered without difficulty in thirty minutes from the birth of the child. The uterus contracted well, and was found firm twelve hours after delivery.

At the last visit the patient expressed herself as feeling as well and strong as though nothing unusual had occurred. The lochia were normal in amount and inoffensive in character.

I left the patient, feeling assured that she would have a speedy and uneventful convalescence, as the usual antiseptic precautions had been observed.

I was hastily summoned on November 19th, and found the patient with a temperature of 106° F., the pulse 130. There was marked tenderness over and about the uterus, together with decided abdominal distention and the history of a chill during the previous night.

I gave an intra-uterine irrigation of 1 : 3000 bichlorid solution and left directions for a brisk saline cathartic, and 1 : 3000 bichlorid vaginal injection to be repeated every four hours, with an ice-bag kept over the hypogastrium. The temperature rapidly declined to 102° F., but this fall was succeeded by a chill and a rapid rise to 107°. Intra-uterine bichlorid douches were now given every twelve hours, followed immediately by one of a pint of hydrogen dioxid.

This course of treatment, together with supporting measures, was continued with fluctuations of temperature between 100° and 104° F. until November 27th, when the temperature fell to normal and so remained for twenty-four hours. A chill again occurred, and was followed by a sudden rise of temperature to 103°, with violent pain over the anterior portion of the base of the right lung. This last was only controlled by morphin hypodermatically. Marked dulness over a well-defined area involving about one-fourth of the anterior half of the base of this lung was readily elicited.

The lochia at this time being normal in quantity and character, with an absence of tenderness and distention of the abdomen, and the sudden rise of temperature, with the marked pulmonary symptoms, embolic pneumonia was diagnosticated. The chest was well strapped and morphin given as indicated and supporting treatment continued. The temperature fluctuated between 102° in the morning and 103° in the evening, until the evening of the sixth day of the pulmonary infection, when there occurred a sudden gush of stinking, bloody pus into the bronchi, which for a time nearly suffocated the patient. This was expectorated into a can and must have amounted to between one and two ounces. The temperature suddenly went down to 101.5°.

Under supporting measures and dram-doses, *ter in die*, of syrup of hydriodic acid, with inhalations of chlorin-gas morning and evening, after the method of Drs. Shurley and Gibbes, the quantity and offensive

character of the expectoration gradually decreased to *nil*, with a corresponding disappearance of the dulness and a decline of the temperature to normal by December 14th, when phlegmasia dolens presented itself in the usual manner and claimed attention. This latter trouble was fortunately mild and of short duration; and now, over two months from the initiation of her serious and complicated illness, the woman is practically well.

HOSPITAL NOTE.

A CASE OF PURPURA RHEUMATICA, WITH EDEMA OF THE GENITALIA, IN A MULATTO CHILD.

Polyclinic Hospital, Philadelphia.

SERVICE OF SOLOMON SOLIS-COHEN, M.D.

[From notes taken by THEODORE A. ERCK, M D., formerly Resident Physician.]

W. G., a mulatto, four years old, was admitted to the Polyclinic Hospital, August 24, 1893. It was learned that the child had been abandoned when he was about ten months old. The foster-parents stated that he had always been healthy until two weeks before admission, when his feet, arms, penis, and scrotum, and one of his eyelids, began to swell and became very tender to the touch; they also noticed dark-red spots upon the abdomen below the umbilicus. Upon admission the child presented purpuric spots upon the abdomen, the genitalia, and all four extremities. There was no eruption upon the face, neck, chest, or back. The joints were all sensitive, and the feet, ankles, hands, and wrists swollen. The purpuric spots were especially numerous in the flexures of the knees and elbows. There was marked edema of the prepuce. It was not deemed advisable to puncture in order to determine if the effusion contained blood. The temperature was 101° F., the pulse 104. The urine was clear, reddish-yellow in color, of acid reaction, with a specific gravity of 1024; it contained neither albumin nor sugar. It deposited a slight flocculent precipitate, and upon microscopic examination granular urates were found, and after twenty-four hours spiculated spheres of ammonium urate. There was no evidence of syphilis. Milk-diet was ordered and the following prescription written:

℞.—Sodii salicylatis . . . . ℥ij.
Tinct. ferri chlorid. . . . f℥ij.
Glycerin. . . . . f℥j.
Acid. citric. . . . . gr. x.
Liq. ammon. citrat. . q. s. ad f℥iv.—M.
Sig.—f℥j, in water, every third hour.

The bowels were kept slightly loose with Rochelle salts. On the third day after admission the swelling of the joints was markedly reduced, and they were also much less sensitive to pressure, though motion was exquisitely painful. On the outer side of the left knee and upon the inner side of the left thigh, irregular-shaped blebs, filled with dark, bloody serum had formed. The purpuric spots on the rest of the body had distinctly faded. The joints were wrapped in lint soaked in a solution of tincture of opium, sodium bicarbonate, glycerin, and water. On the fifth day the swelling had entirely disappeared and the spots were hardly visible. The blebs had begun to heal after a process of ulceration. An examination of the eyes, made by Dr. Risley, showed the eye-ground to be rather paler than is usual in colored children and the lymphatics somewhat distended; but there were no spots; there was a high degree of hyperopic astigmatism in the right eye. The child was discharged on the fourteenth day, entirely well.

BACTERIOLOGIC NOTE.

DETAILED DIRECTIONS FOR A SIMPLIFIED METHOD OF PREPARING LOEFFLER'S BLOOD-SERUM MEDIUM FOR DIPHTHERIA-CULTURES.

BY A. P. OHLMACHER, M.D.,
OF CHICAGO, ILL.;
PROFESSOR OF PATHOLOGY, CHICAGO POLYCLINIC.

THE importance of the culture-test in the diagnosis of diphtheria is widely recognized in recent medical literature, and every conscientious physician feels the necessity of applying this test in practice. The subject has been well presented by Councilman[1] and by Parke,[2] and the reader is referred to these papers for practical details in the clinical application of the culture-test. Unfortunately, however, unfamiliarity with the technique of this method handicaps the practitioner; and, as he is often situated out of reach of laboratory assistance, he is compelled to neglect the valuable aid in the diagnosis of throat-affections which the culture-test affords. This objection likewise applies to an ever-increasing multitude of other laboratory methods in clinical diagnosis, and in his capacity of laboratory teacher, the writer feels the great importance of *detailed instruction in technique*. The hope of meeting this demand in relation to the diagnosis of diphtheria is the motive for submitting the following directions.

The actual knowledge of bacteriologic manipulation demanded in the application of this test may be readily acquired. The appliances necessary for this, as for all ordinary bacteriologic studies, are readily procured.[3]

Granting that the physician has mastered the elementary details of bacteriologic technique, the special application of the diphtheria culture-test still presents one considerable difficulty—that is, in the preparation of the special blood-serum mixture of Loeffler.

Councilman (*loc. cit.*, p. 550) has called attention to a simple process by which the difficulty in the preparation of Loeffler's medium is much reduced. This process consists in the immediate coagulation of the serum-mixture in a steam sterilizer, and the subsequent sterilization of the solid serum by the discontinuous method, as employed in the preparation of ordinary agar and gelatin. In the details of Councilman's method, however, certain precautions are absolutely essential, and we wish to direct attention to these details, which were not, for obvious reasons, included in the contribution of Councilman. At best, the preparation of Loeffler's medium is

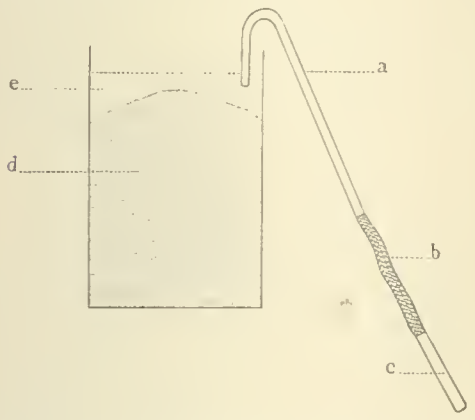
[1] "The Pathology and Diagnosis of Diphtheria," American Journal of the Medical Sciences, November, 1893, pp. 540–552.

[2] Medical Record, February 11, 1893.

[3] The simplified directions, and the descriptions of simple apparatus, in Salmonsen's Bacteriological Technology for Physicians, are extremely valuable to beginners in clinical bacteriology.

a time-consuming task, and the desirability of some more easily prepared medium is felt.[1] It is believed, however, that the following directions will enable a physician to prepare his own blood-serum mixture with a minimum amount of time and trouble.

One or two large glass jars, of a capacity of a gallon each, are sterilized by dry heat; or by washing with a 1 : 1000 sublimate solution, followed by alcohol and ether. The museum jars of Whitall, Tatum & Co. make very convenient receptacles (see Abbott, *Principles of Bacteriology*, p. 70); but any large, covered vessel of glass or metal may be employed, though glass is preferable, because it enables one to view the height of the layer of serum. After sterilization, the jars are taken to the slaughter-house and filled with freshly-shed cows' blood or calves' blood. The blood is to be caught as it spurts from a cut in the throat of the animal. After wiping the sides and edges of the jar the lid is replaced and the jar set aside and kept perfectly quiet until the blood has coagulated firmly. The jar, with its contents, is now to be carried to the laboratory with as little agitation as possible. It is set in a cool place—out of doors in winter, or in an ice-chest in summer—but the mass must not be allowed to freeze.



Diagrammatic. Illustrating the use of a simple siphon for the transfer of blood-serum and other fluids without contamination. *a b c*, the siphon; consisting of the angular glass tube *a*, the rubber tube *b*, and the short glass tube (mouth-piece) *c*. *d*, the coagulum. *e*, the layer of serum.

At the end of twenty-four hours a layer of serum will be seen on the top of the coagulum. This first layer of serum is usually about an inch in depth, and more or less clear and straw-colored. This serum is to be transferred to a flask of sufficient capacity. The most expeditious method of effecting this transfer is by the aid of a siphon, which is to be made from a piece of glass tubing of appropriate length, and bent at the proper angle. The angular glass tube is to be provided with a piece of rubber tubing and a short glass "mouth-piece" on its longer arm.

The length of the angular glass tube, *a*, Fig. 1, will depend on the height of the jar. The rubber tube, *b*, and the mouth-piece, *c*, should each be about three inches in length. The siphon, consisting of the pieces *a b c*, is to be sterilized by steaming an hour or so in the steam sterilizer; or by the employment of a 1 : 1000 sublimate solution, followed by alcohol and ether. The short arm of the angular tube, *a*, is carefully lowered into the serum, where it is to be steadied by an assistant. Then, with the forefinger and thumb of one hand holding the rubber tube, *b*, at its middle, the operator sucks upon the tube, *c*, preventing the serum from flowing into his mouth by pressure upon the rubber tube. The siphon being filled with serum, the terminal tube, *c*, is removed, and the serum is allowed to flow into the previously sterilized flask. The short arm of the siphon is lowered into the serum until the escaping fluid becomes too bloody. A certain amount of blood coloring-matter in the serum does no harm, as will be pointed out; and in fact, it is almost impossible to obtain a perfectly clear serum without a second siphonage.

If the jar containing the coagulum be now set aside for another period of twenty-four hours, a fresh quantity of serum may again be obtained. In this way from 500 to 1000 c.c. of serum may be obtained from a gallon of blood. Of course, the jar of blood and the recovered serum are to be covered and kept in a cool place until sterilized.

While it is advisable to conduct the preceding operations with as much cleanliness and care as possible, it is not necessary to observe the strict precautions required in the effort to obtain *sterile* blood-serum. The sterilization by steam in the present method is sufficient to destroy the ordinary accidental organisms.

Three parts of the recovered serum are now to be mixed with one part of meat-infusion containing 1 per cent. of glucose. This mixture of blood-serum and glucose-bouillon is known as Loeffler's mixture. The meat-infusion, or bouillon, as it is more properly called, is made by macerating one-half pound of lean, finely-chopped beef in a liter of water for twenty-four hours, the mixture being kept at a low temperature. The infusion is strained through a cheese-cloth, and the fluid squeezed out of the beef. To the infusion is added 1 per cent. of beef-peptone, ½ per cent. of common salt, and 1 per cent. of glucose. The mixture is to be rendered *slightly alkaline* by the cautious addition of a strong solution of caustic soda, and then boiled for half an hour, water being added from time to time to compensate for the loss by evaporation. The glucose-bouillon is now filtered through a paper filter, allowed to cool, and then it is ready for mixture with the blood-serum. Of course, if the glucose-bouillon is prepared in advance of the serum, it must be sterilized, after filtering, by heating for twenty or thirty minutes in the steam sterilizer, on each of three successive days.

A sufficient number of test-tubes have, in the meantime, been prepared. For convenience in performing inoculations of the serum with the cotton swabs described by Councilman (*loc. cit.*, p. 550), it is desirable to employ short, wide test-tubes, in preference to long, narrow ones, as containers for the blood-serum. After being carefully

[1] Schloffer (Centrabl. f. Bakteriologie u. Parasitenkunde, 1893, Bd. xiv. No. 20) has directed attention to the value of urine-agar as a diphtheria culture-medium. If the claims of Schloffer be substantiated the matter is one of considerable importance to physicians. Mr. F. E. Wynekoop, assistant in embryology in the College of Physicians and Surgeons of Chicago, is making a series of experiments on the comparative value of urine-agar and other media for the Loeffler bacillus. We will naturally look with interest to the results of these experiments.

washed and brushed, and drained, the test-tubes are stoppered with cotton plugs (the surgeon's plain absorbent cotton is preferable), and then heated until the cotton plugs are observed to brown slightly. This dry sterilization may be done in the oven of a kitchen stove or of a gasolin-stove.

The cotton swabs employed in obtaining the material for inoculation, devised by Prudden and described by Councilman, are prepared in essentially the same manner as the sterile test-tubes. A bit of absorbent cotton is twisted on the roughened end of a piece of wire (No. 16 aluminum wire is a convenient size, and very useful on account of its resistance to oxidation), the length of which is about an inch less than the length of the test-tube that is to enclose it. The wire, armed with its swab, is to be pushed into a clean test-tube, and the test-tube stoppered with a cotton plug. A number of tubes prepared in this manner are sterilized by heating in an oven until the cotton browns.

The mixture of blood-serum and glucose-bouillon is now to be transferred to the test-tubes that have been stoppered and sterilized. At this stage it is necessary to call attention to a very essential precaution—viz., the shunning of *air bubbles* in the serum collected in the test-tubes; for, on subsequent heating, the bubbles persist until the serum begins to solidify, when they burst and leave unsightly and ruinous cavities in the medium. It is necessary, then, to transfer the serum to the tubes with as little agitation as possible, and for this purpose a long glass pipet holding about 8 c.c. is employed. The pipet is plunged into the serum in the flask and filled by gentle suction, its top is closed by the ball of the index finger, and it is then removed from the flask and carefully lowered into the open mouth of the test-tube. The pipet should be steadily lowered into the test-tube, in order to avoid smearing the site to be occupied by the stopper with serum. When the point of the pipet reaches the bottom of the tube, the column of serum is gently released, the pipet cautiously removed, and the tube again stoppered and set aside. In this way the desired number of tubes are filled. About 8 c.c. constitute the proper quantity of the mixture for the wide tubes, and 5 c.c. for the narrower ones.

We have now arrived at the most important step in the preparation of our Loeffler's medium; that is, its solidification and subsequent sterilization. It is here that the steam sterilizer finds employment, and for this method, as for all other bacteriologic manipulations demanding a steam sterilizer, the well-known Arnold steam sterilizer answers every purpose. In the following description this instrument is referred to as the sterilizer.

In the operation now at hand two conditions must be observed, viz.: that only a single layer of tubes be solidified at one time, and that too much heat be avoided. In other words, the heating necessary to effect solidification of the mixture must be uniform and not too intense. These precautions are necessary to avoid an accident which is absolutely fatal to the success of the work; that is, the *production of bubbles* in the medium, which ruin the surface, as already pointed out. We have found, for example, that if more than a single layer of tubes were exposed in the sterilizer, the bottom layer solidified first, and before the serum in the upper tubes had solidified, bubbles had appeared in the lower tubes and spoiled the contained mixture. Further, when the lid of the sterilizer was tightly closed, the heat thus generated seemed invariably to induce the formation of the troublesome bubbles in the solidifying serum. The maxims which we may deduce from these observations are: to expose only a single layer of tubes at one operation; and to solidify the mixture with the lid of the sterilizer ajar.

The surface of the solid mixture, exposed in the test-tubes, must be a slanting one; hence it is necessary to incline the tubes to the proper angle before the medium solidifies. For this purpose the operator may devise a simple basket of wire netting in whch the tubes may be laid at the proper inclination. The sterilizer should be provided with perforated tin or wire-netting shelf, which is placed in the upper portion of the steam-chamber, in order that the tubes may be readily accessible and that the jet of steam may be well diffused. The sterilizer is set on the stove (coal-stove, gasolin-stove, or gas-burner), and when the steam is freely rising in the interior the improvised wire basket containing a layer of tubes of serum is placed on the shelf. The lid of the sterilizer (not the outside "hood") is placed on the top, and so tilted and held in position that a space of a quarter or half an inch remains on one side. The heat under the sterilizer must now be controlled so that, while the steam rises freely, it does not attain a sufficient pressure to raise the temperature to a dangerous degree. From time to time the lid of the sterilizer is removed and the tubes inspected. About fifteen or twenty minutes' heating is sufficient to perfectly solidify the serum. When the mixture is perfectly solid the set of tubes is removed and another batch placed in the sterilizer; and this process is repeated until all the tubes are prepared. On each of the three following days the tubes of solid serum are to be heated for twenty or thirty minutes, in essentially the same manner as just described. However, the rule about a single layer is not quite so absolute, and if due care be exercised about the amount of heat, several layers of tubes in separate baskets may be sterilized at one sitting.

Prepared as here directed, Loeffler's blood-serum medium is an opaque substance, with a beautifully smooth and shining surface. The color of the medium depends upon the amount of blood-pigment in the serum and upon the color of the peptone. With perfectly clear serum and good white peptone,[1] the medium is of snowy whiteness, and, with its smooth, glistening surface, makes an exquisite background for all cultures of chromogenic bacteria. The diphtheria-bacillus, however, usually forms a whitish or grayish culture, and it is therefore evident that the presence of a trace of the chocolate color induced by the blood-pigment would improve the culture medium. It is to the smoothness of the surface, however, that we must look especially in our mixture; for the least trace of a colony is instantly recognized on this smooth surface. This makes clear the disastrous effects

[1] I have found difficulty in obtaining beef-peptone giving the peptone-reaction, and making a colorless aqueous solution. A company of chemists at the Union Stock-yards, Chicago, is however, now making a beautiful product, which it has placed on the market through the agency of E. H. Sargeant & Co., of Chicago.

of bubbles in the medium. A certain quantity of "water of condensation" is expressed out of the serum, and this should be allowed to remain, at least until the serum is to be inoculated, for it exerts an important function in preserving the medium.

Unless certain steps be taken the water in the tubes evaporates, and the mixture rapidly dries and shrinks until it is unfit for use. This may be largely prevented by singeing the top of the cotton plug, pushing it below the mouth of the tube, and then sealing the mouth of the tube with a piece of surgeons' gutta-percha tissue. The neck of the tube is to be slightly warmed, and a piece of gutta-percha tissue placed over the mouth, and then pressed against the warm neck until it adheres all around. The tubes, thus sealed, may be preserved in a tightly covered glass jar that contains an inch or so of water in its bottom; or in a tin pail with a tight lid, the interior of which has been coated with asphalt varnish, and that likewise contains some water at the bottom.

It must be evident that this method may be applied to other blood-serum mixtures than Loeffler's diphtheria-medium, and that, modified in this way, the manufacture of blood-serum media is robbed of much difficulty. At best, however, the preparation of Loeffler's diphtheria culture-medium is a time-consuming task, to which the busy physician will only devote himself under protest, and we will look with pleasure for the announcement of some equally efficient and more easily prepared medium.

Laboratory of Pathology, Chicago Polyclinic.

MEDICAL PROGRESS.

Dysmenorrhea.—In a paper recently read before the Medical Society of the State of New York, Dr. Howard A. Kelly defined dysmenorrhea as pelvic pain at the time of menstrual congestion and menstrual flow, and thus a concomitant symptom of a large variety of diseases of the uterus, tubes, and ovaries.

An analysis of 400 cases in which celiotomy had been performed for pelvic lesions showed that 289 suffered from dysmenorrhea. Of the whole number 255 had some form of obscure pelvic ailment, such as usually escapes the attention of the general practitioner—*e. g.*, pelveo-peritonitis, with adherent ovaries and tubes, tuberculous peritonitis, pyosalpinx and hydrosalpinx, tubo-ovarian abscess, salpingitis and hematoma of the ovary—and among these dysmenorrhea was present in 180 cases. In addition, there were 55 cases of retroflexion, of which 44 also suffered from dysmenorrhea. The majority of these patients applied for relief solely because of their pelvic pains, which were aggravated at the menstrual period, and many of them had been treated for months and years for dysmenorrhea. Small myomata are also the cause of this symptom. Such growths may frequently be detected by careful rectal examination in young women who have been treated for years for dysmenorrhea. A similar manifestation attends the presence of large myomata filling the pelvis. The conclusion thus seems justified that many patients who are being treated for dysmenorrhea have some minor or obscure pelvic lesion as its source.

There is another type of dysmenorrhea common to young girls in whom the menstrual habit is becoming established. This type is usually associated with a variety of dyscrasiæ, the most prominent of which is chlorosis, and does not often persist beyond the twentieth year.

There is also a dysmenorrhea of neurotic and hysteric women, whose entire nervous system is at fault, and in whom moderate pain is described as "agony." This type is especially prone to be associated with defective development of the uterus and ovaries. In the treatment of dysmenorrhea the use of morphin is justifiable under but one condition, and that is when the dysmenorrhea occurs in a patient who is being prepared for the removal of some gross pelvic lesion which is the cause of the symptom. It should be a cardinal rule never to give morphin in any case of protracted disease marked by recurring paroxysms of pain, and which does not tend toward a fatal issue. In young girls attention to hygiene, regulation of exercise and study, and above all, rest in bed are essential in the treatment. Mild sedatives, hot teas, and a full, hot hip-bath, with the administration of aloes and myrrh or asafetida to empty the lower bowel, help to accentuate the pelvic congestion and thus hasten the flow. So-called "local treatment" in young women is rarely of value, and once begun is likely to be kept up indefinitely. If the dysmenorrhea be persistent and excessive in this class of cases, a thorough examination per rectum and abdomen under anesthesia should be made without delay.

When serious pelvic lesions exist which threaten life, or are incompatible with fair health, and there is no prospect of relief from other measures, the tubes, ovaries, or uterus should unhesitatingly be removed. When dysmenorrhea persists and no local lesion is discoverable to account for it, a thorough dilatation of the cervix is often of service. Many cases are thus relieved for a time, a smaller number are permanently benefited and a few are permanently relieved. The most effective field for this operation is in those cases which are distinctly spasmodic in character. As a last resort, it is right in rare instances in which the patient is not neurotic, and occasionally even in the presence of this complication, to remove the ovaries and tubes, even though they are perfectly normal, in order to stop painful menstruation which is wrecking the patient's health.

Acute Yellow Atrophy of the Liver in a Child.—In view of the rarity of acute yellow atrophy of the liver, and more particularly in children, a case reported by Merkel (*Münchener medicinische Wochenschrift*, 1894, No. 5, p. 86) would seem worthy of record. The case was that of a boy, six years old, in whom a day or two after the eating of unripe fruit progressive icterus developed, together with anorexia, malaise, emaciation, itching of the skin, coated tongue, and constipation. The temperature was at times slightly elevated above the normal; the pulse was at first infrequent and strong, subsequently, however, increasing in frequency and losing strength. The hepatic dulness early extended below the costal margin, but later became diminished more than half. The spleen, at first not increased in size, subsequently became enlarged. Finally convulsions set in, coma developed, and death ensued. Upon post-mortem exami-

nation a fairly large thymus gland was found persistent and containing several ecchymoses. The pleural cavities contained a small quantity of icteric serous fluid. The pulmonary pleura presented numerous punctiform hemorrhages. The lungs were edematous, and the lower lobe of the left lung contained an infarct as large as a hazelnut. The margins of the leaflets of the mitral valve were nodular and thickened. The peritoneal cavity contained a small quantity of icteric serous fluid. The mesentery and the omentum presented numerous ecchymoses of various size. The liver was soft and greatly diminished in size, the spleen soft and increased in size. On histologic examination the liver was found to be in a condition of acute parenchymatous inflammation. The kidneys were in a state of cloudy swelling.

Traumatic Cyst of the Pancreas.—BROWN (*British Medical Journal*, No. 1716, p. 1106) has reported the case of a lad, seventeen years old, who was struck violently in the abdomen by the buffer of an engine. The abdomen became swollen and was tapped on the left side, seventy ounces of blood-stained fluid being removed. Six weeks later an additional sixty ounces were removed. The patient did well for eight weeks, when he fell from a horizontal bar and immediately became very ill, complaining of severe abdominal pain. The abdomen was greatly distended, tender and dull on percussion. The symptoms becoming more pronounced an incision was made in the median line below the umbilicus, about three pints of blood-stained fluid being evacuated and a drainage-tube inserted. None of the pancreatic ferments could be found in the fluid. The patient improved for a few days, but subsequently a large swelling made its appearance in the upper part of the abdomen, together with a good deal of pain and some vomiting. The abdomen was now opened close to the umbilicus, the stomach and omentum drawn up, and the wall of the cyst exposed; this was punctured with a trocar, and three pints of dark-colored, peculiar-smelling fluid withdrawn. The opening in the cyst was enlarged, the edges attached to the abdominal wall, and a drainage-tube introduced. The fluid contained the pancreatic ferments. Seven weeks later the boy was discharged, well.

Changes in the Blood of Syphilitics.—At a recent meeting of the Royal Society of Physicians of Budapest, JUSTUS (*Wiener medizinische Presse*, 1894, No. 6, p. 224) detailed the results of observations made in the course of a study of the blood of one hundred cases of syphilis. He found that when the course of the disease was uninfluenced by treatment the proportion of hemoglobin declined with the development of the symptoms, to again augment with the recession of the symptoms. When mercurial treatment was instituted the first intramuscular injection was followed by a marked decline in the proportion of hemoglobin, and this in the course of a few days by a compensatory rise. Subsequent injections were likewise followed by a decline, which varied with the intensity of the symptoms present. Finally, however, a point was reached at which the injections no longer caused a decline, but an augmentation, and this went on until the amount of hemoglobin exceeded its level at the beginning of the treatment. Corresponding changes were observed to follow the employment of mercurial inunctions. In both instances the increase in the amount of hemoglobin corresponded with the setting in of improvement. In the discussion that followed, JENDRASSIK ascribed the diminution in hemoglobin following upon the ingestion of mercury to a dilution of the blood and not to a destructive action upon the blood coloring-matter itself.

Five Cases of Pseudo-hypertrophic Paralysis in One Family.—SIMPSON (*Medical Press and Circular*, No. 2854, p. 57) has reported the occurrence of five cases of pseudo-hypertrophic paralysis in a family of ten children. The oldest child was a boy, fifteen years of age, who was well until he was ten, when, in the sequence of a severe attack of measles, he began to present stiffness and awkwardness in rising from his seat. Then a waddling gait developed, the calves were seen to enlarge, the spine to become curved, and the shoulders prominent. He gradually became weaker and was bedridden for two years. He was much emaciated and only slight movement remained in the arms. The legs were contracted and atrophied; the spine was greatly curved anteroposteriorly and laterally. The facial and lingual muscles were enlarged. The reflexes were normal, and trophic and sensory changes were not present. The second child in the family was a girl, thirteen years old, who was healthy; the third, a boy, eleven years old, who was affected with pseudo-hypertrophy; the fourth and fifth, both boys, died in childhood of bronchitis; the sixth, seventh, and eighth, all boys, respectively seven, five, and three years old, were affected with pseudo-hypertrophy; the ninth, a girl of seventeen months, was apparently well; the tenth, a boy, six months old, was well. The family history was good and free from neuroses. There was no consanguinity.

Erythromelalgia.—LEWIN and BENDA (*Deutsche medicinische Wochenschrift*, 1894, Nos. 3, 4, 5, 6) have gathered reports of some forty cases of erythromelalgia from the literature, including three personal cases, and as a result of their study have come to the conclusion that the symptom-complex is not a disease *sui generis*, but sometimes an accompaniment of diverse spinal and cerebral affections, at other times one of the manifold symptoms of a general neurosis, *e.g.*, hysteria, neurasthenia, etc.; in some instances it is to be viewed as a neuralgia or neuritis, in other instances as a reflex manifestation. The conception of erythromelalgia as a vasomotor neurosis is not adequate to explain all of the conditions. The vascular phenomena are of but subordinate importance, as compared with the neuralgic pain. As a matter of fact, they usually appear later than the pain and bear no causal relationship to this. Besides, vascular disturbance may be present, with an entire absence of pain. The clinical picture of erythromelalgia is viewed as the reverse of that presented by Raynaud's disease, which is also looked upon merely as a symptom-complex (sometimes of peripheral origin, dependent upon a neuritis; at other times of central origin, dependent upon disease of the brain or spinal cord), and not a disease *sui generis*. In some of the cases reported an inter-relation apparently existed between both of these conditions.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

SATURDAY, MARCH 31, 1894.

THE TEACHING OF PHYSIOLOGY AND HYGIENE IN THE PUBLIC SCHOOLS.

WITHIN a few years laws have been passed in most of the States of the Union requiring the elements of physiology and hygiene, as regular branches of study, to be taught to all the pupils in schools receiving State aid. In Pennsylvania the law is very plain in the statement that the subject *must* be taught to all the pupils in the schools, and a decision issued from the Pennsylvania School Department affirmed that all pupils who were old enough to read should possess a text-book on physiology, from which they should regularly recite so long as they remained pupils in these schools. In the village and rural schools this decision has very generally been carried out until quite recently. In the city schools, and in the State normal schools, colleges, and other institutions of learning receiving State aid, practically no attention has been paid to the letter of this State law.

We desire to call the attention of physicians to the text-books on this subject now in use; to the preparation received by teachers for the work; to the time given to the subject, and, lastly, to the undesirability of physiology in the elementary schools at all.

The Pennsylvania law, making physiology a compulsory subject to be taught in the public schools, states that a portion of each chapter in the text-books shall be devoted to a discussion of the effects of alcohol and tobacco on the human body. The law in other States is very similar to that in Pennsylvania, though in some States *one-fourth* of each book must treat of alcohol and tobacco. Each chapter has one or more topics, as, for example, "The Effect of Alcohol on the Bones," "The Effect of Alcohol on the Skin;" "The Effect of Alcohol on the Muscles," on the connective tissue, cartilage, liver, spleen, lungs, heart, blood-vessels, etc., and then for tobacco there are similar topics for each tissue and organ of the body. This is due to an effort to conform to the spirit and letter of the law.

The present law practically rules out of the schools really excellent books, such as LINCOLN'S *Hygienic Physiology*, by DR. D. J. LINCOLN, the expert on school-hygiene, and late secretary of the Health Department of the American Social Science Association; *Elements of Hygiene*, by DR. EZRA HUNT, secretary of State Board of Health of New Jersey; the monographs of HUXLEY and YOUMANS, of WALKER, HUTCHINSON, and others written by educated physicians. Indeed, there is hardly a first-class elementary text-book on physiology and hygiene which to-day fully conforms to the Pennsylvania law.

A second objection to the books is that they are often very loosely and inaccurately written. The more popular the book, the more inaccurate is the rule. A few of these more striking errors are as follows: "Chloral hydrate taken in proper quantities is entirely safe, and is exceedingly pleasant in its effects." "Albumin, when once deposited by the blood, cannot be dissolved and washed away again." Other errors have been recently alluded to by DR. G. G. GROFF, in *Science*:

"One of the best of these books several times makes the positive assertion that tobacco produces carcinoma in its users. Another volume asserts that consumption may be caused by putting on spring clothing too early in the season. One also reads that cider-drinkers are peculiarly crabbed and cross; that tobacco makes old men ill-natured; that sour milk is unwholesome, cheese indigestible, *pork a meat not fit to eat*, and that bile has the properties of baking-soda. Here is a fish-story told in the words of a highly-commended book: 'The Esquimaux who live in Greenland drink one or two quarts of oil, and eat several pounds of candles every day.' But see how a story will 'grow' even in a scientific text-book. In the next number of the 'series,' written by the same author, and from the same reliable notes, doubtless, we read: 'An Esquimaux consumes about twenty pounds of blubber fat daily, besides drinking several quarts of

train oil.' What it will be in the next volume, who can tell?

"As to the style and accuracy of these 'scientific' treatises, the following may be taken as samples: 'The eyeball is a bag (!) almost round, thick, and dull everywhere but in front, where it has a transparent covering called the cornea, meaning a horn. This is fitted into the eye just as a watch-crystal is fitted into a watch. The back chamber' (of the eye) 'also holds a jelly-like fluid, called the 'glassy humor,' which allows the iris-curtain to float and move freely."

In another book it is affirmed that cattle exhaust the lime from old pastures, and become diseased, unless the farmer limes the field—a most silly assertion.

It is of such matter that the more popular of these books is composed.

A third objection to the books is that, in the main, they are treatises on anatomy, with some physiology, and a very little hygiene thrown in. Now, children should be instructed in the elements of personal hygiene, but of anatomy and physiology the less they know the better, because the knowledge will be so imperfect that they will be better off without it. A well-known series of books, for children from eight to twelve years of age, is more difficult to comprehend than would be the anatomies of GRAY and LEIDY. They are simply compends of anatomy, with all the scientific terms retained; things utterly useless to children of the age named.

A fourth objection is that these books claim to give reliable statements in reference to alcohol and tobacco. On this point we again quote from the article in *Science:*

"Many of them contain a statement, printed in a prominent manner in the first portion of the book, that they contain '*a full and fair treatment of the nature and effects of alcoholic drinks and other narcotics in connection with relative physiology and hygiene.*' When the books are examined, however, the 'full and fair treatment' dwindles into statements, true and imaginary, of the evil effects of alcohol on the body. There is no effort at all made to discuss the different effects of large and small doses, of the effects on a full and on an empty stomach; of individual idiosyncrasies, and not a word of the beneficial effects of alcohol and narcotics when properly used. There can be no doubt but this unfair, unscientific, and untruthful manner of presenting this subject is having an effect, exactly the reverse to that which is intended. Children will soon find out that they have been deceived, and the result will be worse than if nothing had been said at all on the subject."

The law requires the effects of narcotics and stimulants on the human body to be taught; it does not require imaginary effects; it does not require one-sided statements; it does not require untruths to be taught. They are a poor sort of temperance-lessons and have the faults of the average temperance-lectures, *i. e.*, exaggeration. This is illustrated by the following passage taken from a popular book:

"It happened that about this time one of these chemists succeeded in distilling some alcohol from a fermented liquid. He tasted it, and at once noticed its power to excite the body and make him forget care and trouble. He felt young again, and was now sure he was the possessor of the long-sought-for 'elixir.' He advised his friends to drink freely of the newly-discovered liquid, telling them it would bring back to them their youth and strength. But, as might be expected, after a wild career of drunkenness he died in a drunken stupor."

Who was this discoverer, and where is to be found the account of his life?

In most of the States it has been apparent that legislators have thought that physiology could be taught without any preparation on the part of teachers, for the laws have been passed, and teachers are required *at once* to teach the subject. No time has been given for preparation. Up to the passage of the laws teachers had not been prepared in this subject, and even to-day probably not more than three or four of the normal schools in Pennsylvania are attempting to give any adequate preparation to their students in this branch. What is true of normal schools is also true of high schools and colleges. One term of thirteen weeks is the usual time allotted to the elements of anatomy, physiology, and hygiene. Any physician well knows how much can be acquired in that time, certainly not enough to teach the subject. It is also to be borne in mind that teachers have had no training in chemistry, and yet, in large part, physiology is a department of chemistry. How can any person ignorant of chemistry teach the effects of alcohol and tobacco on the body? It is sheerest nonsense to attempt it. Even in our normal schools physiology is taught without any knowledge of chemistry. The least possible smattering of the subject seems to be thought all that is necessary on this subject on the part of teachers and superintendents. We were recently asked if we did not think a teacher qualified to instruct in this branch after mastering a certain very elementary primer. The question came from the superintendent of one of the leading cities in Pennsylvania. But this position is not to be wondered at when we recall the position occupied by laymen in reference to medical subjects in general. Teachers are not at present qualified to teach this branch, in the ordinary courses in colleges or normal schools. Special

preparation is required, or the subject should not be taught.

The facts in many of the elementary text-books could all be mastered by a bright child in two or three weeks. For these primers contain only about 100 to 150 pages of large type, heavily leaded. In rural, ungraded schools, from this primer, by an untrained teacher, recitations are conducted every day in the week, and every week in the school year. And for what? Certainly not to instruct the child and to make a better citizen, but rather to satisfy the whims of certain would-be reformers. That this is not exaggeration, the case of a lady teacher may be mentioned, who recently told us that for *three years* she had daily conducted recitations with the same primer and the same class of boys and girls. And this nonsense, as decided by the State Department of Schools for Pennsylvania, must continue through the grammar school and high school, or so long as the children remain in school. The children are early, and justly, disgusted with the subject.

To the question: "Should physiology be taught at all in the public schools?" we answer, positively, no, except in the high school, and then only if a competent teacher is provided. The children of the public schools are unable, without a knowledge of chemistry, to understand the teachings of physiology; nor is it desirable that they should be informed on such subjects. The ugly pictures of the interior of the human body, the skeleton, and the skinned men, showing off their distorted muscles, are sights entirely unsuited to the children in our public schools. They need none of these things, and are, indeed, injured by them.

What should be taught is *the elements of hygiene*, divested of all anatomy and physiology. Very small children can be taught how to care for their eyes, to keep the feet dry, how and what to eat, to avoid dirty and foul water; how to care for the body; the importance of cleanliness, of sleep, and all the rest—in a word the whole subject of personal hygiene can be taught to young children and comprehended by them without the least knowledge of anatomy and physiology.

The reform to be wrought is to secure text-books on elementary hygiene, and then to labor that they displace the books now in the hands of the children.

Since the foregoing was written it is reported that the present Superintendent of Public Instruction for Pennsylvania has decided that all the pupils in the public schools must study physiology.

THE PROPOSED NATIONAL BUREAU OF PUBLIC HEALTH.

The National Quarantine Committee of the New York Academy of Medicine, after a careful study of the subject and much correspondence, has materially modified the bill for a national health and quarantine system which it presented to Congress last winter, and has embodied its conclusions in "A Bill to Establish a Bureau of Public Health within the Department of the Interior of the United States," which it will now urge Congress to enact into a law.

The essential features of this bill are in many respects the same as those advocated by The Medical News in the number for December 31, 1892, p. 739. It separates the executive work of maritime quarantine from the legislative and scientific work to be done, leaving the former to the Marine-Hospital Service, and designating the latter as the special business of the National Health Bureau, which is placed under the Department of the Interior, and not under the Treasury Department. This separation appears to us to be very desirable—a single head is probably best for executive purposes—but the rules should not be made by the person who is to enforce them.

The proposed Bureau is to consist of a Commissioner of Public Health and an Advisory Council. The Commissioner is to be an expert sanitarian, appointed by the President of the United States, with the approval of the Senate, and is to receive a salary of $6000 per annum. The Advisory Council is to consist of one member from each State, to be appointed by the Governor of the State, and to be a physician of good repute and standing. The members of the Council receive no pay, except their travelling expenses and board while actually engaged in the performance of their duties, but it is probable that for all States having a State Board of Health, the salaried officer of that Board would be the member of the National Advisory Council.

The original suggestion of The Medical News was that the members of the Advisory Council should be appointed by the President of the United States, and should include, in addition to physicians and sanitarians, some representatives of the commercial interests of the country. It is probable, however, that a council composed of persons appointed by the several Governors of the States would be more truly a representative body, each member of which would have a certain amount of

influence in his own State, than would be the case if all the members were appointed by the President —but the limitation of the choice of each Governor to physicians of good repute seems a necessity in this case. It might, perhaps, also be well to require that the selection be made from members of the State Board of Health for those States which have such a Board, but this is not an important point.

The duties of the proposed Bureau of Public Health are stated to be "to collect and diffuse information upon matters affecting the public health, including statistics of sickness and mortality in the several States; the investigation by experimental and other methods of the causes and means of prevention of disease; the collection of information with regard to the prevalence of contagious and epidemic diseases, both in this and other countries; the publication of the information thus obtained in a weekly bulletin; the preparation of rules and regulations for securing the best sanitary condition of vessels from foreign ports, and for the prevention of the introduction of infectious diseases into the United States, and of their spread from one State into another, which rules, when approved by the President of the United States, shall have the force of laws; the ascertaining by a suitable system of inspection that these rules and regulations are properly carried out and enforced; the advising and informing the several departments of the government and executive and health departments of the several States on such questions as may be submitted by them to it, or whenever, in the opinion of the Bureau, such advice and information may tend to the preservation and improvement of the public health, and in general to be the agent of the general government in taking such action as will most effectually protect and promote the health of the people of the United States."

There can be no doubt in the mind of any intelligent man that the United States ought to have a Bureau of Public Health, charged with the duties indicated, and it would certainly save the nation many times its cost.

It is possible that opposition to the bill may come from the Marine-Hospital Service of the Treasury Department, at whose hands some of the provisions here contemplated have in the past been carried out. This bill provides that the Treasury Department, which means the Marine-Hospital Service, shall have charge of the carrying out of the rules and regulations pertaining to maritime quarantine made by Congress or framed by the National Bureau of Health and approved by the President. No doubt it will be objected to this, that one department should not make rules to be carried out by another, but as a matter of fact this is frequently done, and must be done—for no department of the Government is an absolutely independent autocratic power. The Post Office Department must enforce rules made by the Customs Bureau of the Treasury, the Navy must do the same, and must also at times act under the direction of the State Department. Perhaps the newest departure in the bill is the provision for inspecting the work of the quarantine officials of one department by officers of another department, but this is not without precedent, and the advantages of having such an independent inspection are manifest, while there is no more reason why it should not be done than why a State or municipal quarantine establishment should not be inspected by officers of the Marine-Hospital Service. We see nothing in the bill which is actually objectionable, while it contains much that is very desirable, and it is in full accord with the views and wishes of the physicians and sanitarians of the country. There are some, it is true, who would prefer to have a separate and independent Department of Public Health, with a Cabinet officer at its head, but it is perhaps doubtful if the time has yet come for the establishment of a department of this kind, and we believe that the New York committee has acted wisely in proposing to put the matter into the hands of a representative bureau in the Department of the Interior, which is the department to which the great majority of public health questions in this country naturally belong.

EDITORIAL COMMENTS.

Legislation for the Prevention of Blindness is needed in every State of the Union; it is simply inhuman as well as financially expensive that such laws do not to-day exist. At the last meeting of the American Medical Society a committee of the Ophthalmological Section was appointed to draft the form of such a law and put in action the machinery to secure its passage by the Legislatures of all the States. The following is the form agreed upon by the committee:

The people of the State of —— represented in Senate and Assembly, do enact as follows:

Section 1. Should one or both eyes of an infant become inflamed, or swollen, or reddened at any time within two weeks after its birth, it shall be the duty of the midwife or nurse having charge of such infant, to report in writing, within six hours, to the health-officer

or some legally qualified practitioner of the city, town, or district in which the parents of the infant reside, the fact that such inflammation, or swelling, or redness of the eyes exists.

Sec. 2. Any failure to comply with the provisions of this act shall be punished by a fine not to exceed two hundred dollars, or imprisonment not to exceed six months, or both.

Sec. 3. This act shall take effect on the —— day of ——, eighteen hundred and ninety ——.

Physicians need no argument or explanation as to the pressing need for such a law. The difficulty lies in getting legislators to devote an instant's time to the matter. In one State a correspondent averred that it would be impossible to secure the passage of such a law because there is, of course, no "blood-money" to pay the lobbyists and the "other necessary expenses."

Dr. Howe, of Buffalo, N. Y. (the chairman of the committee referred to), who has devoted much attention to this subject, calculates that the cost to the United States for support of the blind and for loss of their wages is, at a low estimate, more than sixteen million dollars a year.

In our country there are over 50,000 blind, a very large proportion of whom, as we all know, are unnecessarily blind. It only needs the passage and execution of a law such as that proposed, to at once reduce by large fractions the suffering and expense entailed by what should be legally criminal neglect and ignorance as regards the almost certain prophylaxis of this disease.

Already four States have such a law—New York, Maine, Rhode Island, and Minnesota—and Ohio is about joining the roll of honor.

In Pennsylvania, and in all other States except these four, the disgrace goes on, and year by year our neglect and indifference permit the multiplication of the blind as a result of ophthalmia neonatorum. Every medical (local or State) society should pass resolutions as to the duty devolving upon the law-makers, and see to it that a copy of the resolution and of the desired law is sent to every member of the Legislature. In England, owing to public laws and precautions, the number of blind has fallen from 1021 to the million, in 1851, to 809 per million, in 1891, with a sharp decline still in progress.

The Necessity of a Mydriatic in Prescribing Glasses is a truism denied with considerable persistence by some oculists. If the premises of those who advocate the "uselessness of the mydriatic" were admitted or admissible, then their conclusion would necessarily follow, and both the physician and the patient would, indeed, be spared considerable bother and labor. But the premises so cooly taken as axiomatic are denied by those who stick to the mydriatic.

In the first place atropin is not the only mydriatic that can be used in the majority of cases with satisfaction. The mydriasis from the use of homatropin combined with cocain passes off in about a day, and decidedly lessens the loss of time occasioned by atropin. The trouble to the physician, a profoundly but subtly powerful argument, we suspect, seems a very bad one.

Moreover, the perfect assurance that the ophthalmometer infallibly measures the astigmatism seems to careful men without a necessary basis of fact.

That a mydriatic is not necessary in persons beyond forty years of age is another axiom that is hardly ever, one might say never, true.

That there is any considerable proportion of cases of simple myopia or simple hyperopia, without complicating "astigmatism sufficient to be corrected," is another fallacy, as is also the assertion that the hyperopic eye is a normal eye, "causing no inconvenience until presbyopia is reached," and requiring no attention on the part of the oculist.

Both the theory and the practice of medicine, as well as the theory and the practice of ploughing or shoemaking, depend upon the correct perception and the truthful statement of facts; and as to the facts mentioned, as well as many other related facts, there seem to be sad differences of opinion among ophthalmologists. "The most exact of the specialties of medicine" seems to be in process of speedily becoming one of the most inexact. Either this, or, in order to spare the oculist trouble, there is a distinct reversionary or atavistic tendency toward primitive unscientific practices and types of mind. Which is it?

It should also be noted that those who so zealously advocate the "uselessness of the mydriatic," the divinity of the ophthalmometer, and the commercializing of medicine, are encouraging every quack optician in his delusion that all refraction-work belongs to him by right and alone. We shall soon see every "specialist in lenses for the eye," every jeweler and spectacle-peddler quoting physicians to prove his impertinence, and outfitted with ophthalmometers and phorometers galore.

The Children's Aid Society.—One cannot read the annual report of the Children's Aid Society of Pennsylvania without a profound sense of admiration for the noble work in which this useful Society is successfully engaged. To rescue parentless, deserted, and delinquent children from lives of degradation and to place them in the way of leading useful careers, is surely a work deserving of the warmest sympathy and encouragement and the most liberal support. The Society has doubly felt the results of the universal depression in business, in that its income has been curtailed, while the demands upon its resources have been increased, so that it began the year with a deficit. As is generally known, the work of the Society consists in placing uncared-for, or improperly cared-for, children in the homes of respectable families, at a small outlay for board, meanwhile maintaining a general supervision of the child. Six hundred and eleven (611) children were thus cared for during the last year. In addition, the Society offers its aid to mothers, married or single, for the purpose of securing suitable employment in order to provide for themselves and their offspring. The work is greatly embarrassed for want of funds, and an earnest appeal is made to those able and willing to contribute generously to a most worthy and a well-administered cause. Subscriptions may be sent to the Treasurer, Mr. Charles E. Peterson, at the office of the Society, 127 South Twelfth Street.

To the Trustees of the American Medical Association.—We respectfully call the attention of the Trustees of the American Medical Association to the letter signed "Medicus," published in the *Journal of the American Medical Association* for March 24, 1894, p. 438, and beg to inquire whether the publication of that "dignified and professional" epistle has their approval.

REVIEW.

ESSENTIALS OF PRACTICE OF MEDICINE: ARRANGED IN THE FORM OF QUESTIONS AND ANSWERS. Prepared especially for Students of Medicine. By HENRY MORRIS, M.D. With a very complete APPENDIX ON THE EXAMINATION OF THE URINE. By LAWRENCE WOLFF, M.D. Third edition, revised and enlarged by some three hundred essential Formulæ selected from the Writings of the most eminent Authorities of the Medical Profession, collected and arranged by WILLIAM M. POWELL, M.D. 8vo, pp. 374, 48, 66. Philadelphia: W. B. Saunders, 1894.

WE have on more occasions than one questioned the utility of even the best of the books of the class of that under review. What then remains to be said concerning such as may be characterized by glaring omissions and inadequacies! They are all but too likely to encourage superficial methods of study and perhaps deceive the student into a false notion of his ability.

In the book before us we find on cursory examination that the following subjects have received no consideration: Weil's disease, glanders, anthrax, actinomycosis, hydatid disease, trichiniasis, the intestinal parasites in general, arterio-capillary fibrosis, symmetrical gangrene, hysteria, tetanus, hydrophobia, akromegalia, myxedema, cretinism, syringomyelia, acute ascending paralysis, pseudo-hypertrophic paralysis, postero-lateral sclerosis, analgesic panaris, myotonia congenita. The distinction between infectious and contagious diseases is attempted, but not made. No informed persons would say to-day that an infectious disease is "not capable of being communicated from one individual to another (*e.g.*, influenza, malaria, tubercle)" (p. 19). In the consideration of the pulse (p. 21) the distinction between rapidity and frequency does not appear to be appreciated. In the section on enteric fever we look in vain for any intimation that microörganisms may play any part in the etiology. Relapsing fever is said to be dependent upon the presence of the spirocheta of Ehrenberg; although by others the organism is quite always associated with the name of Obermeier. Malaria is described (p. 47) as "a poison generated by heat and moisture . . . . most likely due to microscopic germs of either vegetable (bacillus malariæ) or animal (plasmodium malariæ) origin. The latter view has been steadily gaining ground of late." This ultra-conservatism might have been justifiable six or eight years ago, but is scarcely warrantable to-day. Erysipelas (p. 81) and diphtheria (p. 85) are each said to be due to "a special poison," while the streptococcus and the bacillus respectively seem to be entirely ignored. In connection with dysentery we fail to find any reference to the ameba coli as an etiologic factor. The bare possibility of membranous croup being of diphtheric origin receives no consideration. Pathology seems to be made easy, as in the description of a tubercle (p. 254), which "under the microscope is seen to consist of a giant-cell which contains the bacillus . . ." In the desire to be abreast of the time in connection with the etiology of tuberculosis, the fallacious statement is made that the bacillus tuberculosis is present in the breath of affected persons. The occupation-neuroses are all included in the description of writers' cramp, which strangely is stated to be "also seen in telegraph and type-writer operators" (p. 345). We think these few random references must demonstrate that any good of which this book might be capable is more than neutralized by the incalculable injury that it can accomplish.

CORRESPONDENCE.

LAMINECTOMY.

To the Editor of THE MEDICAL NEWS,

SIR: In reading an article by Dr. John B. Roberts on "Laminectomy for Spinal Fracture," published in THE MEDICAL NEWS of March 10th, I was reminded of two cases that occurred in my practice, in which this operation was done early, but with negative results. In most of the cases of injuries of this nature there seems to be a lesion of the cord and its envelops that takes place immediately and occasions permanent results. Therefore, even if an operation be performed at once, the only hope is that there may be only pressure upon the cord, and not any disturbance in its molecules. I believe, however, that if the injury has been severe enough to paralyze, its effects will be permanent and no operation will be of any avail. I append a brief history of the cases.

In August, Miss E. fell backward out of a wagon, striking upon her neck and shoulders. She complained of immediate pain in the back, with complete loss of power in the lower extremities. Examination revealed an irregularity in the line of the dorsal vertebræ. Forced extension was employed on the following day in an attempt to reduce the displacement, but without success. A day or two later the operation of laminectomy was performed at the point of displacement, and some small fragments of bone that were broken and somewhat depressed were removed. There was no further depression, as a probe was passed up and down from the point opened, proving all to be free. The patient bore the operation well, and the wound healed by first intention. There was no change in the paralysis, however, nor did any occur during her lifetime. As time went on, cystitis, large bedsores, and other usual conditions occurred, and the patient finally succumbed.

The second case was that of a man who fell into a pit some ten feet deep, and was found a few hours later with complete paralysis of the legs. A line of irregularity in the spinal column was found in the lower dorsal region. An operation was speedily performed, revealing some loose bone, which was removed. The cord was quite reddened. There was no abatement in any of the symptoms or in the general condition, and the man died in a few days from exhaustion. At the post-mortem examination the cord was found flattened, and its anterior surface changed in appearance.

In a third case, in which a heavy body fell across the back of a young man, with resulting complete paraplegia, no operation was permitted, and the case went on in the same way as the first here related, finally terminating in death by exhaustion.

While I am, with Dr. Roberts, a believer in operations, still in view of these cases I cannot see that we can offer encouragement under such conditions, even if the

operation be done early, much less if done later. In neither of my cases did the injury to the cord seem severe enough to cause such complete paralysis, showing evidently that the cord is so constituted that but slight disturbance or pressure suffices to annul its function.

Respectfully, CLINTON B. HERRICK.

TROY, N. Y.

ACETANILID IN SURGICAL PRACTICE.

To the Editor of THE MEDICAL NEWS,

SIR: I desire to add the experience of the accident ward of the Cincinnati Hospital to what you have already published concerning the use of acetanilid as a surgical dressing. Since its introduction I have used the agent in dressing fifty-one scalp-wounds and two hundred and seven other wounds and solutions of continuity. These latter include stab-wounds and pistol-wounds, amputations of fingers, lacerated wounds of the hands from falling weights and machinery, syphilitic and other ulcers, burns and incised abscesses. In a fresh wound, first thoroughly flushed with 1 to 40 carbolic acid solution, then dusted with acetanilid, and protected from desiccation by the use of protective *over* the layers of plain gauze that lie next the wound, I have never seen a drop of pus form. Foul wounds seem to me to take on a healthy action with increased promptitude, and syphilitic ulcers heal rapidly. I feel confident that I have prevented suppuration in oil-besmeared and grimy lacerated fingers, and thus avoided what I would formerly have considered inevitably necessary amputations. Not infrequently, however, when granulations form over an extensive surface, I have had to discontinue the use of acetanilid on account of the burning pain occasioned. This is slight and of short duration at first, but increases in severity and duration with subsequent dressings. The advantages gained in the early part of the treatment, however, justify the use of the drug as long as the patient can stand it. I have never seen any constitutional effects from its use. Apparently we have made a valuable acquisition in acetanilid, and with me it has superseded the use of iodoform altogether. With my present experience I would say that it is an efficient antiseptic, stimulant, non-irritating, non-toxic, odorless, clean, easy to wash from the surface of a wound and the surrounding skin, desiccant, and to a certain extent a hemostatic. In those cases in which it begins to produce pain decided advantages have already accrued from its use. Respectfully,

CHARLES H. CASTLE,
Resident Physician.

CINCINNATI, OHIO.

NEWS ITEMS.

The Association of Military Surgeons of the United States will hold its fourth annual meeting at Washington, D. C., May 1, 2, and 3, 1894. The following provisional program has been arranged: President's Address—"Abdominal Surgery on the Battle-field," by Col. Nicholas Senn, Surgeon-General Illinois N. G., Chicago, Ills. "History," by Col. Charles H. Alden, Assistant Surgeon-General U. S. A., Washington, D. C. "Litter," by Major Valery Havard, Surgeon U. S. A., Fort D. A. Russell, Wyo. "Travois," by Major John Van R. Hoff, Surgeon U. S. A., Governor's Island, N. Y. "Railway," by Col. Louis W. Read, Surgeon-General N. G. Pa., Norristown, Pa. "On Board Ship," by Albert L. Gihon, Medical Director U. S. Navy, Washington, D. C. "Ambulance," by First Lieut. Myles Standish, Surgeon Mass. V. M., Boston, Mass. "Notes on the Introduction of Tent-field Hospitals in War, showing the Advantages of Treating Military Invalids under Canvas on the Battle-field instead of Buildings Improvised for Hospitals," by Col. B. J. D. Irwin, Assistant Surgeon-General U. S. A., Chicago, Ills. "The Medical Officer at the Summer Encampments," by Lieut.-Col. Charles R. Greenleaf, Deputy Surgeon-General U. S. A., San Francisco, Cal. "Easy Methods of Carrying Out the Principles of Aseptic Surgery," by Col. Robert Reyburn, late Surgeon and Bvt. Lieut.-Col. U. S. Vols., Washington, D. C. "Equipment and Instruction of Sanitary Soldiers," by Capt. Charles F. Mason, Assistant Surgeon U. S. A., Fort Snelling, Minn. "A Field Kitchen Wagon, for Cooking Food and Sterilizing Dressings at Dressing Stations and on the March," by Capt. H. O. Perley, Assistant Surgeon U. S. A., Plattsburg Barracks, N. Y. "The Personal Equipment of the Sanitary Soldier," by First Lieut. George D. DeShon, Assistant Surgeon U. S. A., Fort D. A. Russell, Wyo. "The Action of Rattlesnake Venom upon the Bactericidal Power of the Blood-serum," by Capt. Charles B. Ewing, Assistant Surgeon U. S. A., Fort McHenry, Md. "The Relation of the National Guard Surgeon to the Medical Profession and to the Community," by Capt. T. C. Clark, Assistant Surgeon N. G. Minn., Stillwater, Minn. "Saber Wounds," by Col. R. E. Giffen, Surgeon-General N. G. Neb., Lincoln, Neb. "The Special Training of the Medical Officer, with Brief Notes of the Courses of Instruction at the Army Schools Abroad and at Home," by Col. Charles H. Alden, Assistant Surgeon-General U. S. A., Washington, D. C. "A New Sanitary Appliance in the First Line of Battle-field Assistance," by Major John Van R. Hoff, Surgeon U. S. A., Governor's Island, N. Y. "Some Notes on the Late Civil War," by Col. Richard F. Michel, Surgeon-General Ala. State Troops, Montgomery, Ala. "Destructive Effects of the Krag-Jörgensen Rifle Projectile at the Actual Ranges," by Capt. Louis A. LaGarde, Assistant Surgeon U. S. A., Denver, Col. "Camp Hospitals," by Major Lawrence C. Carr, Surgeon N. G. Ohio, Cincinnati, Ohio. "Progress of Medico-military Science in the National Guard of New Jersey," by Brig.-General John D. McGill, Surgeon-General N. G. of N. J., Jersey City, N. J. "The Remote Effects of Gunshot Wounds of the Extremities," by Lieut.-Col. C. M. Woodward, ex-Surgeon-General Mich. State Troops, Tecumseh, Mich. "Notes on the Transportation of Sick and Wounded," by Capt. J. D. Glennan, Assistant Surgeon U. S. A., Fort Sill, Oklahoma Ter. "Case of Gunshot Wound of Liver, with Remarks on Liver Wounds Antiseptically Treated," by Capt. G. E. Bushnell, Assistant Surgeon U. S. A., Fort McKinney, Wyo. "The Treatment of Gonorrhea in Military Practice," by Major G. Frank Lydston, Surgeon Ills. N. G., State and Madison Sts., Chicago, Ills. "Description of a New Litter," by Capt. Francis J. Ives, Assistant Surgeon U. S. A., Fort Sheridan, Ills.

Dr. John H. Rauch, the distinguished sanitarian and advocate of higher medical education, died on March 24th, at the age of sixty-five years. He served faithfully during the Civil War, and at one time occupied a chair in Rush Medical College and also in the College of Pharmacy of Chicago. He organized the first Board of Health of Chicago, and was at another time Superintendent of Public Health in that city. He was also one of the founders of the Illinois State Board of Health, of which he was at different times President and Secretary respectively.

George Albert Lücke, Professor of Surgery in the University of Strassburg, died suddenly on February 20th, at the age of sixty-five years. He contributed generously to medical literature. He was one of the founders of the *Deutsche Zeitschrift für Chirurgie*, and in 1879, in conjunction with Billroth, began the publication of a mammoth work on *Deutsche Chirurgie*, which was expected to appear in sixty-six parts. He was, perhaps, best known for his writings upon new-growths.

The British Medical Association will hold its sixty-second annual meeting at Bristol, July 31, August 1, 2, and 3, 1894. Dr. E. Long will be the presiding officer. An "Address in Medicine" will be delivered by T. Grainger Stewart, of Edinburgh; an "Address in Surgery," by J. Greig Smith, and an "Address in Public Medicine," by Sir Charles Cameron.

Dr. Ezekiel Hartzell, of Carlisle, died at Fayetteville, on March 24th, at the age of seventy-five years. He had been engaged in the practice of medicine for forty-five years. He was the father of Dr. Milton B. Hartzell, of this city, and of Dr. Charles Hartzell, of Fayetteville.

Eleventh International Medical Congress.—The official proceedings of the Congress will be published daily by the new Italian journal, *Il Policlinico*, copies of which will be presented to foreign representatives of exchanging journals.

The Shadow-test.—A course of lectures, demonstrations, and clinical work on Skiascopy, or the Shadow-test, will be given at the Philadelphia Polyclinic during the week commencing April 9th.

Dr. Julius Uffelmann, Professor of Hygiene in the University of Rostock, died February 17th, at the age of fifty-eight years. He made a number of valuable contributions to medical literature.

The German-American Medical Monthly is the name of a new publication emanating from St. Louis, and edited by Dr. Gustav Blech, with the assistance of Dr. Paul Baer.

Wm. P. Northrup has recently been made Adjunct Professor of Diseases of Children in the Bellevue Hospital Medical College of New York.

Dr. Francis Flint Forsyth died at Providence, R. I., on March 11th, at the age of seventy years.

Books and Pamphlets Received.

Mensuration in the Physical Diagnosis of Phthisis. By George A. Evans, M.D. Reprinted from the Brooklyn Medical Journal, 1893.

On the Microbic Origin of Chorea. Report of a Case, with Autopsy. By Charles L. Dana, A.M., M.D. Reprinted from the American Journal of the Medical Sciences, 1894.

Autobiographical Sketches and Personal Recollections. By George T. Angell. Pamphlet. Published by the "American Humane Education Society," Boston.

TREATMENT OF ALCOHOLISM BY STRYCHNIN NITRATE HYPODERMATICALLY.[1]

BY WILLIAM B. BREED, M.D.,
OF SYRACUSE, N. Y.

I WISH to direct attention to the treatment of alcoholism, both chronic and acute, by the use of strychnin nitrate given hypodermatically.

I am aware that when a supposed specific for any disease is brought forward an involuntary smile of incredulity passes about; therefore, whatever my private opinion may be, I will avoid strong statements, relate the history of a few cases, and leave you to deduce your own conclusions.

The following cases occurred in my private practice, and the patients were influenced by no seductive surroundings of a sanitarium or hospital to exert a moral influence upon the cure. Whatever good was done was, therefore, wholly due to the drug employed.

CASE I was a saloon-keeper, thirty years of age, who had drunk heavily all his life. He came to me after a debauch in a sadly demoralized condition, saying that he was despondent all the time; he threatened to commit suicide, and about half the time did not know what he was doing. He was at the time in a semi-delirious and dazed condition, and said that he was dreaming frightful dreams night and day, had horrors all the time, a foolish feeling in his head, and no appetite. It was impossible for him to get out of bed in the morning on account of a "dead feeling" until he had taken enough whiskey to intoxicate, and he had to keep up this condition all day in order to attend to business. This had been habitual with him for years.

I began treatment by injecting nitrate of strychnin, $\frac{1}{20}$ gr., night and morning. I also gave capsicum, valerian, bromid, and sulphonal for the restlessness and nervous symptoms. The sulphonal was most efficient. On the second day I injected $\frac{1}{15}$ gr., and on the third day he said the sight of whiskey or brandy nauseated him, although he continued to drink two or three glasses of beer daily; he had taken no food for four days. On the third day of the treatment he took fish and soup, and slept well that night; he was not nervous or "shaky," but had "a foolish feeling" in his head; the gnawing at the epigastrium had disappeared; the man looked bright, his complexion was clear, his spirits good and the despondency nearly gone. On the ninth day he could get up and eat at the usual hour without difficulty, the "dead feeling" having disappeared. He was taking five drinks of beer only a day. On the twelfth day I increased the dose to $\frac{1}{12}$ gr., and the man says he could not get enough to eat. On the eighteenth day he was taking from six to eight drinks of beer daily, but could not touch strong liquor. On the twenty-sixth day the injection was increased to $\frac{1}{10}$ gr., the patient continuing to improve in appearance. His eyes were bright, clear, and steady, and he exhibited enthusiasm, courage, spirit, and an interest in life, in marked contrast to the dull, dead, listless appearance of the first day. His slovenliness had given way to cleanliness and neatness. On the thirty-third day the injection was decreased to $\frac{1}{20}$ gr., and the dose was then decreased gradually for five days, down to nothing.

At the time of writing he still takes beer moderately, but no strong liquor; he gets up mornings and attends to business all day. His appearance indicates that he tells the truth. This result may be considered good for a saloon-keeper. The treatment did not stop his drinking entirely, but it regenerated him physically and mentally, and enabled him to attend to business like other men. The time of treatment was forty days, with two treatments daily; it is now eight months and twenty-three days since treatment was begun.

CASE II.—A female, twenty-five years of age, came to me with the following history: For two years she had drunk heavily every day and all day, and all kinds of drink; she says she cannot stop without being all undone, and she sleeps poorly. She has had delirium tremens once; she is slovenly about the house and about herself, neglecting household duties and her children. She has to keep well saturated with drink to avoid misery. The woman has the same foolish and uncertain feeling in the head as described in the first case, is very nervous, without appetite, the eyes bloodshot, the actions "boozy," and the conversation maudlin.

I began with $\frac{1}{20}$ gr. t. i. d. The woman took only one drink on the second day. I gave sulphonal nightly, with good effect upon the nervous symptoms. On the fourth day the appetite was good; she was less nervous, the head better, and there was no desire for drink at all. On the fifth day the appetite was still better. She took a drink of cider the night before as an experiment, but had to vomit immediately, and was sick all night, feeling badly in the morning; she still had a distaste for drink of all kinds. On the sixth day she took two glasses of beer. The injection was not increased. The appetite was not so good. On the ninth day the woman took two drinks of beer, but it tasted bitter, and she cared nothing for it. Her appearance has changed con-

[1] Read before the Onondaga County Medical Association, January 31, 1893.

siderably, the face not being so bloated, and the eyes being bright, clear, and calm. The home is kept tidy, and she takes an interest in household affairs. On the eleventh day she had taken no beer for two days, and had a distaste for it. The appetite was very good. On the fifteenth day she still was taking no beer and had no desire for drink. On the twenty-third day she was still abstaining, and without the least effort on her part. The injection was now reduced to $\frac{1}{20}$ gr. once a day. On the thirty-second day the appetite was poor and the patient listless: the injection was increased to $\frac{1}{15}$ gr., and gradually reduced during one week to nothing. Two months after this she began drinking to spite her husband. I gave one injection of $\frac{1}{10}$ gr. Since that time, for eight months up to the present time, she has abstained, and her appearance and actions and general spirit, tidiness, and thrift in household affairs go to show that she tells the truth.

The time of treatment was forty days, with two treatments a day.

Case III was an unusually bright and highly intellectual person, forty years of age. For twenty years he had imbibed enormously and constantly of beer only, so that he was entirely unfit for any business. He had abandoned all hope, and decided to keep up drinking until it should finally kill him, and he thought this happy time would come in about one year. At the first visit he presented the usual deplorable picture of complete despair, with loss of nearly all the attributes belonging to human beings, and suffering untold agony for want of drink.

I began treatment with $\frac{1}{20}$ gr. t. i. d. On the third day the man said he had no desire for drink, and the mental agony had disappeared. He said he felt better than for two years, was beginning to feel hopeful, and "as he used to years ago when a boy." He has great exhaustion upon exertion, and his head still feels badly. I gave sulphonal, with good results. On the seventh day I increased the dose to $\frac{1}{17}$ gr., but it caused a flushing of the face and fulness of the head. I returned to $\frac{1}{20}$ gr. The patient is of an active disposition and nervous temperament, and seems to require less of the remedy. On the twenty-third day I reduced the dose to $\frac{1}{24}$ gr.; on the twenty-fourth day to $\frac{1}{30}$ gr.; on the twenty-eighth day to $\frac{1}{40}$ gr. The head-symptoms were still present. I then injected $\frac{1}{17}$ gr., thinking that the bad feeling in the head might be due to a too rapid decrease in the dose; but it augmented the bad feeling in the head, showing that it was rather due to the withdrawal of stimulants than to diminishing the dose. Sulphonal relieved all the bad symptoms of the head and nervous system. I concluded that he had had enough strychnin, and stopped treatment. Improvement began and continued. I have seen the man at intervals during the time since dismissal, and he is working steadily and looks and feels like another man, and says that he has no desire for drink. It is now seven months since treatment was begun.

The time of treatment was twenty-eight days.

Case IV.—A male, aged forty-four, drinks some every day, and in addition has periodic debauches, mostly on beer; he requires whiskey every morning. This patient had no desire to reform, but was induced to take the treatment by his wife, who was the greater sufferer. During the treatment he was passive, and had nothing to say, except that he had no desire to drink.

I began with $\frac{1}{17}$ gr. t. i. d. After four days he was absent thirteen days, drinking during this interval. At the end of the thirteen days I resumed treatment, giving $\frac{1}{17}$ gr. twice a day. This was continued for fourteen days and was followed by a rousing spree, and he began life again as before, and is still at it, evidently liking beer better than strychnin.

Case V.—A male, aged forty-five, has periodic attacks of intemperance, lasting from one to two weeks, at intervals of from two to twelve months. He had become so irresponsible that his business had to be attended to by other members of the family.

I began with $\frac{1}{17}$ gr. t. i. d. On the third day he said that the sight of people drinking nauseated him, and that he had no desire for any kind of stimulants, nor has he the "gnawing" at the epigastrium. Before beginning treatment he said he could not eat or sleep; he now sleeps well, and cannot get enough to eat. He says he "feels like a newborn babe."

The treatment was continued for only two and a half weeks, twice a day, and the members of his family tell me that he is now always sober and attends to business. Four months have elapsed since the treatment was withheld.

Case VI.—This man had been a chronic drinker for twenty years, is helpless, and getting worse; he used to abstain at times for one week, but now he cannot do so. I injected $\frac{1}{15}$ gr. t. i. d. On the second day he had no desire for drink in the morning, but did have in the afternoon. On the third day he had no desire whatever. He said he had pressure on the top of the head, and slept poorly. Sulphonal relieved these symptoms, but not completely. The patient is hungry all the time and feels like an entirely different man. He says that his feelings "take him back to the innocent days of his childhood." I continued with $\frac{1}{15}$ gr. up to the fifth day, when the dose was reduced to $\frac{1}{17}$ gr. On the seventh day he mixed a milk-punch for a sick friend, and continued to do so every day. He said that not only did he not care to drink the punch, but that the odor nauseated him. On the thirteenth day I reduced the dose to $\frac{1}{25}$ gr., and continued to reduce it until the eighteenth day, and then diminished by $\frac{1}{120}$ gr. down to nothing on the twenty-second day.

The time of treatment was twenty-two days. Three months and eleven days have elapsed since treatment has ceased.

Case VII was a travelling agent, aged thirty-three. The peculiar characteristic of this case is that the patient had no appetite for drink whatever until he had begun to drink for some time for some other reason, such as despondency or depression on account of ill-luck or ill-health. However, whenever he begins he gradually proceeds to a prolonged debauch, drinking most immoderate quantities—as much as two quarts of whiskey in

twenty-four hours. The man has mitral insufficiency and very pronounced aortic regurgitation, which give him frequently considerable trouble. I saw him during a debauch, and began treatment immediately, giving him $\frac{1}{17}$ gr. every six hours, with an occasional drink to relieve the great agitation. After six treatments (during about thirty hours) the patient said that he had no desire for drink and that he had none of the bad feelings usual after a spree, and also, that the recovery was very much quicker. He says that his heart never behaved so well before.

Before giving any injection his pulse was fluttering and the heart was not compensating. Improvement began immediately upon giving the injections. The man said he had never taken any medicine that acted so well on his heart, and he had taken every heart-tonic known. I gave two injections a day of from $\frac{1}{25}$ gr. to $\frac{1}{12}$ gr. for three weeks. One week after stopping treatment he went on another hard spree, and the strychnin was used again, with the same good and quick result in the acute attack. This time I used $\frac{1}{10}$ gr. every four hours, and the recovery was one day more rapid than before. Upon questioning him, I learned that he had taken a drink immediately after each treatment during the three weeks, and had kept it up afterward. He says, also, that he had not a particle of desire for drink, and could as well have let it alone; but that he does not know why he took it. He evidently has no desire to abstain.

In drawing conclusions from the results obtained in these cases, we must make allowance for the fact that those that make up this class of people are notorious liars in the one respect of their habit, and their statements as to total or partial abstinence must be taken with a large grain of allowance, unless they are verified by other evidence, such as the appearance, actions, general environment, and the statements of disinterested persons, or of persons interested more in curing than in concealing. If any variation be made in the treatment, I would suggest using *larger* doses at *shorter* intervals, unless, as in one case reported, the patient be exceptionally sensitive to the drug.

It is to be noted that in every case, upon the *third day* there was a total absence of a desire for drink or *any* stimulant that might replace drink; and, a little later, a *distaste* for drink in some cases. It should also be noted that in these cases the patients were at places every day where drink could be freely had; and still the distaste continued.

Being associated with the two worst cases nearly all day, every day during treatment, I could have discovered any return to drink. The one fact of replacing the appetite of twenty years for drink by a distaste, or at least a lack of desire for drink, shows the remedy to possess a power seldom, if ever, met with in the treatment of any disease, by any remedy—a psychologic power lying wholly within the drug and independent of moral influences.

Since writing these notes an article has appeared in The Medical News (January 28, 1893, p. 90), by H. E. Schmid, upon "Alcoholism," and emphasized later by another article, by J. J. Brownson (Medical News, February 11, 1893) in which he attributes the success of the Keeley cure largely to the moral influence of the surroundings, association of patients, forms, ceremonies, and statements made with a view to frighten the patient, and placing before him the promise of death if alcohol comes in contact with the drug with which he is saturated, upon leaving the institution. I do not credit this statement, and I think we have reason to believe that Keeley has in use a drug similar to, if not identical with, the nitrate of strychnin.

I may mention, by the way, that Mr. Keeley in his circular mentions the complete change that occurs on the third day, as in the foregoing cases.

Upon reviewing the results in these few cases, I think we may fairly conclude:

1. That we have in this drug a remedy that actually, for a period as yet undetermined, removes the desire for alcoholic stimulation in the chronic inebriate, and that *without the least effort on his part.*

2. A remedy that removes the distress and gnawing at the epigastrium, so common upon the withdrawal of alcohol.

3. A remedy that tones up the nervous system, allays the insomnia, the flighty and other bad feelings in the head, the mental disturbances, and the tremulous agitation and uncertainty of voluntary motions due to the withdrawal of stimulants.

4. A remedy that brings back the appetite and general physical vigor of the body.

5. A remedy that temporarily transforms a wholly demoralized creature into a man.

6. A remedy that is of great value in acute attacks of alcoholism.

7. Incidentally, a remedy that is an exceedingly good and safe heart-tonic.

8. More than all, a remedy that exerts a moral influence upon the patient, giving him what he had before wholly lost, to wit: Hope, enthusiasm, self-confidence, and courage, where before was despondency, abandonment, and despair; a steady, straightforward gaze, and a bright youthful expression of the eye, which replaces the shamefaced, sneaking, apologetic air of total depravity of the chronic inebriate.

9. We have in the nitrate of strychnin *not* a remedy that will oblige a man to abstain from drink if he does not want to do so, and such subjects do not deserve one. From the results obtained by the gold cure, the silver-ash cure, the Keeley cure, etc., we may conclude that we have a remedy that is as efficient as any of these, and much safer—a remedy,

moreover, that is not secret and can be used by men who know the action of drugs and can use them with discretion and safety to the patient.

There is no reason why the public, which places its life in our hands daily, should be obliged to offer up sacrifices upon the shrine of quackery, when men can be treated privately, safely, and efficiently by any family physician, and thus avoid publicity, danger, and expense.

Perhaps we have not a specific; probably not, but we are as near to it as the quacks are; and if such cases of doubtful, if not suspicious, death as the one which occurred here lately can be avoided, it is right that the public should, through us, know it and profit by it.

From a scientific standpoint, these few cases afford but scanty statistics from which to draw conclusions. But if, from a humane standpoint, as much good can be done in all cases as in these few, we have done much to better the condition of our fellow-man.

NOTE.—Since writing the foregoing, there has appeared in THE MEDICAL NEWS an article by C. F. Chapman, taken from the *Chicago Medical Recorder*, February, 1893, in which the basis of the Keeley remedies is said to be nitrate of strychnin.

THE EFFECT OF ATHLETICS IN THE PHILADELPHIA PREPARATORY SCHOOLS AS TO MENTAL AND MORAL CHARACTER.[1]

BY A. H. P. LEUF, M.D.,
OF PHILADELPHIA.

IN the consideration of any subject it is well to guard against misunderstanding by defining the meaning we place upon leading terms used in its discussion. It is therefore highly necessary that we should be agreed as to what we mean by athletics and by mental and moral character. I will give my definition of these terms, and ask you to accept them for the time, it being understood that my conclusions are based on the premises given.

The term athletics, in this paper, shall be considered as signifying competition in physical prowess. The term mental character I shall use synonymously with mental growth, and it will mean the evolution of mind from the simpler toward the more complex or most complex operations of the mind. The term moral character I shall use synonymously with moral growth and morality, and it will mean the degree of tendency toward the harmonious blending of egoism and altruism that leads toward absolute equitableness.

The terms of the problem tendered me for solution are absolute, whereas they can in reality be only relative. The question would better have been: "Do athletics, as they at present *seem to be* conducted in our preparatory schools, conduce to mental and moral character?" It is in this form that I shall attempt a careful reply.

Through the courtesy of your Secretary, who furnished me with a list of the head-masters of thirty preparatory schools, I was enabled to communicate directly with those presumably most interested in the subject of this paper. A request was sent to all to forward to me an outline of the system of physical education prevailing at their respective schools.

Judging from what I have seen in several of our best preparatory schools, and from the information received directly in answer to my letters of inquiry, I should say that our preparatory schools now generally adopt some kind of physical exercise as a part of their weekly curriculum. In some it is systematically and compulsorily pursued between study hours as a part of the regular recitative work; in others it is purely recreative and voluntary during recess or after school in a gymnasium, or upon more or less suitable grounds provided for the purpose. The exercises, whether voluntary or not, are usually under the care of an instructor. In a number of the schools a specially qualified physician has been engaged to examine the scholars twice or thrice during the school session for the purpose of prescribing the most desirable special exercises and noting the results.

It has become the custom in even some of the preparatory schools to have a series of competitive athletic contests yearly between a number of schools forming a so-called "league." These contests embrace track and field sports, base-ball and foot-ball. That this is undesirable should be self-evident to any unbiased observer conversant with the strain entailed by the amount of physical work in a given time in children. When it is considered that the so-called training, generally a glaring misnomer, is taken in hand solely by those who desire to take part in the contests, and that their "training" consists in doing their utmost until compelled to stop from sheer exhaustion; and when it is also taken into account that the bodies of children are only in a developmental state, and likely to suffer serious and permanent damage from overwork, *i. e.*, strain, it is at once evident that there is a large element of risk attached to the encouragement of these competitive exertions. This matter has been more fully considered by me in a paper read before the American Medical Association, at Newport, R. I., on June 5, 1889.[1] You will see from that

[1] Read by request before the Convention of Teachers in Philadelphia.

[1] See the Journal of the American Medical Association, April 5, 1890, p. 493, and the Archives of Pediatrics, September, 1889.

how important it is to carefully superintend the physical exercise of children.

The advantages of careful physical education are best summarized in another of my former papers, quoted in the one just mentioned, and reproduced here:

"1. The object is to develop the material body, and, with it, of necessity, the mind and morals.

"2. Like most potent agencies, it is much abused and far too little understood.

"3. It absolutely forbids smoking.

"4. It absolutely forbids the drinking of alcoholic or malt beverages.

"5. It insists upon the necessity of regularity in living, especially as regards time of sleeping, eating, exercise, and recreation.

"6. It enforces a good substantial dietary that will never be forgotten.

"7. It discountenances all kinds of vice.

"8. It is rigid in discipline without seeming so to those disciplined, and develops implicit and willing obedience to advisers.

"9. It has a marked effect upon the growth of the body and mind.

"10. It develops to a high degree the valuable qualities of hope, confidence, courage, deference, obedience where proper, independence, perseverance, ambition, temperance, and determination.

"11. It is, in short, the most valuable preparation of the young for the cares and trials of adult life, and aids young and old alike to ward off disease and mitigate its effects."

I am pleased to report to you that the head-masters who have kindly replied to my queries have generally a correct idea as to what should be done in the physical education of their charges. But soon one is confronted with the "fad," or fashion of the day, variously subscribed to by parents and guardians, each insisting upon his or her own way, until, between the multiplicity of expressed injunctions by them, the opinions of the master or principal, and the question of cost and profit, the heads of schools must become bewildered as to the best course to follow, when all things are considered. The result generally is a compromise, consisting of the best that can be offered for the small additional compensation contributed by the parents. It is a deplorable fact that even wealthy people are prone to begrudge a fair monetary contribution toward the physical care of their children. The inevitable consequence is that physical education in our preparatory schools is not what it should be, and what the head-masters would like it to be.

I have heard of preparatory schools adopting a gymnasium course simply as a business shift to meet a demand. Even that is a healthy sign, though we expect an educational establishment, however modest, to lead the public instead of being led. But though a course in physical exercise is established on what may be called purely "business principles," the cost is considerable and the apparatus and space to place them in are expensive. This purely business reason may be called an illegitimate one. The legitimate reason for establishing physical education in preparatory schools is because it is an educational necessity. It divides itself into the development of the body and of the mind, and incidentally of character, or moral character, if you please.

That proper physical exercise develops the body is so self-evident that it needs no special consideration. It favorably affects every structure and function of the body by increasing its activity and nutrition. And from this simple statement it follows, of necessity, that the activity of the brain is increased by directing the various complex muscular movements for different periods, thus necessitating and causing an increased flow of blood through the cerebral bloodvessels, and a consequent better nutrition of the organ of the mind itself. Cerebral localization, the outcome of the older and extravagant phrenology, has shown that the many faculties of the mind are more or less distinctly mental functions having their seat in rather well-defined parts of the brain. Now, those faculties which are specially exercised upon the playground or in the gymnasium are not the same as those which are brought into play in the study-room, though there are many general faculties, as I may call them, which are used in both instances. Extended memory and computation may be instanced as being special to the latter requirements, and coördination of muscular movement to the former. Energy and perseverance are qualities of mind that are general and common to both.

There are two kinds of facts that I wish to point out as natural corollaries to the foregoing statement. One is, that while a part of the mind is exercised in physical exertion another part is at rest that is exercised during mental exertion in the school-room, and *vice versa*. By a judicious combination of the two there follows that alternating rest and activity that is so conducive to growth and development, comparable to the beneficent diurnal waking and sleeping. The other fact that I wish to bring out is that such qualities as energy and perseverance, that are in constant use during either physical or mental activity, are likely to be overused if the mind and body are kept constantly at work, though alternating. When these common qualities of mind are not too much used there is general beneficence, but when they are overtaxed by excessive use of either body or mind there is general disaster, greater or less, depending upon the amount of overtaxation and the period required for recovery.

At no time of life is it possible for anyone to do his utmost in physical work, be the period long or short, without sacrificing ability to do the best mental work during that time and for varying periods thereafter. It has, of course, been demonstrated upon numerous occasions that college athletes, endowed with superior physical power and nervous energy, have excelled both in athletics and in their studies. I have met with several of these after they had left college. Some of them came to me as patients. The result was the same in all. They had earned a national, or even international, reputation as athletes, had been leaders of their graduating classes in college, but had so sapped their nervous or vital energies in the three or four years' excessive strain, that they had not enough left to ward off the common ailments against which they at one time so confidently considered themselves proof; they had lost their ambition, and they were sick and could not get well: they were getting worse. What was the trouble? They had the great American disease called neurasthenia or nervous exhaustion. Their prospects were not very roseate. Almost their only chance of recovery was several years of comparative ease and change of life. This was utterly impossible except to one. Thus end the brilliant prospects of the renowned college athlete!

The objection to athletics, as I have defined the word, is that they are competitive, that the competition grows, that it breeds a spirit of professionalism, a desire at all hazards and at any price to achieve a victory. Present comforts, future health, studies, and mental development are cast to the winds in the one idea—rush for glory. Too many parents unwisely encourage this fetich-worship, frequently at a dire cost. This competitive spirit saps the energies and leaves little for study. The strain can only be borne by the few, and there soon results such a high standard of excellence that only the best endowed naturally attempt the exercises, and the great many sit idly by and watch the competition, and these in their turn sap their energies with a useless excitement accompanied by no equivalent gain in physical development.

The ideal physical education, viewed from a pedagogic standpoint, is to combine physical and mental exercise so as to entail no strain upon the nervous energy, perseverance, and moral character. To accomplish this result there should be eliminated from physical exercise all undue or excessive excitement. In other words, physical exercise, of whatever kind, to be conducive to the best welfare of the individual, should be recreative rather than competitive, a pleasure rather than an unwelcome duty, a healthy desire that knows satiation within safe limits rather than an unreasonable ardor that knows no safe bounds.

I have found certain *a priori* conclusions of mine verified in my experience at the University of Pennsylvania, where it was the constant experience that the classes did their poorest work in the recitation hours immediately succeeding exercise in the gymnasium. Men in training are likely to neglect their studies unless they have sufficient incentive to regard the warnings of Nature. I shall eagerly await the discussion of this paper to learn from some of the learned head-masters here this evening about the standing of their scholars while in training for a contest.[1]

There can be no doubt that the increased circulation of blood through the body caused by proper physical exercise, especially that which is taught in the schools, results in increased nourishment of the brain, and with it increased mental character. Moreover, the varied and complex acts constituting athletic work cause a decided improvement in the rapidity of the perceptions, judgment, and execution.

The moral improvement is just as decided. The rules governing all games are arranged with the object of excluding anything unfair. Physical education, especially when combined with games, is a moral educator of great force, particularly because its results are natural and spontaneous. The increased manliness and fairness shown by boys after playing games for a few weeks is readily seen by all who watch them. In professional base-ball the finger of suspicion cannot justly be pointed at a single member of the profession. The claim that any of the games of the larger leagues are not honestly and earnestly contested would be declared absurd by the well-informed patrons of the national game.

I desire to say that I know of no moral educator so spontaneous as proper physical education. Its precepts must be followed if disagreeable results are to be avoided. Its active votaries are ever overcoming obstacles that at first seem insurmountable. They learn to go at something hard to do with a confidence that becomes habitual, and serves many a valuable turn in after-life in the battles against the world. That this moral effect is to be observed among all the school-children that take to games and exercises in the right way has probably been observed by all present. That there are brutish natures that prove exceptions does not, of course, invalidate this statement.

My conclusions from a study of the facts are that every preparatory school should discourage competitive athletics, though I should deem it a mistake

[1] All who spoke upon the subject agreed that training for contests caused a falling off in the scholarship-standing of those in training, while the same was true of nearly all, though to a lesser extent, upon the eve of an important contest.

to prohibit them, because it cannot be done if the pupils are unwilling, and it is not required if they follow the advice given.

There should be a physical examination made at least twice a year by a specially qualified physician for the purpose of prescribing necessary exercises to correct defective physical development and malnutrition of the body or of any of its parts. An experienced instructor should be engaged to help the pupils carry out their prescribed work, as no good, and sometimes harm, results from exercises wrongly done or neglected.

Each boy should receive a graphically arranged chart, some of which I have passed around, showing his condition at the time of examination. He can occasionally measure and test himself, and note how he is improving. It is interesting, and makes him more attentive to lectures or lessons on anatomy and physiology, creating a desire for this kind of knowledge.

A gymnasium and a playground are a great desideratum, in fact are indispensable requisites, if the highest aim of pedagogics is to be achieved. If only one is obtainable, I declare in favor of a playground for use all the year round. If neither is obtainable, judicious calisthenic class exercises by the instructors, themselves properly taught, can do a great deal of good.

In reply to the query that forms the title to these remarks, I would say that—

Athletics, as at present conducted in our preparatory schools, do conduce to mental and moral character in varying proportions, depending upon whether the system in vogue approaches the requirements indicated or not; and that in all of them, as well as in our largest colleges and all intermediate educational institutions, there is opportunity for very much improvement in the plan of physical education; and that there is no method of physical education anywhere in vogue that has not serious drawbacks, some of them overbalancing the good sought to be accomplished.

2353 N. Seventeenth St

THE ETIOLOGY OF CARCINOMA.[1]

By JOSEPH McFARLAND, M.D.,
of Philadelphia;
Demonstrator of Pathological Histology in the University of Pennsylvania; Adjunct Professor of Pathology in the Philadelphia Polyclinic.

Carcinoma has baffled the medical skill of all ages. It is one of the most troublesome, yet one of the most common of diseases. Without discrimination it affects the young and the old. Moreover, it is a peculiar disease, and, on account of its terrible nature, has been studied by scientific men as far back as medical literature dates.

It is a strange thing that while medical science has advanced so rapidly in many respects, our knowledge of this disease has remained at a standstill. The physician is still appalled at its unchecked growth, the surgeon is still exasperated that his eradications are without effect, and, despite all we know or do, it pursues a steady course of painful return, extended growth, and lingering death.

For many years carcinoma and tuberculosis were not disassociated in the minds of medical men. This is one reason that the experimenters of early date frequently reported successful inoculation-experiments. It remained for Virchow, and later Koch, to differentiate between these two diseases. Subsequently carcinoma became a disease subjected to careful investigation, but, notwithstanding the many who studied it, its etiology remains profoundly obscure.

When bacteriology first became a science, carcinoma was at once attacked by a host of scientists. The discoveries of Scheuerlen, Schill, and Kubasoff remain with us to day as monuments of scientific error. It was not long after the bacteriologic failures that Malassez, Albarran, and Darier in France, and Thoma in Russia, began to investigate carcinoma with a view to finding other organisms than bacteria whose presence might cause it, being led to this by the discovery of "psorosperms," *i. e.*, coccidia-like bodies, in the cells in Paget's disease. Simple observation of these bodies found in the cells of Paget's disease and subsequently in carcinoma was not sufficient for proof, and inoculation-experiments became frequent at this time; fragments of the carcinomatous tissue were placed beneath the skin of animals, whole tumors were introduced into the abdominal cavities of animals, suspensions of the tumor-cells in the blood-serum, physiologic salt-solution, and bouillon were injected into the circulation of animals and the results carefully noted. I have been able to collect the results of almost five hundred of these experiments, with scarcely one reported successful. Klebs has probably made one hundred experiments, and has met with signal failure. Hanau has been successful three times in experimenting on rats. In all of his three experiments squamous epithelioma was brought about.

Still there is this peculiarity about the inoculation of carcinoma—that, while it is seemingly not inoculable, or only exceptionally inoculable, from one animal to another animal of the same kind, it is distinctly inoculable from one organ to another of the same animal. There are many cases reported in which epithelioma of the lower lip has invaded the upper lip, in which the mammary gland involved the

[1] Read before the Pathological Society, January 25, 1894.

arm when kept in contact with it, in which a carcinomatous uterus affected a contiguous portion of the vagina, etc. There is a case reported of a man with a burn on his arm, who was infected by squamous epithelioma of the face from which he suffered, some of the cells from the facial disease growing well upon the hand and causing the disease there. These cases cannot be correctly called cases of inoculation, but rather cases of modified metastasis. Of course, all these cases carry with them the suggestion of infectiousness in carcinoma and support the parasitic view of the disease.

Haviland has made a special research upon the miasmatic conditions relative to carcinoma, and has found that the disease seems to be more prevalent in those localities in which there is much moisture, *i. e.*, where the lands are marshy or remain inundated for a great length of time.

Dr. Ackerley speaks of a certain house situated on low ground, the cellars of which, being below the level of a small stream about twenty yards away, were pretty constantly inundated. In this house during thirteen years four cases of carcinoma are said to have occurred :

I. A lady who had occupied the house for many years died of carcinoma of the breast and, it is said, also of the womb.

II. The next occupant, a lady, lived seven years in the house, then died of carcinoma of the breast.

III. Two years later the husband of this woman died of carcinoma of the larynx.

IV. The second wife of this man has suffered amputation of the breast for carcinoma, but still lives.

These things may be coincidences, as has been pointed out, but they may mean something more. At present the literature upon this subject is immense. The whole world seems to have become satisfied that carcinoma is a specific disease and is in search of the parasite.

Those who have read of the parasites of carcinoma must have been struck with the fact that the numerous observers find very different things. One asserts that the carcinomatous organism is a protozoan of the coccidia group; another that it is a gregarine; a third that it is an ameba. One can read paper after paper bearing such eminent names as Podwyssozki, Sawtschenko, Soudakewitch, Ruffer, Walker, Metschnikoff, Delépine, Korotneff, Foà, and Virchow, all more or less at variance.

During the last two years it has been my pleasure to make a careful study of such carcinomata as came into my hands, for the purpose of ascertaining whether or not the bodies described were sufficiently characteristic to be called parasitic or not.

My experience in connection with this subject has not been very great. I have been able to get but fifty or sixty carcinomata in a more or less well preserved state. Here let me observe that too much stress has been laid upon the methods of preservation and methods of staining. Ruffer and Walker tell us that the organisms cannot be seen well except in specimens hardened in osmic acid or bichlorid of mercury; others, however, find that they show in ordinary alcohol-hardened tissues.

The same gentlemen see them best when Biondi's stain is used. Soudakewitch prefers hematoxylin and eosin. It makes little difference how one stains; if the thing is there it will be seen. However, the more careful the manipulation the better the result, and, of course, the better the tissue is preserved the more clear the final picture will be.

I have studied squamous epithelioma, cylindric epithelioma of the stomach and intestine, carcinoma of the mamma, and of the bladder and of the uterus, and have found pretty much the same parasite-like bodies in all of them.

The forms of parasites described are easily separated into (1) coccidia, (2) gregarinæ, and (3) sporozoa.

The form first described was thought to be a coccidium. A coccidium is an intra-cellular parasite characterized by the presence of a distinct, generally double, capsule. This form of parasite was thought to be present in carcinoma, partly because similar bodies were found, and partly because of the homology thought to exist between carcinoma and the disease of the rabbit known as *coccidiosis*. These tumors from a rabbit's liver, when examined under the microscope, show an irregular, atypical epithelial growth, described by some as a carcinomatous growth—not carcinoma, but that which has been described as malignant adenoma.

From the best authorities that I can obtain on rabbit's liver I find that these tumors are what we call proliferated cysts, or adeno-cystoma papilliferum. The parasites live in the epithelial cells of the bile-ducts, and set up a chronic catarrh, with polyposis. I do not think there have been any true coccidia found by any authority in the cells of carcinoma. I have looked over the literature very carefully, and cannot find proper description of them.

The next form of microörganism is the gregarine. This is an elongate, unencapsulated form with a nucleus situated at the enlarged extremity, and in its mature condition appearing much like a tadpole. It has been elaborately described by Korotneff, but I have been unable to find any such organism. Adamkewicz, who has written a number of articles on the poisonous nature of carcinoma, says that the carcinoma cells are neither epithelial cells nor derivatives of epithelial cells. Although he does not say so in so many words, he would regard the car-

cinoma-cells themselves as parasitic cells. According to this observer, they arise from very small granules, which develop into round cells, usually regarded as an inflammatory infiltration, and these in turn develop into the fully developed carcinoma-cells; and, moreover, he finds that these cells produce a poisonous substance, *cancroin*, which ultimately checks their growth.

Pfeiffer tells us that the parasite of carcinoma is neither a coccidian nor a gregarine, but belongs to a group of the microsporidia, which are described as amebasporidia.

Lastly come the views of observers who see the majority of bodies described by others, yet who do not find them to be either coccidia, gregarinæ, or sporozoa, but find them to represent various phagocytic and degenerative processes, and who conclude that to call these bodies parasites because they look like parasites is ridiculous. We must base our knowledge in this matter on some stronger fact than that of resemblance, before we can declare these bodies to be parasites. We must be able to cultivate them, or at least to make out some developmental stages of these microörganisms, before we can pronounce them alive, and then must cause the production of carcinoma by inoculation before pronouncing them specific.

Ruffer and Walker say they can see these parasites divide from 2 to 4, 4 to 8, and 8 to 16, and so on. This is evidence of a parasitic nature, but I have not observed such changes in the bodies that I have studied.

The results of my experiments show the presence in carcinomata of bodies that cannot be differentiated from parasites by their appearance alone. No one has been able to cultivate these cells outside of the body as Delépine has done the coccidia, or to produce carcinoma by inoculation of tissue containing them, or to carry out any of those laws postulated by Koch which give conclusive evidence of specificity.

I said a moment ago that there were some bodies in carcinoma that look like parasitic organisms. A great majority of carcinomata occur upon exposed surfaces, the lips, mammary gland, stomach, uterus, etc. All of these organs come in contact with the air, water, clothing, etc., and can receive in this way the spores of parasites and even the parasites themselves. Why could not these organisms, as well as bacteria, which are constantly, but accidentally, present, be found there? It would seem as if some of these bodies might be parasites, and yet have nothing to do with the etiology of the disease.

The most forcible argument that I can bring to bear upon the subject is the one based upon a study of the secondary growths. Carcinoma is a disease that gives rise to metastasis. It has been argued that this is a strong proof of its microorganismal nature. Tuberculosis spreads from place to place by the distribution of its bacilli through the blood and lymphatics; why should not the spread of carcinoma be due to similar distribution of its parasites? On superficial observation this seems to be true, but when examined carefully nothing is more fallacious. Tuberculosis is a simple inflammatory process, set up wherever its cause is operative. Carcinoma never presents a similar appearance, but always consists of an overgrowth of epithelial cells. As there are no epithelial cells in lymphatic glands to be stimulated to overgrowth by parasites conveyed there, a similar explanation of its production becomes impossible. But it may be argued that the carcinoma-parasites are conveyed to the lymphatics enveloped in the epithelial cells, which they subsequently stimulate to proliferation. This may be true; but I think the greatest proof of its unlikelihood is that the epithelium which is accidentally transported to a new environment retains its normal characteristics, even to the formation of quite typical glandular acini. Examination of the secondary carcinomata which grow in the omentum or in the lymphatic glands shows that quite numerous acini, almost typical of the parent-tissue, occur in the early stages of development. My explanation of this is that these cells have been accustomed to divide on a single plane. When they gain entrance into other tissues they retain this tendency, and, continually dividing on the same plane, line the cavities of the tissue with epithelium. This appearance remains for a certain length of time; then the tendency to proliferation continues and the cells multiply so rapidly as to entirely fill up the space. I cannot conceive of a cell which is the host of a parasite behaving in this manner.

It is a well-known fact that the tissue-changes are unusually active, and that epithelium seems to have a tendency to overgrow in old age. Old people are subject to brown patches upon the skin, which occasionally degenerate into epitheliomata. Warts on the hands of old people sometimes take on this change; so that a tendency to proliferation of epithelium is normal in old age. Carcinoma is most common in old age.

Why should not carcinoma simply represent an abnormal increase of this normal process and be the resultant of varied coöperating forces?

Probably the most common carcinoma is that of the mamma. This gland is one accustomed to proliferation of its epithelium and receiving constant reflex stimulation during menstruation, pregnancy, lactation, and the menopause. In such a tissue it is easy to conceive of a loss of proliferative inhibition in old age, increased proliferative stimulation from traumatism, by reflex action, even by bacteria and

protozoa accidentally present, producing the atypical growth called carcinoma, without having any one of these causes properly denominated as specific.

Although much truth appears to surround the parasitic theory, it is at present not proved, and the data that have been adduced are insufficient to establish parasitism in carcinoma.

CLINICAL LECTURES.

SPINAL HEMORRHAGE—EPIPLOCELE—RESECTION OF LEG FOR COMPOUND FRACTURE OF TIBIA, UNUNITED AFTER A MONTH.

Delivered at the Buffalo General Hospital.

By ROSWELL PARK, A.M., M.D.,
PROFESSOR OF SURGERY, UNIVERSITY OF BUFFALO.

SPINAL HEMORRHAGE.

This patient is a Pole, from whom we have with some difficulty obtained the following account: On Friday, while working underneath a large dredging machine, the heavy iron bucket, loaded with dirt, came down on the middle of his back. He became helpless at once, and when seen by the ambulance-surgeon he could not move the legs. In the evening the house-surgeon found an alteration in the contour of the spinous processes, there being a gap at the level of the ninth or tenth dorsal vertebra. There was also extensive bruising; a large hematoma or blood-extravasation having formed on the right side. There was apparently retention of urine, and the man was catheterized. On receiving this report by telephone I decided that it was not necessary to see him that night, and the next morning he had so far recovered that there was fair sensation in the legs and he could move them a little. He has continued to improve, although nothing has been done except to catheterize him thrice daily and to give him ordinary care in bed.

The diagnosis is of interest, as upon it depends the nature of the treatment. The ecchymosis requires no special treatment beyond cold applications. The displacement of bone may mean simply a chipping-off of a spinous process—a trivial injury—or it may mean a fracture of the spinal column proper, which is serious because it almost necessarily involves a disturbance of the contents of the spinal canal. Fracture of the spine is serious in proportion not to the extent of the bony injury, but to the amount of injury inflicted on the spinal cord. An injury to the back may, however, cause compression of the cord, without any alteration in the lumen of the bony tube on account of hemorrhage. Blood may be poured into the spinal canal from different sources. It may leak through from a ruptured vessel outside the spinal canal; it may come from the arteries or veins of the membranes of the cord; the vessels of the cord itself, or of the pia, may pour out blood into the substance of the cord, and finally the clot may be in the central canal of the cord when that is present. Hemorrhage, no matter how severe, requires an appreciable amount of time before pressure-symptoms develop. Dislocation, from fracture or otherwise, is almost instantaneous in producing paraplegia; hence, if an injury is followed immediately by a genuine paralysis, not the mere disability from stunning, the inference is that there is depression of bone. If, however, paralysis comes on within a few minutes or hours, the inference is that the compression is due to more or less rapid hemorrhage. Paraplegia coming on a week or more after an injury is due ordinarily to one of two things—the pressure of pus or a disorganization of cord-tissue following inflammatory changes. In this case we evidently have to deal with a paralysis produced immediately or very soon after an injury, and which has passed away quite rapidly, leaving only a trifling anesthesia and disturbance of function. To-day you see that the patient lifts his leg and moves it about quite freely, though he groans as if it hurt him. This is a marked improvement since Saturday. Trying him with a pin, you see that his sensibility is fair, though not exquisite. It is well also to test the muscle-sense by making gentle but forcible deep pressure. It is impossible to tell whether his lack of response is due to a phlegmatic disposition or to anesthesia. On the whole, sensation is good except in the genitals. The man does not seem to feel the introduction of a catheter or sound. You can see the ecchymosis of the back and note that he flinches when pressure is made over the injured spot.

My surmise is that he has extensive bruising, which accounts in part for the disinclination to move the leg; because any movements of the thigh involve tension on the glutei, which have suffered somewhat. I cannot believe that there has been depression of the spinal arch. In this large and complex group of muscles to which, collectively, we give the name erector spinæ, there is an extensive contused wound. I presume that there was a small hemorrhage somewhere in the spinal canal, for in a large number of cases of bruising alone I have failed to note even temporary paraplegia. However, the supposition of hemorrhage is a mere conjecture which I cannot prove to you. The symptoms are not very complete, nor are the facts upon which an accurate diagnosis would be based definitely known. Two or three of your number have expressed the hope that this would be a case for operation, but you will understand the futility of interfering when there is no indication that the bodies of the vertebræ are displaced.

In the catheterization, which constitutes the principal treatment, care must be taken not to set up a septic cystitis, to which paraplegic subjects are particularly prone. The man is eating heartily, and we must take care to have his bowels move every day. If there were any evidence of atrophy of the limbs we should have to stimulate the nutrition of the muscles by the faradic current and massage. Here, however, the indication is to let him alone as much as possible so as to allow the bruise to heal. He is turned from his back occasionally, so as to make sure that no bedsore is forming.

EPIPLOCELE.

This patient is a lad, eighteen or nineteen years old, who tells me that about three years ago he noticed a slight tumor within the scrotum, more on the right side, which seemed at first to be closely connected with the testicle, but which later separated from it and feels like an extra testis. It is growing gradually and is now as large as a hen's egg. Two questions present themselves: first, what is it? and secondly, what shall we

do for it? I prefer to take up the latter question first. Any neoplasm which grows and gives rise to trouble, I hold, should be removed, and the earlier the better. In regard to diagnosis, among the ordinary conditions with which we have to deal in this location are disease of the testicle itself, hernia, hydrocele of the cord, other tumors of the cord, of which lipomata are the most common. Two or three weeks ago I had occasion to operate on a man for inguinal hernia of the left side, and a small lipoma of the spermatic cord of the right side. This mass seems free from all signs of inflammation, and there is no history of traumatism. There is neither family nor personal history nor any objective manifestation of tuberculosis, and we can leave that out of consideration. Syphilis likewise can be excluded. The tumor is of about the same size and feeling as the testicle. On coughing, a certain amount of impulse is communicated to the mass, but not to the same degree as would be expected in the case of hernia. With the efforts at retching under the anesthetic more of the same impulse is communicated. This mass, which has gradually enlarged and descended, which is free from the testicle, and which is pushed down with the abdominal contents in coughing and retching, I take to be a hernia. Its solid consistence and the absence of tympany lead me to think that it is an epiplocele, that is, a hernia consisting of omentum. The neck of the sac is probably small, and the slight impulse on ordinary coughing is due to the firmness with which the mass is held in place.

The groin and scrotum are shaved and disinfected, and an incision is made obliquely over the course of the spermatic cord. In cutting down on the sac I find a band of muscle-tissue which represents the cremaster. A little serum flows out under pressure. On opening this sac you see a large mass of omentum. This could be put back into the abdomen, but I prefer to ligate it and cut away the redundant portion. It is always well to be extra cautious not to include in the ligature a small loop of intestine which sometimes projects just inside the neck of the sac of an epiplocele. This would be a fatal mistake if not rectified. The catgut ligature which I have applied here certainly includes nothing but omentum, and I will cut away the mass down almost to the thread. I next dissect off the remains of the sac from the omentum and spermatic cord. The latter is much more firmly adherent than usual. My earlier operations for the radical cure of hernia involved splitting up nearly the entire inguinal canal. In this operation, however, I design to follow a modified Kocher's method. Part of the inguinal canal is left unopened. Forceps are pushed down through the canal, brought out through the external ring where the hernia came out, so as to catch the sac and pull it up through the canal, and twist it into a mass at the level of the internal ring. Here it is sewed down to make a plug of tissue at this point. I twist it so that the twist will extend to the internal ring, and I shall attempt to destroy it as a sac, so that the place which knew it as a sac shall know it as such no more.

UNUNITED FRACTURE OF TIBIA.

This case is one of non-union following compound fracture of the tibia. It was seen by Dr. ——, a month ago, at the time of the injury. He found between the larger upper and lower fragments a small pyramidal fragment held in place by a periosteal hinge. Very properly he decided to try to save the leg in its entirety, and, accordingly, he wired the two larger fragments together with a double ligature passed through drill-holes, while a third wire was wrapped about the intermediate fragment. Every opportunity was given for the uniting of the pieces, but the vascular connection has proved insufficient. The middle fragment is now simply so much dead bone, which is not only useless, but a menace to the vitality of adjacent structures. It must certainly be removed. Two lines of treatment are open to us. We may amputate the limb, as was formerly done in almost every case of compound fracture, to prevent the septic trouble which almost immediately set in before asepsis was known; or we may resect the bones of the leg "in continuity." The patient will not listen to the suggestion of amputation; nor do I advise it, for resection offers the chance of a useful though shortened limb.

The limb is scrubbed with green soap, and then with corn-meal, and is irrigated with a bichlorid solution. The Esmarch bandage is applied to prevent hemorrhage. For the sake of convenience I shall dissect down upon the fibula first, cutting between the muscular bundles rather than through them. Wyeth's exsecting instrument is used, metallic retractors preventing the saw from cutting anything but bone. The second division of the fibula I will not make until the fragment of tibia is removed, so that I may know just how much of the fibula to cut away. You see that the intermediate piece of the tibia is irregularly pyramidal, one line of fracture being nearly transverse, the other oblique, and about four centimeters long. An assistant holds the leg firmly while the rough ends of the remaining portions of the tibia are sawed off smoothly with a chain-saw. As a result of the inflammatory reaction from the injury, the bone is very much sclerosed, and, therefore, it comes away with difficulty. The bones were fastened with wire, and a good result was finally secured.

THE INCH-AND-A-HALF INCISION AND WEEK-AND-A-HALF CONFINEMENT IN APPENDICITIS.

A Clinical Lecture at the New York Post-Graduate Medical School, February 24, 1894.

BY ROBERT T. MORRIS, M.D.,
OF NEW YORK.

GENTLEMEN: Three years ago this man suddenly awoke in the night with acute pain in the *left* side of the abdomen. He had bilious vomiting from then until the following noon, when the acute symptoms subsided, leaving general abdominal soreness, which lasted for four days. At the end of that time he got out of bed and resumed his work, feeling perfectly well. During the following year he had two similar attacks. One year ago the most severe attack occurred, and at that time he was obliged to remain in bed for three weeks. The diagnosis of appendicitis with abscess was made at that time, and the pain and tenderness became localized in the right inguinal region. The reason why the pain is felt anywhere in the abdomen excepting at the appendix

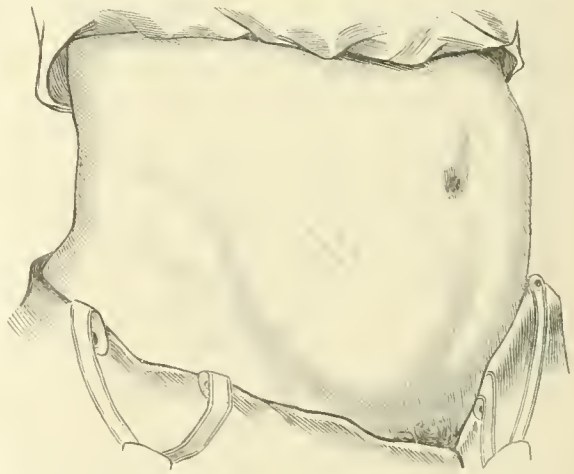
is probably because of the wide distribution of the sympathetic plexus, which supplies the appendix, and because the latter rudimentary structure, of low vitality, does not respond as quickly to irritation as do the other parts of the bowel. This man at present is quite well, but his physician has learned that appendicitis is an infectious exudative inflammation which does not disappear with disappearance of the symptoms, and as a personal friend of the patient he does not wish to witness the suffering incident to another exacerbation of the inflammation. I shall attempt to remove the appendix through an incision in the abdominal wall one inch and a half in length. This operation was not originally devised for cases like the one before us. I intended it for cases in the early stages of the first attack, before the formation of adhesions or pus, and for the purpose of developing an operation simple in itself, which would be dreaded less than a single day of suffering from appendicitis. Gradually, however, one finds himself becoming more expert, so that after a little one will readily remove through the short incision infected appendices that are firmly imbedded in adhesions, and even in patients who are decidedly stout. In cases with pus, or with masses of infected new peritoneal exudate, a longer incision will be necessary. The advantages of the inch-and-a-half incision are several. Scars are unsightly to anyone of artistic taste, and the shorter the incision the shorter the scar. Time spent unnecessarily in bed is time wasted, unless one can utilize such an opportunity for reading. The general disturbance caused by an incision varies in proportion to the size of the wound. An incision one inch and a half long causes very little disturbance, and it confines the patient to his room for only a week and a half. An incision two inches long will confine the patient to his room for two weeks, and an incision three or four inches long will require nearly three weeks for good, firm union of divided tissues.

A line one inch and a half in length is now measured off on this patient's abdomen, in a direction that follows the trend of the external oblique aponeurosis, and at a point in the linea semilunaris which is over the cecum. As soon as the peritoneum is cut I insert a loop of catgut through the transversalis and internal oblique aponeuroses at the cephalad angle of the wound, to serve as a guy-line for pulling up these structures when the wound is ready for suturing. The cut margins of the two deeper aponeuroses are difficult to capture unless we have such a guide, because their muscles pull them far away while we are at work with the appendix.

The colon you all recognize at a glance, because of its longitudinal muscular ribbons, all of which "lead to Rome." We cannot possibly fail to find the appendix if any one of these ribbons is followed; but in order to follow it in the right direction, I determine the direction in which the bowel runs by exciting reversed peristalsis with a little pinch of salt placed upon the colon.

The cecum is drawn up through the wound, but adhesions prevent withdrawal of the appendix. One finger introduced into the abdominal cavity separates the adhering mass from parietal peritoneum and from the mesentery of the ileum.

I would not advise anyone to do this with his first cases. It is better to work by sight until the fingers are trained. Now you all see the appendix, which is covered with adhesions like a spider's-web about a slug, binding it firmly to the cecum. The appendix is peeled out with the handle of a scalpel. Scissors are used for snipping through the peritoneal and muscular coats close to the cecum, and a strand of finest eye-silk is employed to ligate the tube of mucosa still uncut. This leaves the tiniest of stumps, with the tiniest of ligatures, when the appendix is cut away. Three Lembert sutures bury this stump deeply, so that peritoneal adhesions can wall it in securely in a few hours. You observed the result of leaving the stump of an appendix unburied, in a case upon which I operated before the class last Saturday. In that case the infected stump had caused an inguinal abscess and extremely tough adhesions, although the adhesions may have been due to the employment of chemical antiseptics within the peritoneal cavity. Chemical antiseptics and plain water injure the serosa, and adhesions result; but normal saline solution which we use here does not damage the peritoneum. The large ragged-looking portion of cecum that was involved in adhesions in this case to-day is now covered thickly with aristol, and after waiting a full minute to allow a lymph-coagulum to form with part of the aristol, the surplus powder is blown away. Aristol used in this way prevents reunion of adhesions. It is one of the most practical of resources, but one that I have some difficulty in persuading surgeons to adopt. I have separated old adhesions a great many times for former patients whose peritoneal surfaces had been injured by the routine technique of the day, and have relieved them completely with the aristol film.



The inch-and a-half incision appears a little wider than it should because of blurring in the photograph.

In closing this wound an assistant pulls on the guy-line, and the cut margins of peritoneum, transversalis fascia, transversalis, and internal oblique aponeurosis appear in plain sight so that they can be accurately sutured with fine catgut. If we did not do such painstaking work here the patient would not be ready to leave his room at the end of a week and a half. The cut margins of the external oblique aponeurosis are approximated with two interrupted catgut sutures, and last of all we apply the prettiest resource of all. This consists in putting the skin-wound upon the stretch with two

small hook retractors so that skin-margins are adjusted with precision, and united with a continuous suture of the finest catgut. Such a scar is hardly to be seen after the wound is healed. One of the men in our audience you saw me operate upon ten days ago for the removal of a gangrenous appendix. I will ask him to kindly step down into the amphitheater and remove his clothing so that you can see the scar. If it were not for a slight redness which has not quite disappeared, the scar-line would not be visible ten feet away; and yet a week and a half ago some of the members of the class asked me after the operation if the patient could live. They were newly-arrived members who had not seen the inch-and-a-half incision. Two hours from now I shall be engaged in an argument with several physicians who have not been present at any of these operations, and they will explain by apparently clear reasoning that the inch-and-a-half incision is impracticable in appendicitis cases.

CLINICAL MEMORANDA.

LARGE SUPPURATING CYST OF THE PANCREAS; PANCREATOTOMY; RECOVERY.

By WILLIAM W. ASHHURST, M.D.,
OF CHIHUAHUA, MEXICO.

Francisco G., aged thirty years, of Mexican birth, a machinist by trade, consulted me June 1, 1893, in regard to a tumor of the abdominal cavity, which had been troubling him for some time.

He confessed to having been a very hard drinker until about a year before. About six months before consulting me he began to suffer from indigestion, and, seeking medical advice, was told he had gastric catarrh. He was treated by means of lavage of the stomach, but experiencing no relief consulted another physician, who detected the presence of an abnormal collection of fluid in the abdominal cavity. Paracentesis was practised twice, there being withdrawn each time, according to the patient's statement, a small quantity of a clear, yellowish fluid. At no time did he suffer any pain, but he was constantly distressed by his inability to take anything into his stomach without immediate and great discomfort, and by the constant sense of weight and soreness of the contents of the abdominal cavity. Recently he had vomited on several occasions, but the material vomited seemed to be only the food he had eaten. For some weeks he had subsisted entirely upon liquid food, and was able to take only a very small quantity of this at one time. He was now somewhat emaciated, and stated that he had lost twenty pounds in weight during the last six months. He was not aware of having had any fever since being taken sick, and said that his bowels and kidneys acted naturally and regularly. His temperature was at this time normal, and examination of his urine on two occasions failed to reveal anything abnormal.

On examining the abdomen there was apparent a large fluctuating tumor, nearly globular in shape, reaching from the xiphoid cartilage to below the umbilicus, and in a lateral direction entirely filling the abdominal cavity. On percussion the tumor seemed continuous with the liver. My diagnosis was a probable hydatid cyst of the liver.

As it was evident that paracentesis was of no avail in this case, its trial on two occasions having produced no benefit, I advised an exploratory celiotomy with a view of determining the diagnosis, and taking such measures for relief as might then suggest themselves.

On June 6, 1893, the patient was anesthetized by means of chloroform, and the surface of the abdomen was shaved and scrubbed with soap and water, and then with a solution of corrosive sublimate of a strength of one to one thousand. The abdominal cavity was opened at its most prominent part by a linear vertical incision, three inches to the left of the median line, and extending from one inch below the margin of the ribs downward for four inches. Beneath the parietal peritoneum was found omentum instead of the peritoneal covering of the liver, as was expected. It was, therefore, evident that the stomach was above the tumor, compressed between it and the liver, and that the tumor itself was situated in the lesser cavity of the peritoneum.

Cutting through the omentum this was found adherent to another layer of peritoneum beneath, which covered the tumor itself. This was still thought to spring from the liver, but was now believed to be connected with the part of it posterior to the lesser omentum. Satisfactory manual exploration was impossible, owing to the size of the tumor. I now introduced a trocar of about 4 mm. diameter through the cyst-wall, and drew off about a gallon and a half of a turbid, yellowish-green, rather thin purulent fluid, of a sweetish, peculiar smell. After withdrawing the canula there was room enough around the tumor to make a manual exploration of the abdominal cavity. In the upper part of the incision now appeared the stomach, which had found room to descend and now had a little gas in it. Behind and above this could be felt the anterior edge of the liver; the small and large intestines were crowded down far below their normal position. The spleen was normally situated, as were also both kidneys. The base of the cyst appeared to extend from the under surface of the liver downward to the region of the kidneys.

The surface of the cyst was now stitched to the edges of the parietal incision with a continuous silk suture, and a longitudinal incision was made into it. This was followed by the escape of a large quantity more of thin purulent fluid and of a white granular substance, which in appearance and consistence much resembled boiled rice. From the bottom of the cavity I removed with my hand a solid mass about three inches long and an inch broad, which had been floating about in the fluid, and which, on more careful examination, proved to be a piece of pancreas-substance, in appearance somewhat changed from its natural condition. It was of a grayish color and of a flabby, soft consistence, having apparently undergone fatty degeneration, though no microscopic examination was made of it. The sac of the cyst was about 3 mm. thick, and rather weak, the stitches showing a tendency to tear through it.

The wound was closed with silk sutures, a rather thick rubber drainage-tube, eight inches long, being used to drain the cavity, and an antiseptic dressing was applied and held in place by a Scultetus bandage.

The patient's recovery was not interrupted by any serious mishap. At first there was a profuse discharge of pus through the tube, and the dressings required

renewal twice a day. On June 15th I commenced injecting the cavity daily through the tube with a solution of permanganate of potassium, and by July 1st the discharge from the wound had become perfectly clear, very much resembling saliva. The drainage-tube was now entirely dispensed with, but the pancreatic fistula remained open, in spite of attempts to encourage its closure by injections of tincture of iodin, until August 25th, when it closed permanently. For about ten days from the time of the operation the patient was kept on a liquid diet; but this was due to his general condition, and not because digestion itself was in any way particularly disturbed. Since that time he has been able to eat anything without discomfort.

On September 1st he returned to his work as a machinist, and reported that he weighed twenty pounds more than before the operation, which, allowing for the weight of the fluid removed, would indicate a gain in healthy tissue of at least thirty-five pounds.

On February 28th he still remains well, but unfortunately has gone back to the drinking-habit.

The especially interesting features of this case are: First, the difficulty in diagnosis. The dyspeptic symptoms were only such as would naturally have been caused by the mere compression of the stomach, the unaffected portion of the pancreas apparently doing the work of the whole gland. On anatomic grounds alone I believe that, unless seen in an earlier stage, it would have been absolutely impossible before the operation to locate exactly the tumor, although possibly by more frequent examinations the position of the stomach might have been ascertained. By more frequent examinations of the temperature, too, some elevation might have been detected. The diagnosis, indeed, was not made until the loose piece of pancreas rendered it evident.

Secondly, the size of the cyst. The only case of pancreatic cyst or abscess I can find recorded which at all approaches this in size, is Bozeman's case of pancreatic cyst, which contained two gallons and a half of fluid, or half a gallon more than this held.

Thirdly, the contents of the cavity. The loose piece of pancreas-substance is spoken of as occasionally occurring in pancreatic abscesses; but all the other facts seem to me to indicate that this was primarily a simple distention-cyst, afterward undergoing suppuration, perhaps from the use of a dirty instrument when paracentesis was performed. The absence of the constitutional signs of suppuration, the history of a clear fluid having been withdrawn, the great distention without rupture of the capsule of the pancreas, the rice-like substance found in the fluid, the very character of the fluid itself, all suggest to my mind that it was a cyst afterward undergoing suppuration, and not primarily an abscess.

Finally, the etiology and termination. The cause of the disease in this particular case is certainly obscure. No calculus was found. The persistence of a pancreatic fistula after the operation indicated that there was a backward flow of pancreatic fluid from the portion of the gland remaining, possibly caused by continued obstruction of the main duct or one of its branches, or more probably occurring simply because there was less resistance to the flow in this direction than through the natural channel. The final closure of the fistula, without return of the symptoms, indicates that if there was continued obstruction this has been removed, which, in the case of an impacted calculus, is rather unlikely, the impaction having lasted so long; or that the portion of the gland from which the backward flow occurred has undergone atrophy, which is still more unlikely. The probabilities are that all that portion of the gland the secretion of which was originally prevented from passing down the main duct, was removed at the time of the operation, having early undergone fatty degeneration from pressure, or a cutting-off of its blood-supply; that the pancreatic fluid was discharged through the fistula after the operation simply because that was its readiest mode of exit; and that when by the natural process of cicatrization the fistula closed, the fluid found an exit by its natural passage, the canal of Wirsung. As for the cause of the original obstruction, if not a calculus, this was probably of catarrhal origin, perhaps resulting from the man's previous intemperate habits. At any rate, I could learn of no cause that seems more probable.

CARCINOMA OF THE LARYNX, WITH CONSECUTIVE EPITHELIOMA OF THE LIP.

By CHARLES P. GRAYSON, M.D.,
of Philadelphia;
physician to the department of diseases of the throat and nose, hospital of the university of pennsylvania.

In spite of the abundant lymphatic supply of the larynx, metastasis associated with carcinoma of this organ is so rare that its occurrence has been denied by more than one author. The rich experience of Morell Mackenzie could furnish but a single instance of it. During the past decade, however, a number of cases have been recorded in which secondary deposits were found in the mediastinal glands, the lungs, and in the abdominal cavity. As a rule, glandular involvement is a late feature of malignant disease of the larynx, usually not making its appearance until ulceration has existed some time. Contamination of the blood-current, therefore, unless direct, and transportation of the infecting cell (or parasite?) to remote regions, are proportionately delayed or do not occur at all. Of the varieties of laryngeal carcinoma, divided by Krishaber according to their location into extrinsic and intrinsic, the former is the more likely to occasion glandular infiltration, and ample explanation for this difference will be obtained by reference to Sappey's demonstration of the peculiarities of the lymphatic distribution in this region.

This brief preface serves to introduce the two points that make the case here reported an exceptional one, viz., that a labial growth apparently metastatic and consecutive to a laryngeal carcinoma has occurred, and that this latter at the time of writing this report is still wholly intrinsic. The relative situation of the secondary to the primary growth affords additional matter for surprise and speculation.

Frank S., thirty-four years of age, married, and a policeman by occupation, has a family history, recent and remote, quite negative. Two brothers are living, both in excellent health. The patient has three vigorous children, and, until this present illness, has himself enjoyed uninterrupted health.

In December, 1891, a severe attack of influenza confined him to the house for three weeks, but, though greatly reduced by this illness, his recovery was complete and during the ensuing year he was as well and active as ever. In December, 1892, he had a second experience with influenza. This attack was of briefer duration than the first, but left him with what seemed like an obstinate "cold in the head." This remained limited to the cavities of the nose and naso-pharynx for some two or three weeks, and then moved downward and established itself in the larynx. Its invasion of this cavity was announced by the sensations usually accompanying an irritative hyperemia of its mucosa—dryness, heat, and tickling—and these provoked frequent but futile efforts to clear the throat. There was neither cough, dyspnea, nor dysphagia, and for some time the voice was not noticeably impaired. He entered, toward the latter part of January, upon a two months' course of treatment by a homeopath, from which he emerged destitute of voice and with a great increase of laryngeal secretion. There is no obtainable history of hemorrhage.

The patient reported at the Throat Department of the Hospital of the University of Pennsylvania, August 29, 1893, coming, he announced in a harsh whisper, almost solely that his voice might be restored. He did not suspect that anything serious could be the matter with his throat, since there was an entire absence of pain and, excepting the aphonia, he had little to complain of but discomfort. He was of good color, muscular, and seemed in excellent general condition.

Nothing abnormal was discovered in the nasal cavities or the pharynx. The laryngoscope disclosed, also, a normal epiglottis, but at this point health came to an abrupt stop, and of the rest of the larynx disease held complete possession. The two ary-epiglottic folds were swollen to dimensions that wholly obliterated their original outlines. The inter-arytenoid space was represented only by a shallow fissure that marked the line of contact of the huge masses enveloping the arytenoids. The mucosa and submucous tissues were not edematous, but were shown by the probe to be the seat of a dense and resistant infiltration. Within the laryngeal cavity a degree of ulcerative destruction so advanced was found that its existence for some months could not be doubted. This ulceration was limited to the right side, and its upper boundary came within a line or two of the swollen and overhanging ary-epiglottic fold. The ventricular band was deeply excavated, the vocal band had vanished, and the lower margin of the ulcerative process was lost to view in the depths of the sub-glottic space. On the left side there was great infiltratory swelling, but, as yet, no superficial breach of tissue. The borders of the ulceration on the right were marked by a luxuriant fringe of nodular excrescences, and the whole appearance of the growth was unmistakably malignant.

The examination of the larynx being completed, the patient drew the lower lip downward and exposed an ulcer on its inner surface to the right of the middle line. This had been first noticed three weeks before. It had come, he said, like an ordinary "cold sore," but had gradually enlarged its dimensions and changed somewhat in appearance. At this time it was almost circular and about 8 mm. in diameter, its surface almost flush with the surrounding tissue, and with very little induration of its base. Alone, the character of the lesion would scarcely have aroused suspicion, but its coexistence with a certainly carcinomatous laryngeal growth led to its closer scrutiny and a more careful marking of its progress. It was early submitted to Dr. John Ashhurst for opinion and was regarded by him as an epithelioma. In the effort to check its extension several agents have in turn been tried and have failed, the submaxillary glands have gradually enlarged, and, within the past few weeks, the patient has begun to exhibit some signs of the long-delayed cachexia of malignant disease Glandular involvement that can be traced to the laryngeal disease is still very slight. The pre-laryngeal gland can be felt lying upon the crico-thyroid membrane, but the group of glands on either side of the neck beneath the thyro-hyoid membrane, to which the lymphatic vessels of the upper portion of the larynx are tributary, still eludes detection. A few of the glands that flank the trachea are slightly enlarged, but not nearly so much as the stage of the disease in the larynx would lead one to anticipate.

With the completion of this statement of the existing disease the bare report of the case ends, but several questions may suggest themselves that have both interested and puzzled me. If, for a moment, we admit that the labial growth is a metastatic one, by what path did the infecting cell coming from the larynx reach this point—through the blood-current or by way of the lymphatic vessels? Or, putting aside the theory of metastasis, is it possible that the lesion upon the lip was in its beginning quite innocent and that a malignant transformation ensued upon an auto-infection at this point? Or, finally, may we regard the ulcer as having been malignant from its inception, yet at the same time as wholly independent of the laryngeal disease? In other words, is the synchronism of these two growths simply the expression of a diathetic state predisposing to the development of multiple malignant neoplasms?

The first of these questions is not easy of solution. If we consider the lymphatics, we find that they afford no path, either direct or circuitous, by which the carcinoma-cell could have been naturally conveyed to this point by the lymph-current. The downward course of this stream would oppose the upward movement of the infecting agent toward the lip, and unless we attribute to the cell an inherent migratory power of sufficient strength to overcome the force of such an opposing current, we are compelled to look elsewhere for a means of transportation. If, therefore, we turn to the bloodvessels, we are confronted by the facts that up to the day of his placing himself under treatment, which was three weeks subsequent to his discovery of the labial sore, it is extremely improbable that there had been any contamination of the blood, either direct or through the usual medium of the lymphatic system. There had been no hemorrhage from the laryngeal lesion, the sputum had contained at no time even a trace of blood, and glandular involvement was so slight that its detection required a most careful search. It may be offered as further counter-evidence that it has not been until the last two or three weeks that the customary cachexia has been at all discernible.

Abandoning, therefore, for anatomic and other reasons, this theory of metastasis, what has the second

theory to say for itself—that which supposes a primarily innocent ulcer to have acquired malignancy through its constant exposure to the irritating discharges and tissue-débris coming from a neighboring carcinomatous growth? This, at first thought, may not impress one as being a very likely accident, but instances are not wanting in the literature of carcinoma that will afford it a quite substantial support. In the *British Medical Journal*, 1889, vol. i, p. 133, Newman reports a case in which an epithelioma springing from the right vocal band effected in time an erosion upon the opposite band at its point of contact with it, this proving to be the first step in the production of a second and identical growth; one, however, that was unquestionably the result of auto-infection and not of metastasis. Additional cases might be referred to which, though perhaps clinically less clear than this one, yet afford almost equally strong presumptive evidence of a similar mode of origin.

The third and last question affords wide opportunity for conjecture, but of weighty evidence concerning the relationship or dissociation of these two growths there is little to be offered. It may be said, however, that if they are to be regarded as wholly independent of one another the patient presents a remarkable instance of "original sin" in the matter of malignant disease. His family history is entirely without blemish of this character, his parents and grandparents having lived to advanced age and dying from causes that could have exerted no sinister influences upon succeeding generations. Heredity, indeed, is not now admitted to play the same prominent part in the diagnosis and prognosis of suspicious new-growths that it once did. Dr. Herbert Snow, of London, in a recent article in the *Medical Press and Circular* concerning improved methods in carcinoma-treatment, says: "Heredity is an element which is much more likely to mislead in diagnosis than the reverse. I have learned that a person who comes to me with a strong family history of cancer is much more likely to be suffering from some innocent ailment than from this dreadful scourge."

In conclusion, a word may be added concerning the curious frequency with which malignant neoplasms have been recently observed to follow in the wake of influenza. Of course, no specific causal relationship will be alleged to exist between epidemic influenza and carcinoma, but it does at first glance seem something more than a mere coincidence that the one should follow the other so often as the medical periodicals of the past year or two have asserted it to do. It is, not improbably, to the exceptionally exhausting nature of this disease and to the intensity of its depressing effect upon tissue-vitality, as well as to the various vaso-pareses it leaves behind it, that the early appearance and rapid development of malignant disease are due. The recorded examples of this sequence are too numerous to permit of individual reference, but I may add to their number the one that forms the subject of this report, and, also, two others of which I have had charge—one, a hostler in the Veterinary Department of the University of Pennsylvania, who died last spring of a laryngeal epithelioma, the throat having first attracted his attention within ten days or two weeks after an attack of influenza; the second, a clergyman who, two months after a severe attack of influenza in September, 1892, was compelled by loss of voice to give up his church, this being the first symptom of a malignant laryngeal growth the progress of which was so rapid that it necessitated tracheotomy in August last and proved fatal in October.

CASE OF ATTEMPTED SUICIDE BY SULPHATE OF MORPHIN TREATED BY PERMANGANATE OF POTASSIUM; RECOVERY.

By H. D. WALKER, M.D.,
of Franklinville, N. Y.

In view of the recent experiments by Dr. Moor, of New York, tending to show that the permanganate of potassium is an antidote for poisoning by morphin, I think it is proper to report the following case.

Between the hours of two and four o'clock P.M., on March 14th, Mrs. A., aged fifty-eight years, took, with suicidal intent, as nearly as can be ascertained, about forty-five grains of morphin sulphate. I was called to see her at nine o'clock P.M., and found her lying upon a sofa, sleeping soundly; the pulse was 90; the respirations not stertorous, but irregular, and averaging about twelve per minute; the pupils very extremely contracted—like pin-points. She could be roused by speaking loudly to her, but would immediately go to sleep again. She could not walk or stand alone, and when raised upon her feet staggered about and would have fallen if not supported. She responded to questions when thoroughly aroused, and on my asking her how much and when she had taken morphin, she denied taking any, and asked if we thought she would lie about it. The following history was obtained: She was alone in the house from one until four o'clock P.M., when a neighbor called and found her lying upon the sofa in a dazed and delirious condition, her face highly flushed and of a dark-red color. Her husband was sent for and arrived soon. She was then very sleepy, but could be roused, and suspecting she had taken morphin he questioned her about it. She denied this, and not knowing how to account for the state she was in he sent for me. On careful inquiry I could not learn that there had been any morphin or opium in the house for several months, but being thoroughly satisfied from the symptoms that it was a case of poisoning from opium or one of its preparations, and believing that an emetic would avail little, on account of the time that had elapsed since it was taken (at least five hours), I concluded to give the permanganate of potassium a trial. I immediately procured some from my office, a short distance away, and gave her five grains dissolved in a glass of water. In fifteen minutes from this time I gave her two and one-half grains more, in half a glass of water, and the last dose was repeated every quarter of an hour until she had taken fifteen grains of the antidote. Her condition at this time was so much improved that I did not think it necessary to give her more, as she could easily be kept awake. She was then placed in a rocking-chair and given a paper to read. This was exceedingly difficult for her, on account of the contraction of the pupils—so much so, in fact, that she could make out but a few words of the coarsest print. I remained with her until midnight, at which time I considered it safe to leave,

after giving directions that she should be kept awake, and if she became very sleepy she should be given more of the permanganate of potassium.

On my visit the following morning I found that she was greatly improved, and on questioning her she gave me the following history: Having an idea that she was a burden to her husband, she determined to end her days in such a manner that no one would suspect that she had taken anything for that purpose; so she procured a dram of morphin sulphate from a neighboring city, the week before, directing the same to be taken from the vial and sent by mail in an envelop. This she kept until the afternoon of the 14th, when, as the clock struck two, she took the first dose, which was as much as she could conveniently hold in the hollow of her hand, and she believed it was enough to kill her. This, as well as subsequent doses, was taken dry, with a drink of water to wash it down. As the clock struck half-past two, feeling no effect from the dose taken, she took another one. Within a short time after this, in order to make sure, she took two or three doses more. At no time was there any vomiting, so that all of the morphin must have been retained. In corroboration of this, she told us where to find the morphin that was left. We found this where she had fastened it with a carpet-tack, in an envelop, on the back side of a bureau-drawer, when she took the first dose. There were five tack-marks on the drawer, showing it had been removed four times, and from this it is believed that five doses were taken. There were ten grains left in the envelop, so that about forty-five grains were gone.

The foregoing history would be imperfect and misleading did we not record the patient's previous habits in regard to morphin. This will not only help to explain why she was not more seriously affected by the amount taken, but it is also necessary in order that we may not overestimate the effects of the permanganate given as an antidote. I am informed by her husband that for twenty years she had taken morphin, until about the 15th of last October, since which time, I am well satisfied, she has taken none until now. He tells me she took for quite a time before leaving off the habit, about ten grains of morphin three times daily. Now, in view of this history and her symptoms, I am not prepared to say that in her case the amount taken with suicidal intent would have been a fatal dose; on the contrary, it seems probable that she might have recovered without the use of the permanganate. But I am favorably impressed with the action of the antidote, and believe that it aided much in relieving the woman of the effects of the poison. Whether it did this by acting on the morphin which still remained unabsorbed in the stomach, or upon that which was brought back to this organ through the circulation, as suggested by Dr. Moor, I shall not attempt to decide. The first view seems to me more probable than the last.

In regard to the action of the permanganate as an antidote to morphin injected subcutaneously, I confess I am somewhat skeptical. If a large dose were given in this way, I fear that the patient would die before enough of it was brought to the stomach, through the circulation, to be acted upon by the antidote. I certainly should not advise as an experiment that a poisonous dose be given subcutaneously to a person for the purpose of testing the effects of the permanganate through the stomach.

HYDATIDIFORM MOLE; REPORT OF A CASE.

By H. F. C. HEAGEY, M.E., M.D.,
of Cochranville, Pa.

The infrequency of hydatidiform mole, or myxomatous degeneration of the placenta, and our ignorance of the primary cause, make such cases interesting. Many and various have been the opinions advanced as to the nature of the "vesicular mole," but the theory of Virchow, "myxomatous degeneration of the villi of the chorion," is now generally accepted. If the modern erroneous idea that a hydatid must always contain echinococci can be gotten rid of, and the term be taken in its original and correct meaning of a water-like cyst, none need object to the now almost universal designation "hydatidiform mole."

Modern research shows that this formation is not likely to occur independently of conception, and that the usual exciting cause is most probably maternal, and due to some dyscrasia, as carcinoma or syphilis; yet it must not be forgotten that echinococci, from their very nature and habits, might be here, as well as elsewhere in the body, the cause of the degeneration independently of conception, or the cause of the degeneration of the chorial villi. Rokitansky says that it can be an independent growth—a "uterine acephalocyst." Here the microscope will bring the decisive test, and prove quite valuable from a medico-legal status. Parvin (*Science and Art of Obstetrics*) says: "The disease is not frequent. Madame Boivin saw but one case in 20,375 deliveries."

The following case adds testimony to the fact that the disease is most frequent in the aged and multiparous; it very faintly suggests a carcinomatous dyscrasia, while a tuberculous family history here, as noticed in other cases reported, may not be a mere coincidence.

It occurred in a farmer's wife, fifty-two years old, healthy, quite stout, and weighing 220 pounds. She is the mother of eight fairly healthy children, and has had no miscarriages. She had slow enteric fever at seventeen; puerperal fever with her second child; and congestion of the liver after her last confinement, eight years ago. Her mother is living; her father died at eighty-four, with chronic bronchitis and a fractured hip; she has had no sisters; of two brothers, one died at forty, of asthma associated with bronchitis, and the other died at forty-five, of pulmonary tuberculosis. One paternal uncle died of asthma associated with bronchitis; another paternal uncle died of carcinoma. The menses first appeared at fourteen, and were regular from her last confinement until July, 1893. This suppression, except for a slight "show" now and then, and a few very slight symptoms, was supposed by her to be due to the approach of the menopause. I was called hurriedly to her (seven miles distant), October 7, 1893, but by the time of my arrival rest in bed had already arrested a moderately severe uterine hemorrhage. Slight metrorrhagia continued during the next four weeks. There was no pain or any discomfort, except a feeling of weight in the pelvis. Another free uterine hemorrhage occurred on November 6th, which was again arrested

before my arrival. The pulse was 85, the temperature 98.5°. Examination *per vaginam* showed the os to be slightly dilated, but quite securely plugged with some membranous substance. The bowels moved quite freely during the night and on the morning of the 8th, but there was severe headache, nausea, and colic. Bismuth and opium relieved the condition of the bowels, and a combination of bromid and caffein the headache. I was again summoned hastily on the morning of November 10th, and found the woman beginning to rally from a shock. Another severe uterine hemorrhage had taken place, but had been checked by the application of vinegar and a tampon, in which I had previously instructed the nurse. The pulse was 120, but regular, and not very weak; the temperature 98°. The nurse said that the patient had been rather uneasy for a short time, when suddenly she announced that something had given way. A mass was passed weighing probably three pounds, whose characteristic cystic degeneration at once proved it to be a hydatidiform mole. An attack of syncope and the hemorrhage followed this. The os was contracted, but a slight hemorrhage continuing, I reapplied the vinegar tampon. The patient rallied quite readily. Eight hours later the pulse was 85, the temperature 99 5°. There were slight hemorrhages on the 11th and 12th, and a small placental mass, only a part of which was degenerated, was passed. A slight odor indicated decomposition, but there being no signs of absorption, I ordered a vaginal douche of hot water and sodium chlorid. The patient convalesced with no unusual symptoms, except a slight attack of supra-orbital neuralgia on the 11th. A pulse of 80 is normal for her. There was no rise of temperature except during reaction on the 10th. The microscope revealed no echinococci. There was no trace of a fetus. Degeneration was almost complete, except throughout probably one-tenth of the mass. On March 3, 1894, there had been no return of the menses, and the patient was in her usual good health.

I could suggest no better illustration of the degenerated portion of the mass than Fig. 100 in Parvin's *Science and Art of Obstetrics*.

THE VECTIS IN VERTEX-POSTERIOR POSITIONS OF THE FETUS.

BY JOHN GRAHAM, M.D.,
OF PHILADELPHIA.

PROFESSOR S. D. GROSS urged in eloquent language the revival of the lost art of bloodletting, and I wish to send forth my humble appeal, to save from possible loss, by long-continued disuse, an instrument, the vectis, that I have found of great value in obstetric practice. A well-known teacher of obstetrics in Philadelphia calls it a supernumerary instrument. A well-read recent graduate, whom I recently met in consultation, had never seen the instrument.

What unpleasant memories "vertex posterior" recalls to the mind of the obstetrician! Long and weary waiting on the part of the physician, suffering and exhaustion on the part of the woman—a forceps delivery, and probably a torn perineum.

Lusk says that so long as the occiput looks to the rear it is the rule in midwifery practice to refrain from the use of the forceps, which of necessity prevents forward rotation from taking place. He also says attempts to rotate the occiput toward the symphysis by instrumental means are rarely successful; the vagina, being an elastic tube, turns with the head, and when the force is removed the vagina turns the head back. Now, it is undoubtedly true that the vagina is an elastic tube, and it is equally true that in turning the head with the vectis the vagina sometimes, but not always, turns with it; and that in the cases in which the vagina turns with the head on relaxing pressure, the head tends to go back with the vagina. But why relax our pressure? The important point conceded is that the head can at times be turned, and I have found that by keeping up the steady pressure on the side of the child's head with the vectis, a few uterine contractions will generally fix the head well down between the tuberosities of the ischii, and the trouble is over.

Long experience has made me fairly skilful in the use of the obstetric forceps, and many times have I watched cases in which the head was in the pelvis and the vertex pointing to the right or left, and with each pain rotating now 45 degrees to the front, and again 45 degrees toward the sacrum, but on the recession of the pain always returning to its position, crosswise in the pelvis. Watching my opportunity, when the vertex has temporarily turned toward the front, I have rapidly put on the forceps, endeavoring to adjust the instrument to the sides of the head, only to find that in the majority of cases I had converted the case into an ordinary vertex-posterior.

Of late years I have seldom been tempted to use the forceps as a first resort in this class of cases, for I have found that with the vectis a majority of them can be converted into vertex-anterior cases.

When the head is tightly locked in a transverse position in the pelvis, all efforts to turn the vertex to the front with the vectis will, of course, fail; but no harm is done by the use of the instrument, and failing in the endeavor, it is my custom, after long and patient waiting, to try to complete the rotation of the vertex backward, and then apply the forceps, delivering slowly and carefully.

I apply the vectis over the parietal bone, the parietal eminence entering the fenestrum of the vectis, and use the instrument partly as a lever of the first class and partly as a tractor, making my extended fingers and not the woman's soft parts the fulcrum. The traction is a very important and efficient part of the use of the instrument, and largely assists in drawing down and fixing the vertex after it is turned to the front. Used in this manner, the vectis has enabled me to give to many women safe and easy deliveries. By preventing vertex-posterior deliveries it has, I am confident, enabled me to save the lives of children, and failure in its use has never injured mother or child.

326 SOUTH 15TH ST.

MEDICAL PROGRESS.

Changes in a Hand Fifteen Years after Division of the Median Nerve.—GRIFFITHS (*Journal of Pathology and Bacteriology*, vol. ii. No. 3, p. 346) has reported the case of a man, seventy-three years old, who, while engaged in cutting chaff, at the age of fifty-eight, had the left arm caught in the machinery just above the elbow and cut

upon its inner aspect to the bone. There was much bleeding at the time, and the hand at once became numb and useless. About a year after the accident a certain degree of feeling had returned to the skin of the hand. Two years later the tip of the middle finger began to fester and ulcerate, the nail dropping off and the end of the finger disappearing bit by bit, without the coming away of any pieces of bone or obvious sloughing and gangrene of the parts. Some time afterward the same ulcerative process began in the tip of the index finger. This ulceration was attended with but little pain. The activity of the ulceration depended largely upon the state of the weather and the season of the year, being aggravated by cold and ceasing in warm weather. By progressive ulceration, a sort of liquefactive necrosis of soft parts, tendons, and bones, the distal portions of the index and middle fingers were lost. Six or seven years after the accident the ring and little fingers became slightly flexed, the flexion gradually increasing and the fingers becoming quite painful. Some seven years later the extremity of the thumb began to ulcerate, and continued to do so, with slight interruptions during the warm weather, until the man came under observation. The hand and forearm were much wasted from atrophy, especially of the muscles. The index and middle fingers had in great part disappeared, only conical stumps composed of the first and a small portion of the proximal end of the second phalanx remaining. The ring and little fingers were fully flexed, fixed, thin, and tapering, with commencing ulceration on the extensor surfaces of the terminal joints. Ulceration was in progress on the thumb, but had as yet only destroyed the pulp and a small portion of the terminal phalanx, the nail being thickened and curved over the end. The skin of the whole hand was thin and shiny, but over the fingers and thumbs it was of a purplish color, except at the very extremities, where it was tightly stretched and of a pale color and wax-like appearance. Over all of the fingers and the greater part of the thumb, the skin was firmly fixed to the subjacent structures and was also somewhat translucent, as if that which gives opacity and dulness to the natural skin had in great part disappeared. The thenar and hypothenar regions were hollowed from extreme wasting of their respective muscles, and the intervals between the metacarpal bones on the dorsal aspect, normally occupied by the interossei, were also hollowed, so that the outlines of the several bones were very distinct. Owing to the changes that had occurred in the fingers, their movements were either partially or completely interfered with, but there was limited flexion and extension at the wrist, as well as slight flexion, extension, and adduction of the thumb. Sensation was defective over the whole hand, but was nowhere completely absent. On the lower and inner part of the arm, just above the inner condyle of the humerus, was a linear, oblique scar, from two to three inches in length, which was not deeply fixed. Into the scar the brachial artery could be traced, but below it could not be felt. On the outer side of the artery, at the upper extremity of the scar, was a small, rounded or ovoid very tender lump, which was presumed to be the swollen central extremity of the divided median nerve, displaced somewhat from its natural position. The man desired to have the hand removed on account of the pain and the recurring ulceration, and the operation was accordingly performed. Upon dissection of the removed part the median nerve appeared as a whitish, firm cord at the wrist, measuring one-sixth of an inch in diameter, surrounded by an excess of fat and wanting in the glistening appearance of a normal nerve. Upon microscopic examination it was found to be completely transformed into bundles which corresponded with the original nerve-bundles, but consisted simply of wavy fibrous connective tissue. There were, however, no traces of medullated or non-medullated nerve-fibers to be seen. The change consisted simply in a substitution of the nerve-fibers and bundles by connective-tissue fibers and bundles, without much, if any, diminution in size. The ulnar nerve was also of nearly normal size, but tough in structure and also surrounded by much fat, having lost its smooth, glistening appearance. Microscopically, the perineurium and endoneurium were found to be increased, dense, and fibrous, with nerve-fibers in various stages of atrophy, many having altogether disappeared. Most of the fibers had partially lost their medulla, and, owing to the increase of fibrous connective tissue, they were more widely separated than normal. The appearances resembled those found in chronic neuritis. The remaining soft parts were greatly atrophied and in parts replaced by fibrous tissue, the changes being more marked in the distribution of the median nerve than in that of the ulnar.

Hydrocephalic Fetus; Rupture of the Uterus; Removal; Recovery.—Fetherston (*Australian Medical Journal*, vol. xv, No. 12, p. 610) has reported the case of a multipara, thirty-five years old, in which labor set in at term, with weak pains, which lasted four days and then ceased for two days, when she was suddenly seized with severe pain in the left side of the lower portion of the abdomen. Profuse bleeding from the vagina took place, and the woman quickly went into collapse. On vaginal examination a tear was found on the posterior surface of the uterus, connecting with the vagina slightly above the posterior vaginal junction, and extending along the left side of the uterus higher than could be reached. The peritoneum was not torn posteriorly. The os was fully dilated, soft, and flabby, and on the left side the cervix was torn into the uterine wound. The left lateral fornix of the vagina was also torn along its whole length toward the pelvic wall. The membranes were ruptured, and the placenta lay in the opening in the side of the uterus. A hydrocephalic head was found presenting. The hemorrhage being profuse the head was perforated, but could not be delivered without version. The placenta had passed through the rent in the uterus into the abdominal cavity, and some loops of intestine came into the vagina behind the uterus. Slight traction sufficed to deliver the umbilical cord, with the membranes attached. The intestines were pushed back, and pressure kept up upon the fundus to control the hemorrhage. As the patient appeared to be dying from loss of blood, it was decided to open the abdominal cavity. When the accumulated extravasation had been removed it was found that the uterus was torn along the whole length of the left side, from the vagina to about an inch above the opening of the left oviduct. The edges of the tear gaped apart about two inches, and were not bleed-

ing at all. The peritoneum of the posterior wall of the broad ligament was torn from where it was reflected on to the uterus, and out along the floor of the pelvis almost to the pelvic wall. At the outer edge of the tear a large vein was bleeding, and this was controlled by a silk ligature. The pelvic and abdominal cavities were irrigated with hot water. The peritoneum of the left broad ligament was quite black in places, and appeared as if it had been bruised by the passage of the fetal head. The bloodvessels going to the right side of the uterus were ligated; then the body of the uterus was tied in five places with strong silk, and the fundus was removed. All ragged pieces of the torn peritoneum were removed, and the edges brought together with fine silk. The pelvic and abdominal cavities were now thoroughly cleansed, and the stump of the uterus sutured into the lower angle of the abdominal wound, and the abdomen closed with silk sutures. The operation occupied altogether an hour and a half. The patient had for some time been pulseless and cold, in spite of subcutaneous injections of ether, bandaging the limbs, and hot packing. She was put to bed, and received, among other things, ten ounces of hot coffee hourly by the bowel for a few hours. In the course of two hours she showed some signs of rallying, and thereafter gradually emerged from her condition of shock. For the first two days after the operation there was a slight oozing of blood from the vagina. On the fifth day the temperature began to rise and the pulse to become accelerated, and pain in the left lumbar region was complained of. A day later a hard, fluctuating tumor as large as an egg was felt behind the large intestine and below the lower edge of the left kidney. This tumor increased to the size of a man's fist, and on the tenth day exploratory puncture disclosed the presence of nasty, black, offensive pus. The cavity was opened and drained. Recovery was thereafter uninterrupted.

Inferior Maxillary Palsy with Loss of Taste. — Ziehl (*Arch. f. path. Anatomie u. Physiologie u. f. klin. Med.*, B. cxxx, H. 3; *Centralbl. f. d. med. Wissensch.*, 1894, No. 5, p. 95) has reported the case of a man, fifty years old, who, following exposure to cold, experienced a sense of twitching and numbness upon the right side of the face. On investigation it was found that sensibility of all forms was impaired upon the chin, teeth, temple, and tongue in the distribution of the right inferior maxillary nerve, with paralysis of the muscles of mastication upon the right side, and loss of electric irritability and atrophy of the temporal muscle. The sense of taste was also impaired upon the anterior portion of the right half of the tongue, although preserved upon the posterior half and upon the left side. In the course of two months gustatory and tactile sensibility had returned, but even after the lapse of a year the temporal muscle was paralyzed and atrophied.

THERAPEUTIC NOTES.

Alpha Naphthol in Typhoid Fever.—Maximowicz (*Wien. med. Pr.*, No. 10) has employed α-naphthol with success in the treatment of typhoid fever. He maintains that α-naphthol is a more active bactericide and a less toxic agent than β-naphthol. Doses of from 7.5 to 15 grains were administered three or four times daily. Under this treatment the morning remissions were prolonged, the tongue became clean, meteorism and the pain in the right iliac fossa subsided and finally disappeared entirely, and the duration of the attack was shortened. The administration was maintained until the temperature had been normal for three or four days. The following formula was found useful:

℞.—α-Naphthol. . . . . ʒijss–ʒiv.
Bismuthi salicylatis . . . ʒjss.
Pulvis cinnamomi vel
Quininæ hydrobromatis . . ʒj.—M.
Ft. pulv. no. xx.
S.—One from four to six times daily.

In case of pronounced meteorism with severe abdominal pain the following formulæ may be used:

℞.—α-Naphthol. . . . . ʒijss.
Bismuthi salicylatis . . . ʒjss.
Pulvis rhei . . . . . ʒj.
Ext. belladonnæ . . . gr. iij.—M.
Ft. pulv. no. xx.
S.—One from four to six times daily.
Or—
℞.—α-Naphthol. . . . . ʒijss.
Codeinæ . . . . . gr. iij.
Pulvis rhei . . . . . ʒss.
Pulvis cinnamomi cort. . . . ʒj.—M.
Ft. pulv. no. xx.
S.—One from four to six times daily.

Sodium Benzoate. — Liegois (*Deutsche medicinische Wochenschr.*, No. 10) emphasizes the value of sodium benzoate in large doses in the treatment of inflammatory affections of the pharynx. Under this mode of treatment pain and difficulty in swallowing subsided in the course of a few days. Children were given a total dosage of 75 grains daily; adults received from 150 to 225 grains. The drug proved equally efficacious in the treatment of laryngitis and bronchitis, while it failed entirely in diphtheria, both applied topically and administered internally. In combination with tannic acid the drug was found to be useful in the treatment of chronic nephritis:

℞.—Sodii benzoatis } . . . āā gr. lxxv.
Acidi tannici }
Ext. gentianæ . . q. s. ut ft. pil. no. c.
S.—Two pills thrice daily.

Given in small doses in cases of uric-acid formation, sodium benzoate converts the insoluble urates into hippuric acid, and this is readily eliminated by the urine. Sodium benzoate is considered an excellent cholagogue, and may be given in the following combination:

℞.—Sodii benzoatis }
Sodii salicylatis } . . . āā ʒjss
Pulv. rhei radicis }
Pulv. nucis vomicæ . . . . ʒss.—M.
Ft. pil. no. xx.
S.—One pill twice daily.

For Dysentery.—

℞.—α-Naphthol. . . . . gr. xv–lx.
Olei ricini . . . . . ʒiij.—M.
S.—From a teaspoonful to a tablespoonful thrice daily.
Maximowicz.

POPULAR BEVERAGES AND THE PUBLIC HEALTH.

WHATEVER else they do or abstain from doing, Americans drink. With a by no means limited class of the community, "What will you take?" is a salutation almost as common as "How do you do?" Drinks—either vulgar and cheap or imported and expensive, according to the tastes, social standing, frugality or extravagance, of the drinkers—are more common in every community than "leaves in Vallombrosa." Almost anything that can be poured from a cut-glass decanter, or a bottle that wears a label, is periodically and unquestioningly swallowed, regardless alike of its origin, nature, cost, or effects. In many cases even its taste is of little or no consequence, the most nauseous and acrid being imbibed without grimace, and with as little external sign of emotion as the most palatable. So thoroughly is this idiotic drinking-habit engrafted on the nation, and not only this nation, but on all "civilized" communities, and to such an extent has the traffic in artificial beverages become a leading factor in the commerce of the country, that the General Government long since found it to be both necessary and expedient to semi-legalize the business by levying a tax on all fermented and on distilled or "spirituous" beverages. Every municipality also derives a large proportion of its annual revenues from licensing and "regulating" the retail traffic in this class of products.

But there are a thousand and one beverages, in even more universal and yet quite unquestioned use, of which the General Government, the Commonwealth, and the municipal authorities take no cognizance, and concerning which medical men, sanitary philosophers, and political economists make little note; but which, nevertheless, have an important bearing, in their direct or indirect influence, on the public health. This group includes the alleged, but by no means always genuine, products—domestic and imported, natural and fabricated—of the countless springs, whose tastefully-bottled and lavishly-certified waters invariably cure something, and usually help everything, and also all that unenumerated family of still, or sparkling, natural or concocted beverages, saline, "mineral," alkaline, and "soda" waters, the very names of which would fill a respectable volume, including the almost endless list of aërated claimants, from ginger ale to "Thea-nectar" and orange phosphate—the prevailing characteristic of all being that of fizzling trashiness and palpable unwholesomeness.

That our national stigma, *dyspepsia*, and the increasing prevalence of urinary and kidney diseases are largely attributable to this irrational but universal habit of indiscriminate drinking, is too evident to admit of serious question. In this connection it is noteworthy that mortuary reports are beginning to ascribe certain lesions to "a too free use of mineral waters." This bibacity has become a national dissipation. Custom, artificial habit, or ephemeral fashion, and not the sense of thirst or the needs of the body, determine the character, frequency, and extent of the libations. The morbid palate is permitted to become sole dictator, and the deluged and outraged stomach is left to wrestle with the inevitable consequences as best it can.

The increasing outcry against the widespread abuse of alcoholic liquors falls far short of a thoroughly comprehensive temperance movement, as intemperance, using the term in its broadest significance, covers a multitude of sensual sins not in the least degree related to alcoholic indulgence. A majority of the race eat, drink, sleep, work, worry, and even recreate intemperately. They transform the very means of attaining, retaining, and regain-

ing health into insidious sources of deterioration. They prostitute systems of physical culture and bodily development, making them fruitful sources of bodily deformity, mental wreckage, and premature decay. They take work, travel, social life, politics, and even religion in spasmodic and periodic doses; and, as to recreation, they ruin their overstrained muscular systems in frantic contests at foot-ball, rowing, wrestling, or at the bat. They have never comprehended the meaning of the word moderation; and from the time they were coaxed to sleep in their cradles, perhaps by means of soothing syrup and the monotonous lullabies of a hired nurse, they have never known an hour of genuine and restful repose. They consider the hours grudgingly devoted to sleep as so much lost time. If it were a physical possibility they would gladly forego this indispensable function. As it is, they indulge and endure as little of it as possible, and this at unseemly hours, and in spasmodic snatches.

Of all human frailties, crimes against Nature are least excusable. Wilful tampering with physical laws is a crime against Nature and therefore an unpardonable sin—unpardonable in the sense that no individual can hope to escape its consequences. *The body that sinneth, it shall suffer.* No law of vicarious atonement for physical sinners has ever been, or ever will be promulgated. Nor is this fact in any sense negatived by the discovory of anesthetics, cocain, and the other insidious pain-obtunders. Every artificial mitigation unquestionably costs an equivalent in vital reaction.

Of all the wilful lapses from an ideal and rational standard of daily living mentioned, the drinking-habit may be singled out as the one most destructive to health and human happiness, for the reason that it is so universal as to pass without comment. Even the ubiquitous ice-water tank, considered indispensable in every dining-room, railway-car, station, office, hall, and restaurant, is answerable for a mountain of mischief to the digestive organs of the present generation.

In their zeal the temperance people train all their artillery against the "demon of the still"; the pulpit too often handles the subject from a classically conservative standpoint, while the medical profession absolves itself through occasional discussions and dissertations on the necessity or futility, as the case may be, of the use of alcoholics in fevers and wasting diseases, and by suffering their names to be appended to popular advertisements of shotgun formulas and certain conglomerations of saline, mineral, earthy, and organic constituents, as disclosed by the analyses-to-order "pharmaceutical chemist" whose name was never heard of outside the bottling-room of "The Paralyzer Mineral Spring Company," from which he receives his salary.

The list of table-waters, many of them ostensibly, and some of them actually, transported all the way from the Old Country, is almost endless; and of aërated beverages, good, bad, and indifferent, there is an astonishing list. A degenerate drug-trade has stooped to the traffic; the waters are on the hotel and restaurant tables; the saloon relies on them for one-half its profits, and even the corner grocery crowds its shelves and cellars with cases of them. Every year new claimants appear, as old favorites are dropped. Millions of money and whole armies of men are absorbed in the traffic; and the press of the country—secular, religious, and, to some extent, medical—would be materially crippled by a withdrawal of the advertising patronage growing out of it.

It is a fact that, if the direct and indirect business connected with the conducting, controlling, and supplying the trade dealing in beverages of all kinds, could be suddenly withdrawn from the avenues of commerce, the whole machinery of daily business would be dislocated, and the streets would take on the appearance of a perpetual holiday. Omitting all mention of the myriads of mere dispensers of liquid "refreshments," such withdrawal would throw out of employment, in this country alone, several millions of operatives and artisans, including coopers, carpenters, glass blowers, hardware merchants, harness-makers, manufacturers of apparatus, engines, and machinery, plumbers, and wheelwrights, not to mention grain and hop raisers, horse-breeders, and the miscellaneous array of middlemen, who necessarily stand between all these avocations and the marketing of their numberless products. It would require the compass of a goodly volume to make an adequate statement of the mere commercial interests involved; whereas the sanitary aspects of the subject have as yet been but superficially studied by the profession. Furthermore, medical men are to some extent responsible for the present status of the question. Many of them are regular patrons of the traffic, and many are direct abettors and apologists as regards the habit itself.

FERRATIN.

Schmiedeberg (*Archiv f. exper. Path. u. Pharm.*, B. xxxiii, S. 101) points out that when albuminates are formed by dissolving albumin in alkalies and such solutions are rendered acid, an albuminous substance is precipitated. This substance has acid properties, as is shown by its combination with bases. If a neutral solution of potassium albuminate be treated with ferrous salts a precipitate of the albuminate of iron is formed. This precipitate is soluble in alkalies, forming double salts. Ammonium sulphid added to one of these solutions produces an intense and instantaneous blackening, on account of the formation of the sulphid of iron, just as happens on the addition of sulphids to the inorganic salts of iron. However, if an alkaline solution of iron albuminate be boiled for a short time or be kept at a moderately high temperature for a longer time, it becomes brown and after this blackens only very slowly on the addition of ammonium sulphid. The last-mentioned compound is not an iron albuminate but a distinctive iron-containing albuminic acid, and may be designated as ferri-albuminic acid. Ammonium sulphid slowly decomposes ferri-albuminic acid and forms the sulphid of iron.

Ferri-albuminic acids containing varying amounts of iron may be prepared. Those most easily made and most readily soluble in alkalies contain from 4 to 8 per cent. of iron. The preparation of a ferri-albuminic acid with a constant iron-content has not been accomplished up to the present time.

With unchanged albumin iron forms compounds similar to those obtained with albuminic acid. These are known as ferri-albumins and are easily made by the prolonged warming of egg-albumin and iron in ammoniacal solution at a temperature below that at which albumin is coagulated.

Schmiedeberg has succeeded in obtaining a ferri-albumin from the livers of hogs by the following process: The livers are finely chopped, then mixed with three or four volumes of water, gradually heated to the boiling-point and maintained at this temperature for a few minutes. The filtrate forms a yellow, clear fluid, which on the addition of a few drops of a solution of tartaric acid yields a flocculent precipitate which is washed first by decantation and then on a filter. This precipitate is a ferri-albumin which forms on drying a brown mass, containing an average of 6 per cent. of iron, and dissolving in alkalies to a clear brown solution. This ferri-albumin is named ferratin by Schmiedeberg, and he believes that it forms the reserve iron which is stored in the liver to be drawn upon as the needs of the body may indicate. This substance is readily absorbed from the intestines, and as it possesses no corrosive action it may be given hypodermatically.

Schmiedeberg believes that he has thus obtained the ideal therapeutic preparation of iron. However, the separation of this substance from the liver is too expensive and the yield too small to admit of its introduction to the profession as a pharmaceutic preparation. Schmiedeberg states that a certain firm of manufacturing pharmacists has succeeded after some years of experimentation in making ferratin artificially, and that the substance which this firm offers to the profession is in every respect as good for therapeutic purposes as that obtained from the liver. He fails to tell us, strange to say, how this artificial compound is made, and evidently there is an attempt in the article to help the trade of an enterprising drug-house. The advertising by a member of the medical profession of a preparation the manufacture of which is accomplished by secret processes is not regarded with favor in this country. This research by Schmiedeberg may prove to be of great medicinal value, but the manner in which he has announced his discovery and the success of the firm in the artificial preparation of the compound is open to criticism.

EDITORIAL COMMENTS.

The Surgical Treatment of Perforation from Gastric Ulcer.—Few cases offer more temptation to the adventurous surgeon and in few, unfortunately, have his endeavors been rewarded with less success than those of rupture of a gastric ulcer into the peritoneal cavity. The affair seems, on the face of it, so absolutely simple; the patient may be in perfect health, with the exception of this little perforation and the resulting extravasation of the contents of the stomach into the peritoneum, and, moreover, in the majority of cases in which the rupture has been sudden and the symptoms typical, the perforation has been in accessible regions—on the anterior wall of the stomach—and yet, so far, few attempts to sew up the opening seem to have been attended with success. Great interest, therefore, attached to the case reported by Mr. Morse, of Norwich, England, in which a young woman having symptoms of gastric ulcer was suddenly seized with symptoms of perforation, and was treated by him successfully by means of celiotomy and suture of stomach. Abdominal section was performed within five hours of the accident; the contents of the stomach were found in the peritoneal cavity; the viscus was withdrawn and a perforation

found; the stomach was thoroughly washed out and the wound united. No food was given by the mouth for sixty hours, and in three weeks the patient was well. The points of importance conducing to the success of this case would seem to be (*a*) early operation, before irrevocable septic mischief has arisen through absorption from the peritoneal surface; (*b*) washing out the stomach as a preliminary to introducing the sutures; this was managed by introducing a large canula through the perforation, and alternately filling this viscus with water and emptying it until the fluid came away clear; (*c*) drawing the stomach out through the wound, so as to perform the washing and suturing with facility; and (*d*), most important of all, the very great care taken to thoroughly wash out the peritoneum. The maneuver adopted by Mr. Morse, with this object, will probably be useful for other purposes also. Instead of merely passing a tube to the various regions of the abdomen, leaving the return-water to wash out the fragments, two large tubes were passed side by side to every part of the cavity, and the flushing was continued at each spot until the return-fluid was clear; by this arrangement the extravasated stomach-contents were washed out through the tube, instead of drifting in the stream from one part of the abdomen to another. It is to be hoped that other surgeons will be able to obtain like success in the treatment of this otherwise very fatal accident. On a very different footing stands the proposal to treat perforation of the bowel in enteric fever, as was shown by the discussion at the Medical Society of London on March 9th. The patient is already seriously ill, and, although the accident, of course, happens suddenly, the signs of its occurrence are often by no means typical. The stupor of the patient leads to the symptoms being more or less masked, the moment of onset may not be discoverable, the pain may not be severe, and the patient may only seem to pass from a bad into a worse condition. Moreover, the ulcers are generally multiple and the intestine rotten, so that the stitches may have to be inserted in unhealthy tissues, possibly even in the bases of other ulcers! A certain number of such cases also recover under medical treatment. The operation, then, would seem a much less hopeful one than that for perforation of gastric ulcer.

The Pathology of Paralysis Agitans.—The belief seems to be gaining ground that paralysis agitans is but a manifestation of premature senility, the result of changes affecting the nervous system as a part of a widely distributed degeneration, and the pathologic evidence tends to support this view. An interesting contribution to this subject has recently been made by Ketscher (*Zeitschr. f. Heilk.*, Bd. xii, S. 445; *Centralbl. f. allg. Pathologie u. pathol. Anatomie*, Bd. v, No. 4, S. 173), based upon observations made in the laboratory of Chiari at Prague. The tissues from three cases were carefully studied, the material being from subjects between sixty-eight and seventy-six years old. The changes found, and which corresponded with those found by previous investigators, consisted in a varying degree of degeneration and atrophy of the specific nervous elements, the ganglion-cells and the nerve-fibers, as well as of the muscles. There was also hyperplastic increase of interstitial tissue, in brain as well as in nerve, and in muscle, and this was particularly marked in the neuroglia of the posterior columns adjacent to the posterior median fissure. In this situation, in the ependyma of the lateral ventricles, and at the periphery of the cord generally, there were noteworthy accumulations of copora amylacea. There were also present thickening of the walls of the vessels, with dilatation of the perivascular and pericellular lymph-spaces and obliteration of the central canal of the spinal cord by the surrounding increase of neuroglia, together with hyperplasia of the epithelium of the lining membrane, giving rise in places to dilatation of the canal. For comparative purposes studies were made of the spinal cord, peripheral nerves and muscles, obtained from ten persons that had died of other conditions, between the ages of fifty-seven and seventy-six years. In all of these changes were found that differed only in degree from those found in the cases of paralysis agitans. The legitimate conclusions from these observations is that paralysis agitans is but the expression in the nervous system of a premature senile degeneration. Etiologically it may be conceived that as a result of diminished functional activity there occurs defective elimination of matters that, retained, give rise to irritation and bring about degeneration in the nervous system, as well as in the vascular system and in the viscera, and the progression of which leads finally to the extinction of life.

The Falkenstein Treatment of Pulmonary Tuberculosis.—We hear a good deal about the open-air treatment of pulmonary tuberculosis, and the attempts to raise this method into a "system" as practised at Falkenstein in the Taunus Mountains in Germany are worthy of all praise, so far as they demonstrate to the world at large, which is not very believing in such matters, that tuberculous patients are all the better for open windows. At the establishment at Falkenstein, in addition to good food, cleanliness, perfect sanitation, and most careful measures to prevent the diffusion of tuberculous dust, a definite attempt is made to enable the patients to pass their whole time in the open air. Plenty of rugs and clothing are allowed, and the rooms and corridors are plentifully supplied with heating-apparatus, but, except when actually dressing and undressing, the windows of the bedrooms must be open day and night, in all weathers and in all seasons, and during the day the patients dwell in corridors or summer-houses or altogether out of doors. The results are said to be satisfactory. One point is of much interest. The number of patients whom it is found necessary to confine to their rooms hardly varies in the different seasons, being 8.5 per cent. in the summer and 9.33 per cent. in the winter months. It seems clear, however, that a treatment of this sort, if useful at a health-resort, should be equally applicable to home life and that the lessons taught by it are as important to the healthy as to the sick. If these delicate *poitrinaires* can bear open windows and fresh air, so can people in ordinary health, and there can be no doubt that people would be better in every way if they very much lessened the difference between indoors and outdoors as regards both clothing and fresh air. The lesson to be learned, however, from the Falkenstein treatment is that a certain acclimatization is required, and that what is begun must be persisted in; a man who sleeps with open win-

dows one week and shuts them the next is sure to suffer from disorders of the air-passages.

How to Advertise and Seem Not to Advertise—how to break with the spirit of the law while keeping the letter; how to advertise to the public and make the profession believe one is not advertising—all this is an old problem and an old story. But it is the ever-new problem of the born quack who finds himself among men whose instinctive sense of right makes them non-advertisers both in letter and spirit. The only advantage to be gained by those with the secret itch of self-advertisement is only to be gained while the bulk of the profession will not advertise. The day that the majority of one's fellows enter into competitive advertising, that day the profits sink to zero, or come only to those with the most reckless brazenness and the most unprincipled commercial shrewdness. When but a single horn is blown, the most "delicate and proper" blower is easily heard; but when everyone blows his own instrument, then the toughest lungs and the worst horn drown out the others.

This little homily is suggested by the perusal of an editorial in the *Alienist and Neurologist* for January in which it is contended that the Code itself contains, or should contain, adequate provision for the sly fellows, thus to take advantage of their colleagues by placarding on signs, and by any sort of public announcement, the facts as to their graduation, their specialty, capacity, etc. Especially should the expert in nervous diseases be permitted to "let the public know, in a delicate and proper way," about himself and his expertness. This parenthetic "delicate and proper way" is the acme of humoresque cunning. To do an indelicate and improper thing in a "delicate and proper way" is, to a certain class of minds, the very culmination of ethics.

> "It was all very well to dissemble your love,
> But why did you kick me down stairs?"

Personalities in the Journal of the American Medical Association.—The announcement in the *Journal of the American Medical Association* for March 31st, that personalities will not [hereafter] be printed, is to be welcomed, but this tardy confession and repentance do not relieve the editor of that journal from responsibility for having published two personal attacks on the same person—and, that, a member who ventured in respectful, if perspicuous, language to criticise its course. Nor are the trustees relieved from the duty of officially repudiating the editorial action in accepting a letter that a well-conducted and self-respecting journal should have consigned, without question, to the waste-basket.

CORRESPONDENCE.

THE MORTALITY OF THE NEGRO.

To the Editor of The Medical News,

Sir: In The Medical News of February 3, 1894 (vol. lxiv, No. 5), R. M. Cunningham, of Alabama, in an article entitled "Morbidity and Mortality of Negro Convicts," draws attention to the lessened vitality of the negro in prison, and endeavors to show that the greater death-rate is due to anatomic and physiologic characteristics that render the negro particularly liable to diseases of the lungs. Subjected to the same environment the adult negro, it is well proven, is less resistant to disease than the adult white.

Northern prisons, in which no distinctions are made on account of color, show a death-rate from two to three times as great for the black man as for the white. In the Eastern Penitentiary, in proportion to their number, the black furnishes three times as many deaths as the white population. In other prisons similar results are shown.

As Dr. Cunningham has proved for Georgia prisons, so it can be shown for other institutions that the negro convict dies more often of tuberculosis than the white convict, though the percentage for the latter, in prison, is usually high. In the Eastern Penitentiary, out of 100,000 white adults 760 will die of pulmonary tuberculosis, and out of 100,000 negroes 3000 will succumb annually to this malady. Thus four times as many colored adults in confinement die of this disease as whites.

If we compare the high mortality of convicts with the mortality in the cities and towns we shall find that, just as in prisons, the negro has a much higher death-rate than the white. The census for 1890 furnishes us with the following data: The death-rate per 100,000 according to race was, for Richmond, Va.: white, 22.65; colored, 40.80. Lynchburg, Va.: white, 13.53; colored, 44.16. Atlanta, Ga.: white, 18.28; colored, 33.57. Birmingham, Ala.: white, 35.15; colored, 53.24. Philadelphia: white, 20.76; colored, 26. Baltimore, white, 20.41; colored, 32. Again, when we analyze the figures we find, according to Dr. Billings, that while in Baltimore 375 white adults out of 100,000 die of tuberculosis, 575 colored adults die of the same disease. In the District of Columbia the figures are 330 for the white and 690 for the colored.

But the most significant fact is the high death-rate among colored children under five years of age. Thus for Baltimore it is 88.22 in 1000 for the white and 197.62 in 1000 for the negro; in Charleston, S. C., 92.34 white, 227.79 colored; in Richmond, Va., 75.27 white, 222.58 colored. If we can explain this high infant mortality it is possible, it seems to me, to explain the higher adult mortality.

The negro, as is well known, usually occupies the poorest quarters of a town or city. The "shanties" of the colored man constituted the slums before the advent of Italian and Russian emigration. With miserable homes are combined ignorance and poverty—a trio responsible for a multitude of diseases, and among them the most fatal ones.

In the early years are sown the seeds of tuberculosis, which require but the confinement of a prison to mature and develop. Glands that were affected in early life enlarge and break down under confinement, and this is but an instance of the latency of the bacillus tuberculosis. The early infection requires some exciting cause, be it a prison, a disease outside of prison, or fatiguing work—whatever depresses the general bodily vigor—and it is fanned into action and lights up into an acute process. If this early environment is responsible for the greater mortality of the negro, as compared with the white, then we should expect to find an increased mor-

tality among the whites who are subject to the same environment. Unfortunately we have no statistics in medicine that take into account social distinctions. Our mortality-statistics are based on political boundaries, and often the millionaire lives in the same district as the pauper. Even sanitary divisions include classes differing widely from each other in home-life and material welfare.

An attempt has been made by the New York Board of Health to collect mortality-rates for various tenement districts. The few figures I have been able to obtain indicate a similar condition among the Italians as among the negro; a mortality-rate among their children of 150 per 1000, while the average death-rate among children under five years of age for the city generally is 93 per 1000.

Where there is overcrowding, inefficient housing, poverty, and ignorance, the death-rate among infants must be high, and if disease is the cause of this death-rate, then tuberculosis pulmonalis must be engendered in many of those who survive the early struggle, remaining in them, ready to show itself when for some reason or other, the vital powers are depressed.

Make the conditions favorable for the negro from childhood up, and then first can we say that he is less capable of withstanding disease than the white man.

The criminal nature of the negro must be viewed in the same light. At present he does furnish a much larger number of convicts than his proportion in the population entitles him to. The negro forms 2.09 per cent. of the population of Pennsylvania, and furnishes 10 per cent. of those committed for trial, and 16 per cent of all convictions.

In Georgia, the colored population of the prisons is 85 per cent. of the whole, while outside of prison it is but 47 per cent. In Mississippi 60 per cent. of the population generally are colored, and 82 per cent. of the convicts belong to the black race.

Can we discover some anatomic or physiologic something that will explain this characteristic?

In the South, where lynch-law is most commonly dealt out to the negro, we might attempt to ascribe this greater criminality to lack of fair treatment, and prejudice on the part of the white man; but in the North we are supposed to be exempt from this accusation.

In criminal statistics, as in medical statistics, we do not compare classes. The man who is uninfluential, who cannot afford good counsel, who cannot afford to prolong his defence, is more often convicted than the man who is able to obtain these things, irrespective of race-prejudice, and consequently our prisons are crowded with the poor and uninfluential. If the negro is compared with the white man according to social standing, the criminal tendencies may be found to be no greater than the differences in education will explain.

To summarize: I would refer the differences commonly found in the death-rates of the colored race, as compared with the white, to differences in the environment, to the social differences which surround the children, and not to any physical distinctions; at least, until this sociologic factor is studied and taken into account, the so-called hereditary and racial characteristics as witnessed in the adult are liable to lead to wrong conclusions.

We must compare individuals of the same class, in order to obtain proper statistics for medicine as well as for sociology.

M. V. BALL,
Physician to the State Penitentiary for the Eastern District of Pa.
PHILADELPHIA.

EPILEPSY OR HYSTERIA?

To the Editor of THE MEDICAL NEWS,

SIR: In the issue of THE MEDICAL NEWS of March 3, 1894, Dr. Howard F. Hansell reports two very interesting cases in which attacks of unconsciousness, resembling epilepsy, were apparently caused by insufficiency of ocular muscles, and were promptly terminated by tenotomy.

Dr. Hansell will surely agree with me in saying that such reports will mislead if they confuse epilepsy with hysteria; for it is a matter of common observation that hysteric attacks are precipitated by the most diverse causes, and often prevented, even for long periods, by any therapeutic measure that sufficiently impresses the mind.

Now, I submit that the diagnosis of epilepsy is not justified by anything recorded of either of these patients. In both cases there is a significant absence of all the unequivocal symptoms of epilepsy. In the first case the eructations of gas following each attack, and the fact that the first seizure occurred under the influence of powerful emotion, constitute strong presumptive evidence of hysteria.

In the second case "the close connection of the periods of unconsciousness with the use of the eyes at the near-point" makes the hysteric nature of the attacks almost certain. It is only in the rarest cases that emotion or painful effort has any causal relation to genuine epilepsy, but it is precisely these things that most commonly precipitate hysteric seizures. If the cases in question are examples of hysteria, it can hardly be maintained that ocular disturbance caused the disease; it was more probably one of the effects.

Yours, very truly,

HOWELL T. PERSHING.
DENVER.

To the Editor of THE MEDICAL NEWS,

SIR: For the benefit of Dr. Pershing and others who may have been inadvertently misled by my use of the word "epilepsy," which twice appears in the notes on Case I, permit me a brief explanation.

Miss R. complained to Dr. McWilliams of epileptic attacks, but neither Dr. McWilliams nor I had seen her during an attack, and therefore had no opportunity to determine their true nature. In describing her symptoms I employed her own language as nearly as possible, and purposely omitted comment. In the case of Miss O. the word "epilepsy" is not mentioned, and it is hardly possible that the symptoms, as detailed, could be construed to indicate that a diagnosis of that disease had been made. The title of the paper was "Two Cases of Functional Nervous Disease, etc.," and under that heading they can properly be discussed. My main object in publishing the report was to show, by means of the reproduction of the tintypes, the immediate and marked change in the facial expression, and not to state or

imply that two cases of true epilepsy had been cured by tenotomy of the ocular muscles.

Very truly yours,

HOWARD F. HANSELL.

PHILADELPHIA.

MALARIAL INSANITY.

To the Editor of THE MEDICAL NEWS,

SIR: The article of Dr. Edward Anderson, of Rockville, Md., in your issue for March 10th, page 270, recalls to mind several cases that occurred in my practice while located at Boyd's, Md. I was called, July 21, 1882, to see a woman, aged about fifty years, living in the neighborhood of Germantown, situated about eight miles west of Rockville, Md. This patient had been treated (tentatively) for two weeks by another physician. I found her raving, and wild with maniacal excitement, with startled, staring expression of the eyes and quite indifferent as to her surroundings, requiring a number of attendants to restrain and keep her in bed. The house which she occupied stood on a hillside bordering a long meadow or lowlands with an adjacent boggy region. She had been taking quinin, gr. ij, three times a day, with no apparent benefit. I at once put her on quinin, gr. viij, every four hours. This in twenty-four hours calmed the excited condition, and after six days' continuation of the treatment she became convalescent. There was no recurrence of the trouble in the next three years, during which time I had opportunity to observe her.

Another case occurred the following year in the same neighborhood, the patient being a colored man about twenty-four years of age. When I arrived at the cabin a dozen or more stalwart colored men were in attendance, endeavoring to confine him to a cot; he was very wild, and it was with difficulty that he was constrained. During my examination of the case I received an indirect unintentional blow from his arm which I felt quite keenly. Good generous doses of quinin in the course of forty-eight hours changed him into a quiet, well-disposed man. In the family history of neither of these cases was there any trace of mental disturbance, but the malarial poison undoubtedly produced the profound mental effect.

Still another case, with the same cause, but with a different effect, is the following:

I was called, in January, 1883, to see a colored woman, living in a cabin on the banks of a creek, and found her suffering with a severe attack of sciatica from which anodynes of any kind gave no relief, not even large doses of morphin hypodermatically. There was no fever, or symptoms of any kind indicating malaria. After futile attempts for several days I had fifteen grains of quinin administered, which resulted in amelioration of the pain. After this quinin was continued for some time, with no return of the sciatica.

Such cases show not only the peculiar course which disease takes, but that simple causes may produce the most complicated state of affairs.

J. J. COFFMAN.

SCOTLAND, PA.

A BREAD FOR DIABETICS.

To the Editor of THE MEDICAL NEWS,

SIR: The following formula for the preparation of a good and wholesome bread for diabetics is one that I have used for the past five years with marked satisfaction. Besides being a cheap and palatable bread, it has the advantage of digesting well. Mix one pound of gluten flour with one and a half pounds of "fine shorts." Add four cups of warm water and one yeast-cake. Make a thin batter, salt to taste, and permit the whole to rise over night. Then add a sufficient quantity of "fine shorts" to make the batter stiff, working it up well together for fifteen minutes. Roll and work in a little gluten-flour. Then place the mass behind the oven, and let it rise until cracked and fissured, and the bread is ready for the oven, where it should bake for one hour.

If a whiter bread is desired, more gluten-flour should be added. Yours truly,

GEORGE F. KOEHLER.

DEKUM BLOCK, PORTLAND, OREGON.

FRACTURES OF THE LOWER END OF THE RADIUS, WITH FORWARD DISPLACEMENT OF THE CARPAL FRAGMENT.

To the Editor of THE MEDICAL NEWS,

SIR: I shall be greatly obliged if you will inform your readers by a short note that I am particularly anxious to know of any cases of fracture of the lower end of the radius, with forward displacement of the carpal fragment. Notes of cases, references to published reports, or information of specimens in museums will be of much interest to me. Yours truly,

JOHN B. ROBERTS.

1627 WALNUT STREET, PHILADELPHIA.

NEWS ITEMS.

The Association of American Medical Colleges will hold its fifth annual meeting at San Francisco, Cal., June 6, 1894. Action will be taken at this meeting upon the following amendments, to wit:

Rush Medical College, by unanimous vote, submits the following amendment to Sec. 5, Art. III, of the Constitution: "Providing that students who intend to graduate in 1899, or in subsequent classes, four years of medical study and an attendance upon four annual courses of lectures of not less than six months' duration each will be required. Provided, that graduates of literary colleges who have taken a course of scientific studies, graduates of schools of pharmacy that require three years' study and adequate preliminary education, and graduates of dental colleges requiring two years of study and adequate preliminary education, may be admitted to the second year's work or course of lectures in the college without examination."

The present wording of Sec. 5, Art. III, is as follows: "Candidates for the degree of Doctor of Medicine shall have attended three courses of graded instruction of not less than six months' duration each, in separate years."

At a conference held at Chicago, February 7th, the representatives of the twenty colleges represented were unanimously of the opinion that the present requirements of the entrance examination were not sufficiently definite, and directed that the following amendment to Sec. 1, Art. III, be submitted for consideration at the forthcoming session, to be held June 6th: "Colleges, mem-

bers of this Association, shall require of all matriculates an examination as follows: 1. An English composition in the handwriting of the applicant, of not less than two hundred words, said composition to include construction, punctuation, and spelling. 2. Arithmetic—fundamental rules, common and decimal fractions, and ratio and proportion. 3. Algebra—through quadratics. 4. Physics—elementary, Gage. 5. Latin—an amount equal to one year's study, as indicated in Harkness' Latin Reader."

The present wording of Sec. 1, Art. III, is as follows: "Article III, Section 1. Members of this Association shall require of all matriculates an English composition in the handwriting of the applicant, of not less than two hundred words, an examination by a committee of the faculty, or other lawfully constituted board of examiners, in higher arithmetic, algebra, elementary physics, and Latin prose."

It has been recommended that Sec. 5, Art. III, be amended to read as follows: "Colleges, members of this Association, shall require of all applicants for the degree of M.D. attendance upon three courses of lectures of not less than eight months each, or four courses of six months each, in separate years."

A committee consisting of P. S. Conner, of the Medical College of Ohio; Victor C. Vaughan, of the University of Michigan: Wm. E. Quine, of the College of Physicians and Surgeons of Chicago; N. S. Davis, Jr., of the Chicago Medical College; C. B. Stemen, of the Fort Wayne Medical College, unanimously recommended that the Constitution be amended by the following addition: "Colleges, members of this Association, shall require at least an amount of work in each branch as follows, to wit:

	Hours didactic and recitation.	Hours Laboratory.
Histology and Embryology	50	100
Anatomy	150	300
Physiology and Physiological Chemistry	200	75
Chemistry	125	125
Materia Medica and Therapeutics	125	
Practice	200	
Surgery	200	
Regional and Operative Surgery	50	50
Obstetrics and Gynecology	150	
Ophthalmology and Otology	25

Laryngology	25	
Clinical Instruction.		

Mutter Lectureship of the College of Physicians of Philadelphia.—The next course of ten lectures, under the bequest of the late Professor Thomas Dent Mütter, M.D., LL.D., "On Some Point or Points Connected with Surgical Pathology," will be delivered in the winter of 1896–97, before the College of Physicians of Philadelphia. The compensation is $600. The appointment is open to the profession at large. Applications, stating subjects of proposed lectures, must be made before July 1, 1894, to William Hunt, M.D., Chairman of Committee on the Mütter Museum, Northeast corner Thirteenth and Locust Streets, Philadelphia, Pa.

Brown-Sequard, the distinguished French physiologist and *savant*, died at Paris on April 2d. He was born on the island of Mauritius April 8, 1817, and graduated in medicine in 1840. In 1858 he delivered a series of six lectures before the College of Surgeons of London. He was for a time, until 1864, physician to the London Hospital for the Paralyzed and Epileptic. From 1864 to 1869 he occupied the chair of Physiology and Pathology of the Nervous System in Harvard College. From 1869 to 1871 he filled a professorship in the School of Medicine of Paris. In 1873 he removed to New York, but he returned to Paris in 1878, succeeding Claude Bernard in the chair of Experimental Medicine in the College of France.

Séquard made numerous and valuable contributions to medical literature, and will always be admired and esteemed for the originality and ingenuity of his researches.

The Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons for 1894 will be delivered at the New York Academy of Medicine on Wednesday evenings, April 4th, 11th, and 18th, at 8 o'clock, by Professor Russell H. Chittenden, Ph.D., of Yale University. Subject: Digestive Proteolysis. I. General Nature of Proteolytic Enzymes; General Nature of Proteids. II. Proteolysis by Pepsin—hydrochloric acid, with a Consideration of the General Nature of Proteoses and Peptones. III. Proteolysis by Trypsin; Absorption of the Main Products of Proteolysis. Members of the profession are cordially invited to be present.

The Philadelphia Pathological Society will hold its semi-annual conversational meeting on Thursday, April 26, 1894, in the upper hall of the College of Physicians building, Thirteenth and Locust Streets. Dr. Simon Flexner, Associate in Pathology in the Johns Hopkins Medical School, will deliver an address entitled "An Experimental Study of the Nature and Action of Certain So-called Toxalbumins." Members of the medical profession are cordially invited to be present.

A Memorial to Semmelweiss will be unveiled at Buda-Pesth the coming September, on the occasion of the Congress of Hygiene and Demography.

FURTHER REMARKS ON THE OCCURRENCE OF A FORM OF NON-ALBUMINOUS NEPHRITIS OTHER THAN TYPICAL FIBROID KIDNEY.[1]

BY D. D. STEWART, M.D.,

CLINICAL LECTURER ON MEDICINE AT THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

RECENTLY,[2] under the title "The Occurrence of a Form of Chronic Bright's Disease, Other than Typical Fibroid Kidney, Without Albuminuria," I directed attention to a hitherto unrecognized and apparently not uncommon class of cases of chronic nephritis, representing a type clinically distinct from that viewed as interstitial nephritis. Briefly it may be said to be one the clinical symptoms of which place it quite without the boundary of the well-known varieties of the so-called Bright's diseases, such as chronic desquamative nephritis, or the fibroid or granular kidney. I dwelt upon the wide difference clinically between the group of cases I described and that with which these are most likely to be confused—interstitial nephritis, the red, granular, or fibroid kidney. I pointed out that it has long been known that cases of fibroid kidney could occur, especially in the early stages of the malady, without the presence of albumin in the urine, or with albumin existing, if constant, only in traces, or to be found in certain portions of the twenty-four-hour urine.

The occurrence of typical granular kidney without albuminuria, I said, had been first remarked by Wilks, of Guy's Hospital, nearly a half-century ago, but it was Mahomed some three decades later who especially investigated cases of this phase of the disease, describing a considerable number of them in the *Guy's Hospital Reports* for 1879 and 1880–81. I stated that it was doubtful if many of Mahomed's cases, such as I cited, were actually cases of renal disease, though they could be properly included in the category of chronic Bright's disease as Mahomed employed the term. The symptoms of numerous of Mahomed's cases were in the main referable to other organs, and in a minority of those in which a necropsy was obtained the kidneys were stated to be normal.[1]

I also observed that—

"Apart from the doubtful cases of renal disease among those reported by Mahomed, in which albuminuria was absent, there remains a good number in which, with the urine free from albumin, undoubted granular kidney existed. Be that as it may, Mahomed's cases were all in middle or advanced life. There were present decided cardio-vascular changes, such as hypertrophied heart and thickened vessels. These cases were reported especially to show that in the stage of Bright's disease in which epithelial alterations in the tubules were absent—or, if occurring, were but transitory in character—albuminuria was absent, the urine remaining practically normal, and symptoms referable to the kidney, *i.e.*, those of renal inadequacy, were uncommon. Death in these cases, as Mahomed remarks is usual in granular kidney, resulted from failure of other organs, notably the heart."

The class of cases described by Mahomed, and subsequently referred to by Millard,[2] and especially by Purdy,[3] related only to the typical arterio-capillary fibroid kidney so ably portrayed by Sir William Gull:[4] an affection occurring in the degenerative period of life, and part and parcel of a diffused cardio-vascular decay. In this class it is well recognized that with an accompanying polyuria, or with urine, less commonly, perhaps, unaltered as regards amount, the excretion of urinary solids, especially the nitrogenous, is often not far from normal, as in these the histologic renal changes may be but slight in character, the secretory structure not being sufficiently implicated to show marked

[1] Read before the College of Physicians of Philadelphia, April 4, 1894.

[2] The American Journal of the Medical Sciences, December, 1893.

[1] I stated that "Mahomed adopted the term chronic Bright's disease as a convenient generic name for a condition which Gull and Sutton had previously described of generalized arterio-capillary fibroid change. Contrary to the view of Johnson, an extension of that of Bright, and following in the lead of the above-mentioned investigators, Mahomed viewed the condition underlying the various stages of granular or fibroid kidney as a systemic disorder, in which the cardio-vascular alterations were not dependent upon, but either antedated the development of the kidney fibrosis, or more rarely existed without renal change. It was not necessary for him that the kidney be the seat of degeneration to constitute Bright's disease. Fibroid kidney was but an unnecessary, if more or less to be expected, incident in the general morbid state. Renal fibrosis did not always appear, though general arterial change occurred."

[4] American Journal of the Medical Sciences, 1886, vol. xci, p. 407.

deviation from healthy function. When such deviation, however, becomes apparent, it is likely to be coincident with the appearance of decided amounts of albumin and of casts in the urine, with dropsy and marked uremic symptoms.

Until the appearance of my paper no mention had been made by systematic writers of the likelihood of the occurrence of a non-albuminuric form of chronic kidney disease[1] other than that regarded as a typical interstitial nephritis, with characteristic symptoms, although a case here and there has been occasionally reported, notably such as one recently detailed by Reed,[2] to which my attention has just been directed, in which the few symptoms detailed suggest that it is closely akin to, if not actually identical with, the class I have described. Its withdrawal, however, from one of the time-honored categories is not thought of. As Purdy, following out the lines drawn by Mahomed, refers to such cases under the title of the pre-albuminuric stage of chronic Bright's disease, so Dr. Reed discusses the case he relates under the caption the "diagnosis and treatment of the *early stages* of chronic Bright's disease." What I especially desire to emphasize is that there certainly exists a class of cases probably of common occurrence, with symptoms which place them in a group entirely distinct from what is known as chronic interstitial nephritis. In these the most aggravated symptoms of renal inadequacy may be present, such as are common only in an advanced stage of kidney-disease, and yet albumin remains totally absent from the urine.

That these cases have a pathology distinct from the so-called arterio-capillary fibroid kidney (the red granular or contracted kidney, or interstitial or catarrhal nephritis) I have no doubt; but the most exact post-mortem investigation into the character and distribution of the histologic change is necessary in cases which, dying, still preserve the usual symptom-grouping, in order to determine the actual differences. Probably a lack of comprehension of certain facts so lucidly expressed by the late Sir William Gull, who, in considering the pathology of fibroid kidney, so ably argued against the unity of renal disease, has done much to prevent a faithful and exact study and a proper differentiation of the various forms of chronic nephritis.

Gull adverted to the erroneous inference so often drawn by the illogical, that, because *post mortem* in the several forms of renal disease histologic changes are encountered common to all forms, it should follow that these are of a kind, with an identical pathology. He says it is "as though one should assert that all scars of the skin, seeing that they have largely common histological characters, have also one pathology."

It is a well-recognized fact that whatever the form of chronic nephritis, whether it have distinctly arisen in tubule, glomerulus, or in interstitial renal structure, eventually, in the later stages of the malady, the histologic changes are liable to have become so diffuse, with coincident symptomatic change in the type of the ailment, that a necropsy totally fails to throw light on the exact character or anatomic seat of the original morbid condition, however limited its nature may have been for a long time.[1]

In cases of the sort that I described, therefore, the exact pathologic footing must remain a matter of conjecture until a series of necropsies are obtained with death occurring before marked change in type is manifest, before generalized fibrosis has become evident, or albumin has appeared in the urine. This may be possible only after a period of years, but will be the earlier the greater the number of these cases that are recognized, collected, and followed. Light may only be thrown on the pathologic position of such cases through death from an intercurrent malady.

It certainly seems logical that a group furnishing more or less prominently symptoms so distinctive and separable from those of the well-recognized forms of chronic nephritis has a distinct pathology. With an oliguria as persistent and as marked in certain cases as in the most outspoken type of chronic parenchymatous nephritis, and with a urine as concentrated, yet with absence of cardiac debility and of dropsy to indicate its source, there occur as grave continuous symptoms of renal inade-

[1] Apart entirely from the disadvantages of a cognominal nomenclature, I have thought it better to discard the term *Bright's disease*, especially in referring to non-albuminuric forms, as here employed it is essentially misleading—Bright's researches referring solely to affections of the kidney having as their chief mode of recognition the invariable presence of albumin in the urine.

[2] Medical Record, New York, April 1, 1893.

[1] In reference to this point, Sir William Gull argued that, although within limits, the morbid anatomy of the kidney is distinctive of the pathologic condition from which it originates, yet "It would seem not to be sufficiently considered that, in the nature of the case, the morbid forms of histological expression are limited, whatever may be their pathology, and hence these lines of morbid tissue-change will have a tendency to approach each other as they proceed. For example, interstitial nepbritis, and its results in fibroid tissue and contraction, may occur in kidneys in which the morbific agencies may entirely differ among themselves. In catarrhal nephritis there are various grades of interstitial nephritis, which may produce granulations of the organs, though such interstitial changes may have quite a different meaning from that which occurs in the fibroid kidney . . . And the same might be said of the nephritis of scarlatina, of pregnancy, and of other forms. In fact . . . in all cases of renal lesions there will be an approximation more or less to histological changes common to the whole. . . . For, however the lesion may have begun, and from whatever cause it may have sprung, its results are destructive; and in the process of destruction they must approximate toward each other, and, therefore, contraction, granulation, and atrophy may occur in any nephritis, so that the exclusive morbid anatomist will readily find on the post-mortem table a strong confirmation that there is but one nephritis, one Bright's disease."

quacy—those, indeed, of pronounced uremia. These are associated, too, as in chronic parenchymatous nephritis, with as marked diminution in urinary solids, notably diminution in urea and mineral ingredients, indicating undoubted secretory involvement; yet totally unlike what is distinctive of parenchymatous nephritis, albumin is so persistently absent from the urine, even with the existence of the aggravated symptoms of renal incompetency, as to clearly indicate that its presence need form no part of the assemblage of symptoms or have any relation to the morbid condition.

The following table graphically presents the chief points of differentiation characterizing the well-known chief varieties of chronic nephritis and the few cases of the non-albuminuric form studied:

Chronic parenchymatous nephritis.	Chronic interstitial nephritis.	A form of non-albuminuric chronic nephritis closely resembling neither.
Urine always albuminous. In amount it is scanty, except during secondary atrophy; then it may be abundant. It is light-colored, depositing urates readily. Specific gravity normal or higher than normal, though low for the total amount passed.	Urine not constantly albuminous. Usually, however, albuminous in degree recognizable by HNO_3 (Heller's method). Urine profuse in amount (unless indications of cardiac failure present, with accompanying signs, dropsy, etc.), light-colored, low gravity. Sediment usually slight; often none visible.	If urine is ever albuminous, it is probably not as an incident of the malady, as the most decided symptoms of renal inadequacy may be present, even producing chronic uremia, with albumin persistently absent from the urine. Urine subnormal in amount; usually quite scanty and high-colored, and this totally without evidences of cardiac weakness, and with persistent high blood-pressure and absent dropsy, indicating that the source of the oliguria is probably not of vascular origin. The specific gravity is normal or higher than normal, though relatively low for the amount of urine voided.
Casts numerous and in great variety; epithelial, granular, waxy, and hyaline. Blood-corpuscles and connective-tissue shreds not infrequent. Microscopically, urates and phosphates predominate; oxalates less common.	Casts not frequent. When detected commonly hyaline, and less often granular. Renal epithelium and blood-cells generally scanty or absent. Oxalates common.	Casts common, although, as a rule, not very numerous; principally hyaline, but finely granular present in all in less number. Epithelial casts rare; seen in very small number in two of the cases. Waxy casts noted in one. Cylindroids present in all: in several very numerous—both mucous and hyaline. Renal epithelium in all. Oxalates very common. Urates often in relative excess. Occasionally blood-cells and pus-cells.
Urea usually much diminished in amount. Uric acid practically normal.	Total solids often normal. Urea may be normal. Usually somewhat diminished. Uric acid usually diminished.	Total solids—urea and mineral salts—always diminished in amount. Uric acid normal or diminished.
Cardiac hypertrophy not invariable, although blood-pressure tends to be habitually raised. Atheroma of arteries not common early in the affection.	Cardiac hypertrophy usual. Blood-pressure habitually raised. Fibrosis of arteries almost invariable, usually to a pronounced degree.	Cardiac hypertrophy not detectable in any of the cases, although in all the first sound is more or less forcible, and in none is it weak. In all the aortic second sound is also accentuated at the apex. Blood-pressure is habitually raised in all save one. This elevation is not detectable in two while on a strictly non-nitrogenous diet; arterial fibrosis not evident in any.
Uremic symptoms common, although often less frequent than in interstitial nephritis. No loin-pain.	Uremic symptoms common. No loin-pain.	Uremic symptoms common. Loin-tire, or pronounced aching, usual.
Dropsy usual and obstinate.	No dropsy, and even edema often not detectable until disease advanced.	No dropsy; edema not common.
Occurs most frequently before age of forty. Patient pale, waxy looking.	Occurs most frequently after forty, at degenerative period of life. Patient for a long time shows only signs of failure of nutrition. Complexion grayish.	Three of the seven cases under thirty; others at or approach middle life. None show signs of a degenerative process. Facies pale, but not marked anemia.

The six cases previously reported agree quite closely as regards the chief symptoms and the urinary condition. In all there are more or less marked symptoms of impairment of the general health, suggesting an underlying general ailment. There is imperfect gastric digestion, as shown in several, by examination of the gastric secretions, to be of the nature of subacidity and delayed propulsion. There are headache, vertigo, loin-pain, oliguria, with diminution in the most important of the urinary constituents, and the presence of casts. In all of the cases diminution in the amount of urine is a prominent symptom. During the period in which continuous observations were made on the urine of one of the series,[1] however, the urine was nearly normal in amount, averaging a daily quantity of 1085 c.c. The season was cold and water was drunk much in excess of thirst to stimulate diuresis. Subsequently the amount of urine much diminished, and now but 500 c.c. are commonly passed. There is marked increase in uremic phenomena. The patient became so

[1] Case I, W. B., see p. 662, American Journal of the Medical Sciences, December, 1893.

debilitated that he was compelled to abandon his occupation, and is wintering in Algiers, without, however, deriving benefit from the change of climate. Case II, a brother of the preceding, also has steadily declined in health. The amount of urine voided is habitually low. There are now present, besides more or less constant headache, aching in the loins, prostration, spells of vertigo, and, not infrequently, at night, attacks of slight convulsive seizures of unquestionably uremic nature. Without the appearance of albumin in the urine, these symptoms were common on leaving this city for a warmer climate three months ago. Cases V and VI, which have also been under observation, show no change from the condition noted in the previous paper. Cases III and IV I have, unfortunately, been unable to follow, despite every effort. Case III was an office patient; the other was seen in consultation; she changed her residence, and has not since been located.

The following case, not before reported, which I have had under observation for some time, corresponds clinically so closely, respecting the most prominent of the symptoms, with the histories of the others that it is worthy of study as another example of how pronounced the symptoms of chronic nephritis may be without the presence of albumin in the urine. Its recital will serve to emphasize the fact of the occurrence of such cases, which are doubtless very often overlooked in the consulting-room, in consequence of too blind faith being placed upon negative results reached from an examination of single unmixed specimens of urine for albumin and by the use of the urinometer:[1]

Mrs. F. S., a widow, aged fifty years, weight 110 pounds, by occupation a hospital nurse, has borne two children, one thirty-two, the other now thirty years of age; she has had no miscarriages and has led a correct life. There is no history of any disease of childhood, save measles. There is no history of diphtheria, typhoid fever, malaria, gout, syphilis, or lead-poisoning. There is on the maternal and paternal side a history of tuberculosis pulmonum, but she has never herself shown a tuberculous tendency.

She never at any time had a serious illness until about fifteen years ago. Then she was confined to bed for some eleven months by an ailment or complication of ailments the nature of which, from the best description the patient can now give, is not clear. The most lucid description she can give of her prior condition and that of the illness mentioned, is that she had not been well for a considerable time preceding the sudden development of the latter. She had felt weary, mentally dull, and incapable of exertion, and had vertigo, all somewhat after her present symptoms, though then felt less markedly. There had been anorexia, but on the day of the onset of the illness she had excessive appetite. The same night vomiting and purging appeared. She then became very sick, too much so to now recall the exact symptoms which subsequently developed. Her physician, since deceased, diagnosticated the condition as one of "abscesses in the liver, inflammation of the kidneys, and dropsy in the left chest." The left side of the chest was at first the seat of severe pain and subsequently of enlargement. The feet and abdomen were also somewhat swollen. She recalls nothing being said as to the condition of the urine at this time. Subsequent to this attack, which, whatever its nature, was finally recovered from, she remained in quite fair health until two or three years ago, when there appeared noticeable, yet then not so aggravated, symptoms of renal disorder such as are now manifest. She can recall at no time in her life of voiding more than a moderate amount of urine, but believes that until the past few (perhaps three or four) years the quantity habitually passed was about normal. At all events it was never in excess of normal. Within three or four years she has been surprised at the small quantity habitually voided. This has rarely exceeded a pint daily unless a diuretic was taken, and lately has been persistently less. During the winter of 1892 and 1893, and the spring of the last-mentioned year, the amount fell below a pint, and at one time, by measure, for some weeks averaged only about from ten to twelve ounces. A sample was then examined by a physician whom she consulted because of her symptoms and the oliguria. It was reported to her that the examination showed the urine normal. At this time the abandonment of work and a prolonged rest of several months in the country, with tonics, improved her condition. The urine then rose to about a pint daily and thus continued until the autumn of 1893. She has noticed for a long time a tendency to perspire quite freely when the quantity of urine has diminished, so that probably the action of the skin in her case is very complemental and prevents the occurrence of pronounced uremic symptoms which otherwise might arise.

The face and ankles have had a tendency to puff slightly lately, but there has been no more than a very moderate edema manifest. She has had, with persistent anorexia, frequent spells of nausea, and sometimes vomiting, even while the stomach is free from food. Vertigo is common, especially while on the street. Headache has been for a long time quite persistent. Though she has had symptoms of impaired digestion, the bowels have been quite regular until the past year. In this time attacks of slight diarrhea have been common, occurring at intervals of a few months, coincidently with attacks of severe abdominal cramps and the passage of more or less large quantities of mucous casts from the bowel. When she first consulted me it was especially for relief from this condition. So little was said regarding her general ill-health during the

[1] That is, not examining as to the daily amount, and judging, with freedom from albumin and with normal color and specific gravity of single specimens, that this practically excludes a renal ailment.

first few times that I saw her, that it was not until the bowel-trouble was relieved that I began to suspect a latent renal affection, apart from movable kidney, which I had previously looked for and excluded.

I examined several unmixed, and subsequently mixed, specimens of her urine during the time she was under treatment for the attacks of mucous enteritis. These were always free from albumin as tested by picric acid, and of proper color and specific gravity for a normal twenty-four-hour amount, which quantity then I did not note. During the following month (November last) the general symptoms of ill-health detailed, such as headache, vertigo, nausea, somnolence, apart from the bowel-condition, which for the time was removed, became so decided and seemed so suggestive that I began examination of the twenty-four-hour urine both chemically and microscopically. As before, I found no albumin. The urea was low and there were present numerous cylindroids and hyaline casts. Several twenty-four-hour specimens were so examined at odd times, with the same result, before the consecutive daily examination to be detailed was undertaken. As regards general symptoms, during these visits, I noted as follows: Cardiac examination, repeated on several occasions, showed no evidence of enlargement; the apex was normally placed; the impulse, though forcible was not heaving; there were no murmurs; the sounds were clear; the second was especially accentuated, and markedly so at the apex. Signs of arterial sclerosis were totally absent. Though the patient was not fleshy, the temporals were not discernible, save to palpation, and then gave no evidence of thickening; nor did the radials, the feel of which, however, was that of raised tension; for though some pressure with the proximal finger was required to obliterate the blood-stream, when a greater amount was applied it was impossible to clearly palpate the artery by the distal finger. Appended are her sphygmograms, with which many others since taken at intervals of from a week to ten days correspond. The tracing is typically that of high arterial tension. The second shows anacrotism, in her case very often produced on increasing the amount of sphygmographic pressure on the pulse. This anacrotic condition here, with total absence of evidence of aortic stenosis or other cardiac disease, indicates resistance in the arterioles, so characteristic of chronic nephritis.

Tracing No. 1.

Sitting. Pressure, three ounces.

Tracing No. 2.

Anacrotic tracing. Sitting. Pressure, three and a half ounces.

Headache is constant. Vertigo is common when in the erect posture, and at times it is so decided as to render her gait unsteady. There is persistent slight nausea. At times vomiting occurs and is independent of taking food. She is perpetually drowsy, though she sleeps very badly and is disturbed by night-terrors. Recently dull aching in the loins has been common—a symptom so constantly present in the other cases.

Dr. C. A. Oliver kindly examined her eyes, rendering me a very complete report, of which the following, having sole reference to the eye-ground, is a summary:

"A well-pronounced perivasculitis in each eye, more marked in the right eye, which is associated with a slight concentric contraction of the visual fields, these being the only ocular changes of any pathological significance; the first symptom indicating probable general vascular disturbance of a similar type."

On being unable to detect albumin in any of the single or mixed twenty-four-hour specimens of urine, even by delicate tests, I later began a systematic examination of daily consecutive twenty-four-hour specimens over a period of thirty-two days to ascertain whether albumin might not exist on some occasions. At this time as well, the total consecutive daily amount of urine passed, the urea, uric acid, and chlorids were estimated as noted here. During this period of somewhat over a month, the patient was upon ordinary diet, eating animal food once or twice daily. The precaution was always observed to void urine prior to stool. I am absolutely certain that the figures as cited represent the actual amount passed. No laxative, save a small nightly dose of cascara, was taken during this period, and no other drugs were then used.

Average daily amount of urine in 32 consecutive days, 356 c.c. or 12 fl.oz.

Average daily amount of urea in 32 consecutive days, 10.52 grams or 162 grs.

Average daily amount of uric acid in 14 consecutive days, 0.3660 gram or 5.6364 grains.

Average daily amount of chlorin in 14 consecutive days, 1.82 grams or 28 grains, or calculated as NaCl, 3 grams (46.2 grains).

Average daily specific gravity for 32 consecutive days, 1025¾.

Approximate average daily amount of the total urinary solids during the period of 32 days, 20.65 grams or 309 grains.

The color varied from red, when the amount was below 300 c.c., to yellowish-red, reddish-yellow or yellow, when the amount was above this figure.

The urinary solids[1] in this case are very low, representing for the body-weight and ordinary diet not more than what the excretion of urea should be, while the urea-excretion is about one-half the normal. The only mineral ingredient of the urine estimated in this case was the chlorids. These were taken, as representing that found pretty constantly diminished in chronic nephritis, and also as the habitual diminution of the urinary chlorin in face of a coincident diminution in secretion of HCl in the stomach

[1] The total solids here approximately estimated are calculated by the very simple method of multiplying the last two figures of the specific gravity by the number of ounces of urine passed; this equals the amount in grains. If an accurate urinometer is used and corrections for temperature noted (as should always be done for whatever purpose observations on the specific gravity are made) and urea and chlorin calculated coincidently, this method furnishes results that are of the greatest clinical accuracy.

(as was ascertained here) shows unquestionably incompetent kidneys, sodium chlorid remaining in excess in the blood, if ingested with food, as in this case, in ordinary quantity. Here the chlorin-excretion, like that of urea, is markedly subnormal; the figure, 1.82 grams (= 3 grams NaCl), is less than half the ordinary output. Uric-acid excretion is apparently diminished also, though not to more than a slight degree.

The influence of various remedies in common use for their diuretic effect in cases of inactive kidneys, such as the vegetable acid salts of potassium, the solution of iron and ammonium acetate, and, later, cantharides, was successively tried. The alkaline diuretics and Basham's mixture were without effect. The tincture of cantharides in doses of from 3 to 12 drops, three times daily, did not influence the amount passed, which at the time lay between 240 c.c. (8 fluidounces) and 380 c.c. (11 fluidounces) until taken for a week; then an increase occurred to 480 c.c. (16 fluidounces), and thence gradually to upward of 700 c.c.—this last for one day only. This augmentation was not subsequently maintained, although the remedy was continued in varying doses. The amount gradually fell, despite the cantharides, to the old figure. Regularity of the bowels was maintained by cascara. An occasional free calomel purge was given. No marked effect was apparent in the symptoms from these procedures, save that vertigo and headache were temporarily diminished by free purgation.

From the now well known effect of thyroid extract on the urine in cases of myxedema, increasing the urinary water and nitrogen,[1] it seemed worth a trial in this and analogous cases with incompetent kidneys, the secretory function of which was so profoundly affected. It is not beyond theoretic probability at least that such a remedy as this, exerting a specific effect upon the secretory epithelium, might also, if continued sufficiently long in disease of the viscus, which normally it can so influence, exert more than a transitory effect for good. The patient has now taken thyroid extract steadily for a month. It will be continued for some time should no untoward effect arise. At first the extract was administered in doses of 5 grains three times daily for a period of four days only, to note its effect upon the urine both before, during, and after using. Subsequently it was re-begun in doses of from 3 to 5 grains three times daily, and is so continued.

Daily amount of urine for 5 consecutive days before thyroid extract, 396 c.c.

Daily amount of urine while taking thyroid extract for four days, 574 c.c.

Average daily urea-excretion before, 11.19 grams.

Average daily urea-excretion during, 12.91 grams.

As already indicated, a sharp diminution in amount succeeded the rise under thyroid extract, on temporarily discontinuing the latter. Subsequently the urine again increased in amount on resuming the remedy. It has since maintained itself at a fair average, running between 450 c.c. and 900 c.c. There is as yet no more than slight symptomatic improvement.

On several occasions prior to the period in which the continuous daily estimations of urine were made, while no drugs were taken, throughout this time, and subsequently, until the patient began thyroid extract, under which the urine became too turbid for careful testing, extended examinations for albumin of the twenty-four-hour urine were made. Daily consecutive examinations were carried out, always on an identical plan, from November 29th to December 31st, save on three days on which no tests were made for albumin. It was not unusual for the urine, because of its concentration, to be turbid from urates with a room-temperature of 55° to 60° F. This turbidity occurred with about three-fourths of the specimens. The urine always cleared perfectly by heat, and no trace of cloud occurred on prolonged boiling—a process that a small portion of the urine was put through on each occasion that the turbid urine was tested.[1] A considerable number of microscopic examinations were made, chiefly of the specimens in which no great turbidity occurred from precipitation of amorphous urates after standing, but also in some of the latter when this condition persisted for several days. Then nearly the total bulk of urine, after the application of a gentle heat to assist in the solution of the urates, was diluted from the few ounces representing nearly the twenty-four-hour quantity to that equalling a more normal amount, and a little sodium carbonate added to maintain the urates in solution. For microscopic examination the urine was always allowed to stand in a tall glass from twelve to twenty-four hours, and the sediment thus obtained centrifugalized. On all occasions cylindroids were found and usually in large amount. On several instances the number was surprising. They were, as a rule, mucous, but not infrequently perfectly hyaline. Typical hyaline casts, medium-sized, broad, and narrow, were often found, but were less in number than the cylindroids. From time to time a few undoubted finely granular casts were also encountered. The sediment, from the concentration of its diluent, was always highly rich in cellular elements from the extra-renal passages. There were in the slides of nearly all specimens examined a few cells detected, the appearance of which suggested origin from the convoluted tubules. Epithelial casts were not found. Calcium-oxalate crystals were always present, and frequently those of free uric acid.

The most interesting feature of this urine is that relating to the probable total absence of traces of serum-albumin, in the face of diminution in bulk of that fluid and indubitable evidence, both rational and physical, of renal disease. Very critical and searching examinations were pursued on all occasions, both on each of the days on which estima-

[1] See a paper by Ord and White, British Medical Journal, July 29, 1893.

[1] Its usual high acidity did not render necessary the coincident use of acetic acid with the boiling test, save on two occasions in which a slight phosphatic cloud occurred, dissipated by the use of a few drops of dilute acid.

tions were made of the nitrogenous excretion, as already recorded, and frequently since. Yet at no time have I obtained a reaction by any test which indicates the presence of serum-albumin. The methods employed for testing were very similar to those detailed in my former paper, with the exception that dialysis was often also used. In the application of the tests, the filtered, acid urine, which if turbid from urates was cleared by gentle heat, was first carefully overlaid with picric acid; a second specimen was similarly tested with Millard's solution, and still another with glacial phosphoric acid. Any indication of a contact-ring occurring within a few minutes after application of the tests—in about one-third of the occasions a slight contact haze or ring was usual to picric acid after the tube stood a few moments, usually, however, only when the urine was greatly concentrated—350 c.c. and under—on which occasion also mucous cylindroids were found to abound in the urine—the urine was treated with acetic acid (5 c.c. of 25 per cent. glacial acid to 15 c.c. of urine), thoroughly agitated, allowed to stand, and then filtered. The urine so treated became slightly cloudy, and subsequently deposited fine flakes of mucin. This mucin-reaction was more apparent when the specimen was first diluted with an equal bulk or more of water, though no large additions were practised with specimens to which it was intended to apply tests for albumin, lest minute traces of the latter present might by too great dilution escape detection even by the delicate tests employed. The acidified specimen was then repeatedly filtered and the excess of acid was neutralized by a concentrated solution of NaHO from a buret. After subsequent filtration and acidification the picric-acid test was once more applied. Note of the amount of acid and alkali added was always taken, and a second control-solution of the urine diluted with distilled water to the bulk of its treated companion was tested for albumin similarly to the other, that it might be known whether the occurrence of the disappearance of this reaction to these was rather in consequence of too great dilution than to separation of a substance coagulable with acetic acid, such as mucin or nucleo-albumin. It was found that invariably with urine so treated, had a previous response occurred to the contact-test with picric acid not dissipated by placing the tube in hot water, and this response on no occasion amounted to more than a slight ring or contact-haze, of tardy appearance,[1] none subsequently occurred when the picric-acid test was applied to the specimen so manipulated, though the reaction was always evident in that of the control diluted with water, as stated. The result was similar when Millard's solution[1] was employed, as it was on a number of occasions, to supplement but not to supplant the picric acid. With metaphosphoric acid, used in the glacial state, had a haze occurred with it, as was frequently the case when the contact of the portion of acid was of greater duration than from three to five minutes,[2] no reaction occurred in the acidified, non-mucinous, unneutralized specimen. After the addition of soda, though the specimen was subsequently rendered acid, at the end of from ten to fifteen minutes a narrow, opaque ring would develop, quite unlike what is the case with an albuminous response, just above the portion of acid. This was noticed on two occasions in which this test was so applied. It probably indicates, as Dr. Leffmann suggests to me, a reaction between the metaphosphoric acid and the excess of sodium salt present or some substance contributed by the NaHO.

Thorough ebullition of the upper stratum of the undiluted acid urine in a test-tube was always negative as regards even a trace of comparative haze. The result of boiling specimens dialyzed to a specific gravity of about 1008 and 1004, by which dialysis most of the salts and coloring-matter were removed, was likewise negative unless a small amount of a weak acetic-acid solution was first added to the yet acid urine. On several occasions, dialyzing carefully to quite a low gravity, the urine still remained transparent and free from more than a slight haze. On a number of occasions but a trace of haze was present, though brought to a gravity of but from 1002 to 1004. This was especially notable when portions of the twenty-four-hour amount which had equalled 400 c.c. or over were dialyzed. When 1002 was reached (which occurred when dialysis was continued for from sixteen to twenty hours) of samples of the urine representing originally great concentration (about 300 c.c.), the specimen was usually too turbid from spontaneous precipitation of mucin for the application of tests. Dialyzed specimens from the daily quantity which had equalled or exceeded 400 c.c., and still remained sufficiently free from cloud for testing, treated with HNO_3 by the contact-method,[3] and by heat and acid, gave no reaction. When the dialysis was car-

[1] No drugs were administered during the time these tests were made, save a nightly dose of cascara, as stated. Dilutions were always carried after the first few trials up to two and a half times the amount of urine used, so that if 300 c.c. equalled the twenty-four-hour quantity, after dilution the amount would equal a twenty-four-hour specimen of 700 c.c., still but about one-half the average normal quantity. Dilution was rendered necessary to obviate danger of reaction between the excess of sodium acetate formed in neutralizing and the tests for albumin employed, thus obscuring the response of the latter. The addition of an excess of acetic acid was necessary to insure any marked precipitation of mucinous substance in a urine so concentrated—rich in salts, the latter preventing separation of the soluble mucin unless acted upon by a great deal of acid.

[1] This solution does not react so strongly to mucin as other of the delicate tests, such as trichloracetic acid, Tanret's and Sebelein's reagents. In Millard's solution acetic acid exists as a base which has little or no precipitating influence in this direction.

[2] A slight response is common in all non-albuminous concentrated urines with metaphosphoric acid at the end of from three to five minutes. This is probably mucinous. Dr. Leffmann, who has for years employed the metaphosphoric acid in albumin-testing by preference to all others, tells me he disregards a response not occurring within three minutes' contact.

[3] After dialysis, by which salts and coloring-matter are removed, the contact HNO_3 test is of far greater delicacy for the detection of traces of serum-albumin than before. See a very interesting and instructive paper by Kirk on mucin-testing in the urine, *Lancet*, April 26 and May 3, 1890.

ried to 1001 to 1002, a few drops of 2 per cent. acetic acid alone, or this plus heat, produced some turbidity; and subsequently, after standing, fine, flaky strings, characteristic of mucin, separated. That this turbidity was due solely to mucin I think there is no doubt. The addition of more acid to a second portion, without the employment of ebullition, allowing also this portion to stand until precipitation of the mucin was assured, prevented more than the slightest contact-haze, when any was apparent to the contact-test with picric acid and with Millard's solution. This same dialyzed urine always responded markedly by the contact-method to citric acid, especially when used in 25 per cent. solution, giving a much broader contact-haze than did picric acid. This was evident, too, in the undiluted, undialyzed urine. Here, in testing with various percentages of citric acid, from a saturated solution to a low dilution, it was found that a 33 per cent. solution gave the most marked contact-response. With this percentage the reaction was always quite pronounced. In the dialyzed urine the addition of a few drops of a 25 per cent. citric-acid solution always induced some opacity.

The urine under consideration was especially interesting for study because of the small quantity voided. It represented in amount one already reduced by concentration from a normal 1200 c.c. to an average of 350 c.c. On some days it was considerably less in amount than this, the lowest being 250 c.c. (8⅓ fluidounces). It would be surprising, indeed, if a urine so concentrated and so rich in cellular elements as this was shown microscopically to be did not respond to the more delicate tests for albumin, because of the concentrated normal amount of nucleo-albumin, or mucin, it must contain, derived from the urinary passages outside the kidneys, disregarding even that no small quantity probably present in this case, as in all of this sort, derived from the renal cells themselves, due to their defective metabolism.[1]

It seems now established that serum-albumin as an exudate from the blood takes no part in the formation of casts. That these may be present without an accompanying albuminuria is certain. This dissociation was well illustrated in the previous series of cases of non-albuminous nephritis that I reported. In the urine of all of these casts were more or less frequently present, as in the present case. Casts are now regarded on the best of evidence as the product of faulty metamorphosis or inflammatory irritation of the renal epithelium,[2] by which a secretion from or a disintegration of the protoplasm of the latter occur, resulting in the formation of cylindroids or true cylinders. With the presence of mucous cylindroids in any amount, should the urine be concentrated, mucin is also present in amount usually detectable by acetic acid when added in excess, and unless regarded will mislead when delicate tests for albumin are employed, as these, without exception, also react to mucin.[1]

I think that it may be accepted in the case just detailed, as in those of the others previously reported, in all of which a more or less concentrated urine occurred, that even small amounts of serum-albumin are in all probability absent, and that from the behavior of the urine to picric acid, when a slight reaction with it was obtained, as sometimes occurred, that this was in all probability due to the presence of an albuminoid of a mucinous (or nucleo-albuminous) nature. The urine of several of these cases, especially when much concentrated, was rich in mucin yielding cellular elements derived from the genito-urinary passages, apart from that probably originating from the epithelium of the kidney. In granular kidney, in those cases in which the urine is often singularly free from sediment, and of low gravity, showing diminution in salts, and in which the prior use of acetic acid without heat causes no cloud, but with which the most reliable finer tests for albumin respond, the reaction in all probability is that of serum-albumin. I recently examined the urine of a case of this sort over some days. It had been suspected by the physician to be albumin-free. The patient was senile, with an hypertrophied heart and rigid arteries. The urine was subnormal in amount, of low gravity, low urea, chlorids, and uric acid, and deposited no sediment, even after twenty-four hours' standing. Specimens centrifugalized likewise yielded none. No reaction occurred to Heller's contact-test with HNO_3, but to picric acid and metaphosphoric acid a response was evident, and on two occasions a slight opacity was detected by boiling, with the addition of acetic acid.

2620 North Fifth Street.

The Eighth International Ophthalmological Congress will be held at Edinburgh on the 7th, 8th, 9th, and 10th of August. Owing to the death of Professor Donders, who has presided on previous occasions, the Edinburgh Congress will be under the presidency of Dr. Argyll Robertson. In response to a previous circular, about two hundred British and foreign oculists have intimated their intention of taking part in the proceedings. Arrangements are being made for holding a discussion on the subject of "Intra-ocular Therapeutics." Dr. George A. Berry is the General Secretary.

---

1 As to this, see the last portion of the second part of Kirk's paper, before referred to. Kirk there calls attention to a *renal mucinuria* independent of albuminuria and to the frequent association of the two in ordinary nephritis. This last is well known. In my case the persistent low excretion of urinary salts and the presence of numerous casts and cylindroids well indicated the tubular disturbance of function.

2 See Lubarsch, Centralbl. f. allgem. Path., Band iv, No. 6, and Aufrecht, Centralbl. f. klin. med., June 30, 1893.

1 I have left the further consideration of this part of the subject to be taken up in a second paper devoted to fallacies attending the employment of certain delicate tests for serum-albumin, notably the trichloracetic acid.

CESAREAN SECTION AND SYMPHYSIOTOMY FOR THE RELATIVE INDICATIONS.[1]

With a Report of Cases.

By EDWARD P. DAVIS, A.M., M.D.,
PROFESSOR OF OBSTETRICS AND DISEASES OF INFANCY IN THE PHILADELPHIA POLYCLINIC; CLINICAL LECTURER ON OBSTETRICS AND GYNECOLOGY IN JEFFERSON MEDICAL COLLEGE; OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

The problem of successful delivery to mother and child in complicated labor derives new interest from the results of modern obstetric surgery. At the present time obstetricians have better grounds than formerly for the hope that such cases may be terminated with but little mortality and comparatively little suffering. Symphysiotomy under antiseptic precautions is as yet sufficiently new to render of interest a report of its results, especially as affording a basis of judgment in determining its scope. It is the purpose of this paper to report two symphysiotomies for the relative indication, and a third case in which symphysiotomy was declined, and the Cesarean section chosen in its stead. These contrasted cases will lead to the discussion of the reasons for choosing the operative procedures mentioned.

By the phrase "symphysiotomy for the relative indication" is meant the performance of the operation in cases in which it would have been possible to extract a dead child by craniotomy without dividing the mother's symphysis, and in which some might claim that a difficult and tedious application of the forceps might possibly have resulted in the birth of a child capable of surviving without the operation of symphysiotomy. It is my belief, however, that it is the duty of the obstetrician, whenever possible, to avoid difficult extraction with the forceps, not only on account of the fetal mortality that sometimes results, but also because of the fetal morbidity, especially after injuries to the skull and brain, that not infrequently follows such delivery. To my mind cases in which there is a strong probability that the fetus will sustain serious injury in delivery, as evidenced by failure of the fetal head to engage after sufficient uterine contractions have persisted for a reasonable time, call for surgical interference in the interests of both mother and child. The cases of symphysiotomy are briefly as follows:

Case I.—J. McN., aged twenty-five years, an Englishwoman, entered the Jefferson Maternity during last autumn. Her previous history was not obtainable at the time, because of the patient's reticence and intentional misstatements. It has been learned, however, that she is married; that five years ago she bore a small, ill-developed fetus, after a spontaneous labor lasting five days; she has also had an abortion at four months.

On admission she was found to be in the eighth month of pregnancy, her fetus occupying the first position, the head at the brim of the pelvis, and capable of being brought just within the brim by pressure; it could not, however, be made to engage. Her pelvic measurements were as follows:

	CM.
Anterior superior spines	24
Crests	25
Trochanters	24.5
External conjugate	16
Internal by measurement	7.25

The fact that the head of the fetus could not be made to engage led me to omit the induction of labor, and to allow the patient to go to term, with the expectation of delivering her, by suitable operative interference, should the head then not engage. She engaged in housework with the other patients, and was carefully examined at intervals of ten days or two weeks, when it was found on each occasion that the head could be brought to the brim of the pelvis, but could not be made to enter the pelvic cavity. The fact that the head presented at the pelvic cavity led me to believe that but little enlargement of the pelvis would be needed to accomplish its delivery. On December 22d labor began, the uterine contractions being regular and of considerable force; labor progressed with increasing pains, the membranes ruptured, but complete dilatation was tardy, and the pains were ineffectual in causing engagement. The os was accordingly dilated with Barnes' bags and the patient anesthetized with ether, and a careful effort made by suprapubic pressure and uterine massage to cause the head to engage. As these efforts failed, and the heart-sounds of the fetus indicated that the child was in excellent condition, symphysiotomy was performed. It was necessary to dissect away the recti muscles to gain free access to the joint, and also to completely sever the subpubic ligament; the method employed was by an incision above the pubes, terminating three quarters of an inch above the joint, thus leaving an unbroken cutaneous surface directly over the symphysis. The joint was severed with the Galbiati knife, inserted from below, traction being made from below upward and from in front posteriorly. The pubes separated three-quarters of an inch after section, the head engaged in the left oblique diameter, the occiput behind, and was readily delivered by Tarnier's axis-traction forceps; the pelvic floor and perineum were uninjured. A strand of iodoform-gauze was carried behind the symphysis, to prevent the bladder and adjoining tissues from being pinched between the parts of the symphysis as the pelvis was brought together. The wound was closed in the usual manner, an open stitch being left at the lower end, which was tied when the gauze was removed twenty-four hours after operation.

The patient made a good recovery, retarded only by gastric irritability arising from her previous excessive indulgence in tea. She was kept recumbent for four weeks, and was dressed with an antiseptic dressing over the wound, antiseptic absorbent pads over

[1] Read before the College of Physicians of Philadelphia, April 4, 1894.

the vulva, with a single strip of adhesive plaster, eight inches wide, drawn tightly around the pelvis, the center of the strip being over the trochanters of the femora. She was lifted out of bed daily, and care taken to prevent irritation of the skin, and to maintain cleanliness. Her child was a well-developed male, 46 cm. long, weighing 7 pounds, 11 ounces; the measurements of his head were as follows:

	cm.
Occipito-frontal	11.5
Occipito-mental	14
Maximum	13
Biparietal	11
Bifrontal	9
Trachelo-bregmatic	9.75
Suboccipito-bregmatic	10
Bisacromial	11
Circumference	36

Since her convalescence the patient has been kept in the Maternity, and employed in domestic service, in order to accurately observe the condition of her pelvis. She has been examined by Dr. Robt. P. Harris and Dr. H. Augustus Wilson. She has firm and complete union at the symphysis, whether osseous or fibroid cannot be stated. She experienced, when first allowed to get up, some lameness in the right sacro-iliac joint, which has since disappeared. She is able to carry coal up and down stairs, to scrub and lift, as well as other women in the Maternity who have not been subjected to symphysiotomy, and who are not in a pregnant condition. She has nursed her child, and is in good general health. The measurements of her pelvis at the present time show a slight increase, possibly as the result of the symphysiotomy; thus, very careful measurement shows that in the distance between the crests of the ilia and between the trochanters there is an increase of 0.5 cm. Her external conjugate is 1 cm. greater than before the symphysiotomy. Her internal conjugate is 0.75 cm. greater. According to her own calculation, and from the appearance of her fetus, she had, when delivered, gone several weeks over the period of normal gestation.

CASE II is that of M. F., a young married woman, aged twenty years, whose previous history was negative. She did not know the date of her last menstruation, and had never recognized fetal movements. Her general development was poor; she was poorly nourished when admitted, and manifested an unstable condition of the nervous system. An examination of her pelvis gave the following measurements:

	cm.
Anterior superior spines	22.5
Crests	25
Trochanters	27
External conjugate	19
Internal conjugate	9.5

Her fetus occupied the first position, the head presenting. The period of her pregnancy was the end of the seventh or the beginning of the eighth month. An examination of the urine revealed a deficiency in excretion. The percentage of urea remained below the average, the specific gravity being less than usual, although albumin and casts were absent. The woman remained in fair health until the 7th or 8th of March, 1894, when she manifested symptoms of toxemia; she complained of headache, disordered vision, great restlessness, and had exaggerated melancholia, and nausea. An examination of her urine for several consecutive days revealed a rapid diminution in the percentage of urea, although albumin was present in a mere trace, and casts were absent. The amount of urine diminished progressively. The percentage of urea, which should have been from 1.4 to 1.8, fell as low as 0.01. Instructions were immediately given that the induction of labor should begin; this was accomplished by the introduction of bougies, which was followed by uterine contractions characterized by excessive pain. The patient was given calomel in small and repeated doses, a hot bath and pack, fed upon skimmed milk, and made to drink freely of water, when the percentage of urea rose to 1.4. After forty-eight hours of very gradual labor by the stimulus of bougies in the uterus, the patient came into active labor on the 16th; her pains were vigorous, and caused great suffering; dilatation being tardy, Barnes' dilators and McLean's dilators were employed, and dilatation being complete, the patient was anesthetized with ether, the membranes were ruptured, and an endeavor was made to bring the head to engage; this could not be effected; the head presented, the occiput posteriorly and upon the right side. After a fair trial had been given to secure engagement, symphysiotomy was performed, as previously described. In this case, as the disproportion between the head and the pelvis was much less than in the previous case, the subpubic ligament was but partly severed; the head at once engaged, although the parietal bone presented at the brim of the pelvis. An effort was made to apply Tarnier's forceps to the sides of the head, but it could not be readily locked. Simpson's forceps was then applied with the axis-traction tapes, and the head gradually brought to the floor of the pelvis, where incomplete rotation occurred. The occiput was delivered posteriorly, the pelvic floor being uninjured. The child was asphyxiated, but was revived without great difficulty. The head at birth measured:

	cm.
Maximum diameter	12.5
Suboccipito-bregmatic	10
Occipito-mental	12.5
Occipito-frontal	11
Fronto-mental	9
Biparietal	9
Bitemporal	9
Bisacromial	11
Total length	46

Sex, male.
Weight, 5 pounds 11 ounces.

The child was placed in an incubator, and fed with breast-milk pumped from the mother's breasts and dropped into the mouth with a medicine-dropper.

Eighteen hours after delivery the mother was seized with eclamptic convulsions; as she had received $\frac{8}{30}$ of a grain of strychnin hypodermatically in divided doses, and as her convulsions were not typical, there was doubt as to their precise nature. Dr. Hare saw her in consultation, and found

no evidence of strychnin-poisoning. Under the use of the hot pack her convulsions ceased, and did not return. Her percentage of urea remained nearly normal, and has risen to normal, and her convalescence has been uninterrupted. She is able to nurse her child, which is developing normally. Her wound has healed, although she has not yet been permitted to assume the erect posture.

In contrast with the foregoing is the next case:

Case III.—In this case the Sänger-Cesarean section was chosen instead of symphysiotomy. Mrs. E. H., aged twenty-seven years, of excellent general health and good physique, married at eighteen, had been pregnant five times previously. Her first, third, fourth, and fifth labors were terminated by the use of forceps, each labor resulting in the birth of a dead child. All of the children were large; the first was twenty-three inches long, and weighed thirteen and one-half pounds; the others weighed more than twelve pounds. Her second labor terminated spontaneously, a small male child being born, although her medical attendant at the time despaired of a successful termination of the labor, and had sent for assistance, when under strong pains the head emerged with defective mechanism of labor. The exact manner of delivery neither the patient nor her husband can describe. The child, however, was small, but is living and in good health. The patient corresponded with me during the winter, stating that she was resident in the mining regions of the State; that she had endured repeated unsuccessful labor, and was desirous of obtaining at the termination of her present pregnancy a living child. She gladly came to the city, and presented herself at my office for examination. In general appearance, physique, and width of her hips she seemed an exceptionally robust woman; it was evident from the size of the abdominal tumor that her uterus contained an unusually large child. An examination of her pelvis gave the following measurements:

	cm.
Anterior superior spines	28
Crests	30
Trochanters	29.5
External conjugate	19.5

Vaginal examination showed the rami of the pubis approximating each other much more closely than normal. Palpation of the inner surface of the pelvis revealed a funnel-shaped pelvis, the cavity narrowing very appreciably toward the outlet. In comparison with the breadth of the patient's shoulders and the width of the iliac bones, it was seen that she had a flattened and converging pelvis. The fetal heart-sounds were heard upon the right side of the abdomen, four inches above the umbilicus, indistinctly over a wide area. The os uteri was patulous, but no presenting part could be detected. The symphysis pubis was two and one-half inches in height.

The patient was convalescent from influenza, and had an obstinate cough; she was told that an operation would be necessary for her safe delivery, to which she assented. She was instructed to go immediately to the Polyclinic, where it was intended to prepare her for delivery by surgical means; she neglected, however, to report at the hospital for twenty-four hours, when she came in at midnight on January 14th, in labor. In the early morning of January 15th her pains became frequent and severe; the membranes ruptured, and a breech-presentation could be detected; the child remained high in the mother's abdomen, the breech failing to engage. Dr. Robert P. Harris met me in consultation over the patient about six hours after the beginning of labor; his first advice was to perform symphysiotomy, but when palpation and auscultation confirmed the diagnosis of breech-presentation, and the large size of the child was apparent, together with the fact that version could not be performed on account of the loss of amniotic liquid, Dr. Harris and my colleague at the Polyclinic, Dr. Baer, agreed with me in choosing Cesarean section.

On account of the patient's condition of bronchial irritation, chloroform was administered by my assistant, Dr. Wm. H. Wells. In listening for the heart-sounds it was found that the placenta was attached to the anterior wall of the uterus, and would probably be encountered in the incision. The abdomen being opened, the uterus presented, large in size, and rotated from right to left upon its axis. While Dr. Baer skilfully controlled hemorrhage by taking the broad ligaments between his fingers, I incised the uterus, finding the placenta directly beneath the incision. The placenta was immediately severed, stripped from the wall of the uterus, and the child, placenta, and membranes delivered in a few seconds. The child was delivered by the feet, was asphyxiated, but speedily revived. The uterus was turned out of the abdomen, and closed by four buried sutures of heavy silk, six stitches through the muscle and peritoneum, and seven fine silk stitches in the peritoneum only. There was but little hemorrhage, although bleeding from one of the sinuses required two additional stitches. The size of the uterus required an abdominal incision extending above the umbilicus, which was closed by continuous suture through the aponeurosis, and fourteen interrupted stitches. The patient showed little shock, the uterus contracted well, and there was no secondary hemorrhage or relaxation. The child was a female, weighing 11.75 pounds, and 52 cm. long. The measurements of its head were as follows:

	cm.
Occipito-frontal	13
Suboccipito-bregmatic	11.25
Biparietal	10.25
Bitemporal	9.25
Occipito-mental	14
Maximum	15
Bisacromial	12.5

The mother's convalescence was jeopardized by two complications: her cough continued obstinate for several days, and catarrhal pneumonia seemed threatened for a short time. These conditions gradually subsided. Her failure to report promptly at the hospital had given insufficient time to disinfect the surface of the abdomen, and a single stitch-hole abscess required attention for a few days. With these exceptions, her convalescence was uneventful; she nurses her child and is living in good health in

the city. Because of the length of the abdominal incision, the stitches were retained as long as possible in her case, as it was feared that violent cough might reopen the incision.

This case is of interest in connection with the preceding, because symphysiotomy was declined for two reasons: first, the funnel shape of the pelvis promised less in gain of space after symphysiotomy than in pelves shaped as in the preceding cases; second, Dr. Harris informed me that breech-presentation is less favorable for delivery after symphysiotomy than head-presentation, and as the membranes had ruptured, it was impossible to turn the child before operating. Dr. Harris was positive, on seeing the child, that it could not have been safely delivered by breech-presentation after symphysiotomy. Five weeks after delivery, examination of the patient revealed the following condition: The cervix uteri pointed downward and slightly backward; the uterus was adherent to the abdominal wall, reaching a hand's breadth above the pubes. Involution of the uterus had proceeded fairly well; a slight amount of mucous secretion from the cervix was present.

The report of these cases is offered as an illustration of what I believe to be a fair deduction from the results of modern obstetric surgery, namely, that in cases in which the fetus is disproportionate in size to the mother's pelvis, and in which after spontaneous efforts have failed to secure engagement of the presenting part in a reasonable time, and these efforts have been supplemented by thorough examination under anesthesia and a fair trial to secure engagement by manipulation and suprapubic pressure, that if the fetus be living and in good condition, it is the duty of the obstetrician to refrain from application of the forceps, and to deliver the patient by some form of abdominal section, either by symphysiotomy or by the Cesarean operation.

CLINICAL LECTURE.

ADVANCED PHLEBITIS, WITH CALCAREOUS DEGENERATION.[1]

By CHARLES CARY, M.D,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, UNIVERSITY OF BUFFALO.

This patient, a German woman, aged seventy-one, presents an interesting condition of the veins of the lower extremities. She is very talkative, and her statements are not reliable. On entering the hospital she was pale; her abdomen was distended from constipation; there was edema of the lower extremities; and her general condition was one of low vitality. You notice that in trying to tell her age she has become very much confused, and now she turns the conversation very abruptly by saying that she wants "to see the angels in heaven." The patient was sent to the hospital on account of the general mental and bodily enfeeblement of old age. The edema of the lower extremities has nearly disappeared after several days in bed.

On examining her I find an eczematous patch on the left forearm, which has the appearance of a cicatrix, but the skin is neither thicker nor thinner than in neighboring parts. On the right forearm you will notice the discoloration of hemorrhagic exudates such as frequently occur in old persons with degenerate vessels. I wish, however, to call your attention especially to the superficial veins of the legs. The varices are very evident, and the veins are not only dilated, but they have undergone calcareous infiltration. They feel like lead-pencils and can easily be picked up and rolled about under the skin. On striking them with a hard object the sound is like that produced by striking a piece of lime. Undoubtedly, the circulation is entirely obstructed in some of the veins. The internal saphenous vein can be traced to its disappearance in the saphenous opening. It is sacculated in places, and the valves have doubtless long ago been obliterated. The chronic inflammation and distortion of the veins are analogous to arteritis deformans, but they are much less common, because the veins are not subjected to the high blood-pressure which is constant in the arteries. After the inflammation in the veins has gone on for some time and the inner coat has become broken, calcareous salts are deposited in the intravenous ulcers, and there is a marked tendency to the formation of thrombi. Many of the coagula have doubtless been detached and have occluded the vein higher up, and probably some have passed into the arterial circulation and become lodged as emboli in the smaller arteries. So far as we know the history of the case, none of the emboli has lodged where it could cause sufficient interference with function to attract attention. You can readily understand that the condition of the veins of the lower extremities might interfere so much with the return circulation as to cause an exudation of serum into the cellular tissue. As a matter of fact, however, another cause was found for the edema in this case, which affords an illustration of the necessity of careful examination and of the unwisdom of hastily jumping at conclusions. The patient's urine was found to contain a small amount of albumin, some granular casts, and showed an elimination of only eight grams of urea in twenty-four hours, thus indicating the existence of contracted kidneys.

The time for the treatment of these veins was many years ago. When the varix was recent, even the elastic stocking might have prevented their further degeneration. Now the only radical relief would be surgical, and at her age and in her weak state, operation would be contra-indicated. So we must acknowledge frankly that nothing will be undertaken for the treatment of the vascular condition. The mental state, however, can be improved by appropriate management. Our attention must be given to the chronic nephritis, but the only condition to which I care to call your attention to-day is the exaggerated and advanced disease of the veins, which in its degree is a pathologic curiosity, although the disease itself is not uncommon.

[1] Delivered at the Buffalo General Hospital.

CLINICAL MEMORANDA.

INJURY TO THE CAUDA EQUINA, PROBABLY DUE TO INTRA-MENINGEAL HEMORRHAGE; WITH RECOVERY.[1]

By HERMON C. GORDINIER, M.D.,
of Troy, N. Y.;
Instructor in Physical Diagnosis and Lecturer on the Anatomy of the Nervous System, Albany Medical College.

S. L. R., forty-one years old, is an American, married, and by occupation a grocer. His father and mother are living and in good health. The patient has been in perfect health since childhood, and, with the exception of gonorrhea, has had no venereal disease. He has of late drunk whiskey and other alcoholic liquors quite freely. On April 16, 1891, while under the influence of alcohol, he was thrown from an electric car, striking on the lowermost part of the spine; the patient places his hand over the region of the sacrum as the seat of pain and injury. He was found in an unconscious condition, and was then taken home. On the way he regained consciousness, and it was then discovered that he was totally paralyzed as to motion in his lower extremities, not being able to flex or extend his toes. On the following day it was discovered that there was a total "paralytic incontinence." The bladder was carefully emptied by the catheter, the introduction of which was entirely unrecognized by the patient, showing anesthesia of the mucous membrane of urethra. The feces, when semi-solid or liquid, would pass uncontrolled, but if they were very hard mechanical measures were necessary to remove them. On several occasions, when feces became impacted, the mechanical manipulation necessary to remove them excited no pain, and he had but little knowledge of what was going on in the rectum. He complained bitterly of pain over the sacral region, of a sharp, shooting character, and greatly aggravated by movement; the pain was at times of an agonizing character, and was mostly localized over the sacrum, but would occasionally pass down the distribution of the great sciatic nerves. The urine was carefully withdrawn at stated intervals. In May the man had recurring chills and high fever, with marked changes in the urine; this was ammoniacal, contained pus and bladder-epithelium, proofs of a "retention-cystitis." This state of affairs was soon corrected by salol and thorough irrigation with a boric-acid solution.

My first acquaintance with the case was on May 1, 1891, when I saw the patient in consultation with my friend Dr. John Morris, of Troy, who had been his medical attendant. I found him recumbent and unable to move his lower extremities; there remained slight power of abduction; adduction was entirely lost; the paralysis of motion was most marked from the knees down. There was a characteristic foot-drop, and he was unable to move the toes or to flex or extend the feet. There was marked atrophy of the peronei muscles, the anterior and posterior tibials, and the muscles of the calf, with considerable wasting of the vasti and of the gluteus maximus. The paralysis and atrophy were much more noticeable throughout the whole right side. By actual measurement a difference of three-quarters of an inch was discovered, the smaller circumference being on the right side; the limbs were flaccid, somewhat swollen, cold, and cyanotic. The patella, plantar, and cremasteric reflexes were absent on both sides, and there was no foot-clonus. The umbilical reflex was present. The sphincter ani was relaxed, and offered no resistance to the introduction of the finger. There appeared to be a decided blunting of sensibility of the rectal mucous surfaces, because when the finger was in the rectum considerable pressure with the nail was not followed by pain. There was no response to the faradic current in all of the atrophied muscles, namely, the gluteus maximus, vasti, peronei, the tibial, and the calf muscles. There were slow, worm-like contractions of these muscles in closing the current with the positive pole; there was no

The transverse lines represent the areas of complete anesthesia.

response to the negative pole, forty cells being in the circuit—in other words, there was decided degenerative reaction. The sexual power was entirely lost, and the man had had no erections since the accident. A sensory loss of peculiar distribution was discovered; this loss can best be explained by the diagram shown herewith, namely, an entire loss of the tactile, pain, and temperature senses over an area extending about two inches to either side of the tuber ischii, involving the region of skin between the gluteal fold; this loss involved particularly the skin of the perineum, that of most of the scrotum, and the skin of the penis to near its root. A narrow patch of anesthesia extended down the posterior aspect of the thighs, and involved also the soles, and extended up the posterior aspect of the legs. Over the anesthetic area there was no perception of strong electric currents. Bedsores never developed, which I think may have been due to the extreme care on the part of his nurse. There have been no feelings of con-

[1] Read by title at New York State Medical Society Meeting, 1894.

striction about the legs or thighs. The catheter could be introduced when the patient was blindfolded without eliciting any response or knowledge of its presence. Careful examination of the lower lumbar and sacral regions showed nothing abnormal. There were no abnormal symptoms as regards the cranial nerves, and the upper extremities were normal.

The treatment consisted of moderate doses of potassium iodid, with tr. nucis vomicæ thrice daily, and three electric treatments weekly. At the expiration of five weeks the following indications of improvement were noted: The man was able to adduct, abduct, flex, and extend the left thigh. Two weeks later he began to be able to contract the left calf-muscles, and ten days afterward he was able to flex the foot on the leg, but there was absolutely no motion of the toes, nor could he raise that member from the bed. Ten weeks after the accident he could extend and flex the thigh of the right side, and there was at same time slight evidence of ability to contract the calf-muscles. Three months after the accident he could move the toes of the left foot, and was able to lift that member from the bed. At about the same time there was an ability to flex, extend, and separate the toes of the right foot. Fourteen weeks after the injury he could raise the right leg from bed and sustain it in that position for some time. At this time a careful examination was again made. The muscles that were decidedly atrophied were regaining their size, losing their flabby appearance, and responding sluggishly to strong faradic currents. The reflexes remained as at first. The anesthetic areas were becoming sensitive at the periphery. The condition of the skin of the perineum, scrotum, and penis was not at all improved. The catheter excited no pain or feelings of its presence. The rectal sphincter had slightly recovered its tone. The only change in treatment was the substitution of increasing doses of strychnin and the addition of massage.

Five months after the injury there was a decided improvement, the patient being able to walk with the aid of crutches, and could stand alone, and the patellar reflexes were present. The patient felt the introduction of the catheter, although not in a normal manner. During the past two weeks he had had two nocturnal emissions. He knows when the rectum is full, but has no power over the sphincter muscles. There was a gradual fading away of the anesthetic zones. The atrophied muscles responded to negative closing with forty cells, and to strong faradic currents. On October 1, 1891, the man walked from his home to my office, a distance of about one mile, with but slight fatigue. There was a slight shuffling gait, and the toes "stuck to the floor." There was an entire return of sensation, save over the perineum and the inferior part of the scrotum. He felt perfectly the introduction of the catheter, and was able to control the bladder and urinate at will. The rectal sphincter had regained very much its tone, although it offered no great resistance to the finger, and he still resorted to enemata to evacuate the rectum. Sexual power was perfect.

The interesting clinical features of this case, and those upon which one may be almost positive in making a correct diagnosis of the nature and location of the lesions, seem to be as follows: Most noteworthy was the peculiar sensory loss, being in the anatomic distribution of the lesser sciatic, the pudic, inferior pudendal, and hemorrhoidal nerves, all arising from the lower sacral plexus. Secondly, the early involvement of the sphincters of the bladder and rectum, and the very late disappearance of their paralysis, arising, as they probably do, from the third, fourth, and fifth sacral segments, and being supplied by the fourth sacral nerve. Thirdly, the distribution of the muscles most affected and last to recover, namely, the anterior and posterior tibials, those of the calf and the intrinsic muscles of the feet, with the gluteus maximus, receiving their nerve-supply, with the exception of the gluteus maximus, almost entirely from branches of the great sciatic nerve; with a more moderate involvement, a lesser degree of atrophy, and a rapid improvement of the extensor quadriceps and the adductors of the thigh. Lastly, the absence of any external evidence of fracture or dislocation. All of the symptoms point to an intra-meningeal hemorrhage, compressing the leash of nerves that go to form the cauda equina, exciting inflammation in those nerves, with, as absorption took place, a release of the pressure and a rapid recovery.

AN ERYTHEMA OF LEPRA CONTAINING GIANT-CELL-LIKE STRUCTURES, SIMULATING SOMEWHAT THE GIANT-CELLS FOUND IN TUBERCULOSIS.

By DOUGLASS W. MONTGOMERY, M.D.,
Professor of Diseases of the Skin, Medical Department of the University of California; Consulting Physician for Diseases of the Skin and for Pathology, German Hospital.

On May 4, 1892, an American, thirty-three years of age, and unmarried, was brought to me by a fellow-practitioner. There was a reddish-brown, elevated, flattened, erythematous patch with fairly steep edges, about as large as a fifty-cent piece, over the left malar bone, which had appeared as a small pimple about two years before. It had existed for a long time as a small spot, and once had almost entirely disappeared. There was also a red, desquamating patch, about the size of a silver dollar, over the anterior surface of the lower third of the right radius. This patch the man said had appeared, in shape like a ringworm—a reddish-brown circle with a white center—about three months before. It had not the ringworm appearance when I saw it, because he had accidentally burnt it six weeks previously.

The muscles of the arm and those of the face were normal. There was no atrophy and no fibrillary twitching of the muscles. Both ulnar nerves could be felt distinct and hard as they passed over the internal condyles; they were somewhat more irritable than normal.

There was marked analgesia, but no appreciable anesthesia of the patches. I cut a good-sized piece out of the patch on the face, and he felt very little pain. He said he felt pain when he burnt the patch on the forearm six weeks before. Heat he sometimes appreciated, but cold not at all, on the spot on the face. Both heat and cold appeared to be about equally obtunded on the spot on the arm. The sense of pressure and that of locality seemed to be normal. There was no summation of pain, that peculiar symptom which is elicited by pricking the skin a great number of times, when the pain is not felt

as a lot of individual twinges, but as one pain, the sum of all the pricks. Eyesight, smell, taste and hearing were good. The patellar tendon-reflexes were normal, and there was no foot-clonus.

In 1883 he had gone to the Sandwich Islands, and remained one year. He then came back to the United States for a year and a half, after which he returned to the Islands for five years.

He had a weakness for liquor, and indulgence was accompanied by venereal abandonment. In this way he had frequently acquired venereal sores, but gave no further history of syphilis.

Although there could be no reasonable doubt that he was suffering from leprosy, yet, on account of the history, and also because some "bald patches" were found on the dorsum of the tongue, it was determined to try the effect of antisyphilitic medication. Both protiodid of mercury, a grain a day, and potassium iodid, sixty grains a day, were tried without effect.

The juice (smear-preparations), as well as sections of the piece cut from the patch on the face, were examined carefully for lepra-bacilli, but fruitlessly. This is exactly what was to have been expected, as lepra-bacilli are exceedingly difficult to demonstrate in such lesions. Dr. Armauer Hansen told me in a letter anent this case, that he himself had often searched vainly for them, although they had been demonstrated in such patches about one year ago (in 1891) by Dr. Looft, of Bergen, Norway.

But the chief interest in the sections lay in the presence of structures which were wonderfully like, yet in many respects unlike, giant-cells, for it has been asserted on good authority that giant-cells do not occur in the lesions of lepra. They were like giant-cells in that they consisted of a hyaline center surrounded by nuclei, but in many respects they differed from true giant-cells—they were too circular, and they were surrounded by one row, usually complete, of round nuclei, while the nuclei of Langhans' giant-cells are usually oval, and frequently heaped up more numerously at one end of the cell than at the other. They could hardly have been derived from the confluence of the epithelial cells lining the sweat-duct, for, as Hansen remarked, they frequently lay close up under the papillary layer of the skin. Dr. Hansen suggested, and I think the suggestion is undoubtedly correct, that they were capillary blood-vessels, the nuclei of which were undergoing proliferation.[1] These capillaries were not filled with blood, but with a hyaline, possibly gelatinous substance, which gave the appearance of the center of a giant-cell. Many other widely dilated capillaries were found, with nuclei projecting into the lumen, but without the hyaline filling. There was a considerable amount of round-celled inflammatory infiltration in the connective tissue.[2]

The further history of the case, with the treatment, is also interesting.

After the failure of the antisyphilitic treatment, the patient was given sodium salicylate, about twenty grains a day for six weeks, when salol was prescribed in doses running from forty to sixty grains a day, and continued for several weeks. Then the salol was reduced to thirty grains a day, and has been continued ever since, with intermissions of variable length, during which sodium salicylate was prescribed. Sixteen weeks after first coming under my notice a hard, tense cord, about as thick as ordinary twine, was found extending from the patch on the lower outer side of the right forearm upward and inward toward the middle of the bend of the elbow, which it almost reached. This cord, when twanged, gave a "funny-bone" sensation in the radial half of the dorsum of the right hand. There was one node on this cord situated about midway between the patch in the skin and the bend of the elbow. This cord afterward became much more nodular.[1]

Toward the end of September, 1893, a little over sixteen months after first seeing the patient, the upper part of the patch on the arm had a segment of a circle of brown pigment in it; the lower part of the patch was devoid of pigment, being whiter than the surrounding skin. I ran a needle through the skin without causing pain, and touch was hardly perceptible in the middle of the altered area. The lesion on the side of the face had vanished, and the appearance and sensations of the skin of its site were normal, but it grew redder than the rest of the face when the patient became heated.

The question of cutting down upon and extirpating the diseased nerve was now mooted, but decided against, as the manifestations on the face and in the ulnar nerves had shown that the affection was not localized.

At present the only evidence of active disease is this knotted nerve in the forearm and the slightly enlarged ulnar nerves, and these lesions do not seem to be progressive; it even seems to me that the nerve running up from the anesthetic patch is somewhat smaller than it used to be.

Can we say with any degree of positiveness that the

[1] Dilated bloodvessels with proliferating endothelium have frequently given rise to errors in diagnosis; for instance, Von Winiwarter, in speaking of plexiform angiomata, says that "the endothelial cells are stout, and the nuclei project decidedly into the lumen of the vessel. The individual endothelial cells are sometimes placed so closely together that they simulate cylinder-celled epithelium, and one may be in doubt whether the structure before one is a bloodvessel or a sweat-duct." Die chirurgischen Krankenheiten der Haut und des Zellgewebes. Von Dr. A. von Winiwarter. S. 529.

[2] Others have also been puzzled by these structures. For instance, Danielssen, in an article ("Zur Therapie der Lepra," Ergänzungsheft zum Archiv für Dermatologie und Syphilis, February, 1893, No. 1), says: "Dr. Abraham sent some slides to the laboratory of the Lungegaards Hospital, and both Armauer Hansen and Dr. Looft agreed that the supposed myeloplaques found in them were transverse sections of bloodvessels, with nuclear proliferation of the intima. Dr. Looft showed in similar slides, by serial sections, that these structures were transverse and oblique cuts through bloodvessels. Neither Hansen nor Looft, although they have examined thousands of slides, have ever been able to find myeloplaques in leprous tissue."

[1] It might be thought that this knotted cord was not a nerve but a lymphatic, because of its course upward and inward toward the median line, but a superficial nerve could easily take this course, as the cutaneous branch of the radial pierces the superficial fascia far over toward the median line in many cases. But it might be objected that this structure was grossly implicated, far too grossly, if a nerve, to give so few indications of interference with its functions. Herein lies one of the peculiarities of leprous neuritis, as a nerve attacked by leprosy may display very decided evidence of disease anatomically, and almost none functionally, as set forth in a case reported by Arning and Nonne, "Weiterer Beitrag zur Klinik und Anatomie der Neuritis leprosa," von Dr. Ed. Arning und Dr. M. Nonne, *Virchow's Archiv*, Band cxxxiv, S. 319.

disease is going on to a cure, and if so, what part had the therapeutics to do with the improvement? We can neither say that the disease is improving, nor that the medication is having any influence over it. It is not an uncommon thing for leprosy to attack a nerve, and then remain apparently quiescent for many years. It seems to me, however, from the comparatively small experience I have had in this direction that both salol and sodium salicylate have some beneficial effect on the course of leprosy. Leprosy, like tuberculosis, however, is subject to striking and unexpected improvement without the use of any drug whatever, or simply from the hopefulness of trying a treatment. We all know what an amount of misery many of these new treatments have caused, especially in tuberculosis. The lepers, being almost without exception poor, have escaped receiving so much attention. The contributors to this misery are in some instances culpable and in others innocent. When a medical man is not of a judicial and critical temperament he is likely to honestly attribute too much to the treatment, and the golden rewards he reaps from his rose-colored reports of cases come to him guilelessly. But there are others whose wings are not those of the angel of healing, but of an obscene bird, and whose reports to medical journals are for the distinct purpose of filling the office with patients.

A CASE OF "GOLD-CURE"; MENTAL DERANGEMENT WITH EXTREME PROSTRATION FOLLOWING.

By ALEXANDER McPHEDRAN, M.B.,
Associate Professor of Medicine, University of Toronto, Toronto, Canada.

Although much less has been heard of late of the "gold-cure," the business is still widely carried on. The following case shows how very deleterious the effects which result from the treatment may be.

Mr. L., a young Englishman, of good family, had drunk to excess for some years. He had on several occasions stopped drinking for periods varying from a few weeks to a year or more. During last winter he drank very heavily. He entered a "gold-cure" establishment in March, 1893. He had then been drinking less for several days, and chose to go to the institution for the treatment himself. He remained there for twenty-four days, when he was pronounced "cured" and discharged. He returned to his friends, but his manner had changed much and was peculiar. He took no alcoholic liquor, but drank fresh cider very freely. His health failed, he lost flesh, and his mental change became so marked that he required a man to look after him, especially at night. On May 26th he returned to the "gold-cure" establishment, but he became so difficult to manage that he was transferred to the Toronto General Hospital two days later by the manager of the establishment.

When I saw him there on May 28th, he presented the appearance of one recovering from delirium tremens. In a few days he again grew worse and required three men to care for him. He lost color and flesh rapidly; vomiting was troublesome for two days. By June 10th he was extremely prostrate; there was marked internal strabismus of the right eye, and the left eye could not be turned outward beyond the direct line of the body. The pupils were alternately active and inactive, so that at one moment they responded readily to light, and the next remained quite immobile, even under a strong light; and in a minute they would respond again. The fundus oculi was quite healthy. Sleep was much disturbed and the speech was drawling. Liquid food was taken fairly well. After a few days the man began to improve and by June 20th his eyes had become normal and his mind fairly clear. The hemoglobin was reduced to 37 per cent. (v. Fleischl). The stomach-contents, after a "trial-breakfast," showed only a trace of HCl. Lavage was practised daily for a few days, and later every second day. Nitro-hydrochloric acid, iron, and strychnin were given freely. The man improved rapidly and by August 1st the hemoglobin had increased to 70 per cent., and he had gained correspondingly in weight and color. He returned to his home in England and remained there until November, when he came back in excellent health. He has so far abstained from drinking, but time only will prove if this reform will be more enduring than several previous ones.

The symptoms he describes as occurring during the "cure" treatment are those of belladonna-poisoning. When he took any alcoholic stimulant he received a special "jab," which caused intense nausea and vomiting, due, no doubt, to apomorphin.

Another man who lately took the "cure" is at present in the hospital. There is no HCl in the gastric contents. He is weak and incapacitated for any occupation since he left the institute in November last. The symptoms produced by the treatment in his case were those of decided belladonna-poisoning, but there was less vomiting and he did not notice that any special "jab" was administered after taking stimulants.

A PELVIC ABSCESS OF UNUSUAL COURSE AND TERMINATION.

By W. E. SHOTWELL, M.D.,
of Denver, Colorado.

On the evening of January 11th I was called to attend a young married woman, twenty years of age, whom I found suffering from intense pain in the left inguinal region. Upon examination I found a tumor that extended from a point a short distance within the true pelvis to the superior spinous process of the ilium on the left, and nearly to the umbilicus and median line of the abdomen on the right side. It was closely adherent to the left and posterior portion of the uterus. I could not elicit fluctuation. The tumor was very tense, was movable, and was sensitive to touch. The left tube and ovary were incorporated in the mass.

While the possibility of its being a pelvic abscess occurred to me, I could obtain no history of pus-formation. The patient had been and was in good health and flesh. She had had exacerbations of pain in this side at long intervals since childhood; otherwise she had suffered no inconvenience from the tumor and was not aware she had one. There was no history of pus-discharge through the utero-vaginal track. Menstruation was regular and normal; she denied ever having had an abortion. As she had just had her menses, she attributed her present trouble to taking "cold." Fearing the

grave nature of the tumor, I endeavored to impress upon the woman the constant danger to which she was exposed and urged an immediate operation. As she was soon relieved of suffering and felt "all right again," the proposition was rejected, at least for the present. On February 9th she came to my office to consult me on another matter, and before leaving I questioned her about the tumor. She said it gave her no trouble and she felt perfectly well on that side.

On February 22d she came to my office suffering, as she thought, from "piles." Upon examination I found an inflammatory mass nearly surrounding the lower part of the rectum and extending well into the lower portion of the left ischio-rectal fossa. It was very sensitive to touch and gave her a great deal of pain. She was feverish and very nervous. There was a line of tenderness along the rectum leading toward the tumor. The tumor itself gave her no trouble and presented the same general characteristics as on the former examination, excepting an absence of all pain and tenderness. While the symptoms were in the main those of a pending ischio-rectal abscess, I was suspicious of the line of tenderness along the rectum. On the evening of February 23d, as there was considerable tumefaction of the parts, I made a deep incision at the most prominent point, about one inch in length and a half-inch posteriorly, and to the left of the anus. I obtained no pus at the time, but within a few hours, she told me, it began to discharge through the incision, and for two days the pus "poured" out.

On the 27th of February the discharge ceased. The pain, fever, and nervousness were gone, and the patient felt perfectly well. She said to me, "Doctor, my bowels feel so flat, and I cannot find the tumor." It was true that there was not a trace of the tumor left. Such a favorable termination of so large a pelvic abscess must be very rare.

AN UNUSUAL ACCIDENT AFTER CELIOTOMY.

By E. H. KING, M.D.,
of Muscatine, Iowa.

In a celiotomy performed during the past year, the abdominal stitches—silkworm-gut—were removed on the eighth day, primary adhesion of the wound having occurred without suppuration. There had been persistent ether-nausea from the time of the operation. No opiates had been used. The bowels had been freely opened on the third day by enemata and salines. There was no distention of the abdomen and but slightly elevated temperature.

On the evening of the ninth day violent nausea, retching, and straining occurred, when two-thirds of the extent—about three inches—of the wound were torn open, allowing a part of the colon and omentum and a mass of small intestines to escape. I found the patient in extreme mental and physical shock. The protruding viscera were covered and protected by a towel wrung out of hot water until an assistant could be obtained, when they were returned within the abdomen and the peritoneum secured by fine catgut, and the parietal tissues with silkworm-gut sutures, all without anesthesia. Drainage was provided for by a small roll of iodoform-gauze. At the conclusion of the operation the patient's pulse was too weak and rapid to be counted; she was in great pain, and very restless. Free use of morphin, atropin, and strychnin was made, and enemata of hot beef-juice and whiskey were given. This was kept up at regular intervals for forty-eight hours, without any perceptible effect save to relieve pain, nausea, and restlessness; but after this the pulse began to increase in volume and decrease in frequency. The peritoneum united primarily and the parietal tissues secondarily, with but slight and superficial suppuration. The patient made a slow but good recovery. There is at present a small linear cicatrix, with no tendency to hernia.

It occurs to me, in view of the possibility of such an accident, that in clean celiotomies—that is, in operations in which the wound can be completely closed without the necessity of drainage—it would be a safeguard to fasten the omentum to the abdomen behind the incision, securing it by a stitch at the lower end of the wound, where by adhesion it would be interposed between the viscera and the weakened part of the abdominal wall, thereby reinforcing and strengthening it.

HOSPITAL NOTE.

TWO ATTACKS OF TYPHOID FEVER IN THE SAME PERSON.

German Hospital, Philadelphia.

Service of L. WOLFF, M.D.

[Reported by Alfred Hand, M.D., and Arthur J. Patek M.D., Resident Physicians.]

Second attacks of typhoid fever in the same individual are so rare as to make the following record of a well-authenticated case of practical importance:

M. Y., a female, aged nineteen years, was admitted to the hospital March 29, 1893. She had been feeling unwell for several weeks, with headache and moderate diarrhea, and had been confined to bed for six days before admission. The tongue was dry and coated, the pupils were dilated, the spleen was enlarged; there were a few rose-colored spots, and gurgling in the right iliac fossa was present. The pulse was weak, but improved in quality under treatment, consisting of systematic cool bathing. The temperature was taken every three hours and a bath administered, preceded and followed by a little wine, whenever the thermometer registered 102° F. The disease ran a mild course, and the patient left the hospital five and a half weeks after admission in good health.

On September 21, 1893, the patient was readmitted, suffering from a second attack of well-marked typhoid fever, being apparently at the ninth day of her illness. Her condition was as follows: Great depression, both mental and physical; severe headache, dilated pupils, constipation, dry and coated tongue, enlarged spleen, abdomen not distended, pain and gurgling in the right iliac fossa, and typical typhoid spots on the abdomen. The fastigium was of about one week's duration, and no complications arose during convalescence. The bath-treatment was adhered to, as in the first attack, and thirty-eight baths were administered. The patient was discharged four weeks after admission.

The striking similarity between the attacks is worthy of note. The number of baths was nearly equal—forty-three in the first and thirty-eight in the second attack. The temperature fell to normal on the same day on each occasion, as is shown by the appended record of the morning and evening temperatures of the attacks:

	First attack.	Second attack.
Evening temperature . . .	102.8° F.	103.4° F.
Morning " . . .	102.0	104.0

MEDICAL PROGRESS.

Successful Pyloroplasty.—SHEPHERD (*Medical Record*, No. 1213, p. 135) has reported the case of a farmer, twenty-nine years old, who during a period of fifteen years had from time to time suffered with gastric derangment, recurring attacks of gastritis lasting from two weeks to two months. In the intervals there were pain and heaviness after eating and gaseous eructation. The attack in which the patient came under observation had been in progress for three months, and severe vomiting had set in. The vomitus consisted of greenish materials and mucus and frequently looked like coffee-grounds. Pain usually came on two or three hours after eating. There had been a loss of fifty-five pounds in weight. The man was able to swallow only liquids, and even these caused distress until ejected by vomiting. On palpation the epigastric region was found to be excessively tender. The entire abdomen appeared to be occupied by a distended and dilated stomach. No tumor could, however, be detected. Examination of some of the vomited matter disclosed the presence of free acid and sarcinæ. A diagnosis of dilatation of the stomach dependent upon pyloric stenosis, probably not malignant, was made. Lavage was practised for a time with considerable relief. The case was deemed one for operation and the necessary preparations were accordingly made. For three days the patient's stomach was washed out daily with a warm solution of boric acid. At the end of this time an incision four inches long was made in the median line above the umbilicus. The pylorus was brought out of the wound and found to be surrounded by a dense mass of hard tissue about the size of a small egg, the anterior aspect of which was marked by a stellate scar. An incision was made into the stomach near the pylorus and a large mass was seen below the pyloric opening, and this appeared excavated, as though it had been the base of an old ulcer; it bled freely on manipulation. The pylorus barely admitted the tip of the little finger and only with some difficulty a small grooved director. The incision in the stomach was now extended through the constricted pylorus and into healthy duodenal tissue beyond for a distance of two and a half inches. The edges of the incision were now seized at about the middle with tenacula and retracted, thus rendering the wound a transverse one. In this way healthy stomach-tissue was approximated to healthy duodenum, the angles of the wound being formed by the old cicatricial tissue in front of the pylorus,which was now replaced by healthy tissue. To bring the angles of the wound together it was necessary to remove a V-shaped piece of the cicatricial tissue (which cut like cartilage) and to enlarge the original wound in the duodenum and stomach. Two rows of sutures were introduced, commencing at each angle, the central portion being sutured last. The abdominal wound was closed by a row of deep and one of superficial sutures. The patient was nourished by the rectum for three days and afterward carefully by the mouth. Recovery was uninterrupted. The man was dismissed at the end of four weeks. Five months after the operation he had gained sixty pounds in weight and stated that he had never felt better, having no trouble with his digestion.

Successful Treatment of Tuberculous Meningitis by Trephining and Drainage of the Sub-arachnoid Space.—ORD and WATERHOUSE (*Lancet*, No. 3680, p. 597) have reported the case of a girl, five years old, that had suffered with pain in the head for a month, with occasional vomiting, impaired appetite, constipation, and fretfulness. The child was dull and heavy in appearance and was very restless, from time to time uttering a shrill scream. She lay with her head bent forward and her legs drawn up. The temperature was slightly elevated, the pulse regular and accelerated, but weak, the respiration normal. No lesion of the thoracic or abdominal viscera could be detected. There was marked *tache cérébrale*. The knee-jerks were normal. There was commencing optic neuritis in both eyes, more marked in the left. The pain and the optic neuritis increased in intensity, the pulse became irregular, the child became lethargic and apathetic, and from time to time uttered a hydrocephalic cry. The pupils, at first contracted, subsequently became dilated, but strabismus or ptosis was not observed. The membranæ tympani were healthy. It was agreed that the condition was one of tuberculous meningitis, and in view of impending coma as a result of intra-cerebral pressure it was decided to open the sub-arachnoid space and afford drainage for a few days. A trephine-opening was made in the skull on the left side, between the mastoid process and the external occipital crest. The dura bulged into the opening, but no pulsation was visible. The dura and arachnoid were incised, and some thirty drops of a slightly greenish fluid escaped. The cerebellum then bulged into the opening. A silver probe, bent at a right angle, was then introduced between the cerebellum and the arachnoid, and directed inward

toward the falx cerebelli. As soon as the latter was felt the probe was rotated, so that the end projected toward the sub-arachnoid space, between the cerebellum and the medulla. Some drams of serous fluid at once escaped. A drainage-tube was then passed along the probe and left in position. It was found that the fluid passed very slowly along it. The dura was then sutured and the fragmented disc of removed bone replaced, room being left for the drainage-tube. The flap was adjusted with horsehair sutures and the wound was covered with cyanid dressings. The child bore the operation well. The wound discharged rather freely, and the optic neuritis gradually receded. On the eleventh day the wound appeared to be breaking down, and the stitches were removed, presenting gelatinous-looking granulations, in which, however, no specific elements were found. Neither was it possible to find tubercles or hemorrhages in the choroid. The drainage-tube was removed on the eighteenth day, and the child was well at the end of a month. Although, in view of the fortunate result, it is admitted that the evidence is not conclusive, it is nevertheless maintained that the case presented the classic picture of tuberculous meningitis, a diagnosis which was concurred in by all of the eight medical men who saw it before operation.

Paralysis of the Diaphragm.—Suckling (*Practitioner*, No. 309, p. 177) has reported the case of an adult male who complained of numbness in the feet and legs, and in a lesser degree in the upper extremities also. He was weak, and walked with difficulty. He spoke in a whisper, so that the possibility of hysteria was considered. The knee-jerk, however, was completely lost on both sides, and there was slight anesthesia in both lower extremities. The cough also was aphonic. The leg-thrust was feeble, but there was no absolute paralysis anywhere, and the power of dorsal extension of the feet still existed. There was no interference with the bladder or rectum. The grasp of the hands was weak; there was slight numbness in the arms, but no anesthesia. There were no ocular symptoms, and the patient made no complaint referable to the throat. On further inquiry it was learned that there had been a slight sore-throat two weeks previously, and on examination the pharynx was found somewhat anesthetic; but there had been no definite sign pointing to diphtheria and no paralysis of the soft palate or of the ocular muscles. On applying the hand in the hypochondrium the diaphragm was found to be weak upon both sides, only a slight degree of pressure being appreciable during inspiration. There was slight over-action of the lower intercostal muscles, and the respiratory sounds at the base of each lung were feeble. The patient himself was much alarmed about his condition, had experienced a sense of difficulty in breathing, and feared that he was going to die. The conclusion was reached that the case was one of peripheral neuritis consecutive to diphtheria, and that the aphonia was due to weakness of the diaphragm. Two days after this examination a thin, brownish membrane was discovered upon the soft palate, but the condition was otherwise unchanged. The patient was propped up in bed, to facilitate the action of the diaphragm, blistering fluid was applied over the course of the phrenic nerve on each side of the neck, and iron and strychnin were administered, together with alcohol and plenty of nourishing food, while inhalations of oxygen gas were given at frequent intervals. The difficulty of breathing, however, gradually increased and the patient died in the course of a few days, of asphyxia.

Virulent Staphylococci in a Latent Circumscribed Osteomyelitic Process after Many Years.—Schnitzler (*Centralblatt f. Bakteriologie u. Parasitenk.*, B. xv, Nos. 8, 9, p. 270) has reported the case of a man forty-two years old, without hereditary predisposition, who suffered a contusion of the right lower extremity at the age of seven years, followed in the course of two days by severe pain in the right tibia, together with marked swelling, in association with chills. At the end of six weeks, the patient meanwhile being in bed, the swelling ruptured spontaneously, with the discharge of pus, and subsequently of several pieces of bone. The suppuration gradually subsided, and in the course of half a year healing had taken place—*i. e.*, the fistula had closed and the symptoms had disappeared. The man remained in good health for thirty-four years, when severe pains in the right tibia suddenly appeared, together with febrile symptoms and a variable tumefaction in the right tibial region. For a time the phenomena were intermittent, but subsequently they became continuous. On examination the right tibia was found to be elongated and thickened in its lower half. The corresponding soft parts were edematous and the overlying skin was reddened. The lower third of the tibia was extremely sensitive to pressure. An operation was determined upon, and an incision was made through the cicatrix of the previous sinus. The periosteum and the bone were thickened, and the adjacent tissues edematous. There was nowhere any indication of a fistulous tract. The sclerosed bone was opened with the aid of a mallet, and at a depth of almost an inch a small cavity was found, perhaps as large as a walnut, everywhere surrounded by sclerotic bone, and containing granulations, bone-dust, and a small quantity of pus. The cavity was thoroughly scraped and curetted, and an iodoform-dressing applied. The discharge from the wound gradually diminished in amount, and at the end of four weeks the patient was dismissed, cured. On bacterioscopic examination only the staphylococcus aureus was found in the contents of the cavity, and this proved virulent to rabbits, in whose lesions the same organism was again found.

Fatal Secondary Hemorrhage following Removal of Faucial and Pharyngeal Tonsils.—Barkan (*Occidental Medical Times*, vol. viii, No. 3, p. 118) has reported the case of a strumous boy, six years old, who presented considerable enlargement of the faucial and pharyngeal tonsils. The child was a constant mouth-breather and experienced great respiratory difficulty during sleep; the voice was altered, but hearing was not impaired. The mother of the child likewise had enlarged tonsils. The right and then the left tonsil were successively removed with the guillotine. There was a more profuse hemorrhage than usual, though not enough to interfere with the immediate removal of a large pharyngeal tonsil by means of a Gottstein curet. The bleeding was copious, but soon subsided. A half-hour after the operation the child was sent home with his father, and instructions were given to

keep him quiet and give him iced-milk and liquids. Several hours later, after nausea and restlessness, the child vomited a large amount of clotted blood. On examination of the throat no bleeding-point could be detected; neither was there hemorrhage from the nasopharynx. Three hours later, after a period of excitement and restlessness, the boy cried and coughed a good deal, bringing on an attack of vomiting, large clots of bright-red blood being ejected, and clear blood flowing from the mouth and nose at the same time. The child now appeared moribund. Several injections of whiskey were made, a large enema of warm salt-water was administered, bottles of hot water were applied, and milk and whiskey were given. It was now determined to etherize the boy and cauterize the exposed surfaces with a thermo-cautery, and this was accordingly done. After the operation and the child had recovered, it was noticed that blood was trickling from the nose. An attempt was made to examine the throat, to determine the source of hemorrhage, but the child resisted. During the struggles, a sudden gush of blood took place, accompanied by a peculiar sound, as if blood had found its way into the trachea. The child gave a gasp and ceased breathing, and all attempts at revival proved fruitless.

Tuberculosis of the Bladder.—Hunter McGuire (*Virginia Medical Monthly*, vol. xx, No. 12, p. 1073) has reported the case of a man, twenty-two years old, with a strong tuberculous family history, who for two years had suffered with occasional symptoms of vesical disorder, although there had never been an attack of gonorrhea or syphilis. Three months before coming under observation, during the act of micturition, the man was suddenly seized with pain at the end of the penis, and the last few drops of urine passed were admixed with blood. Thereafter there was increased frequency of micturition, which became a source of great distress. The symptoms were intermittent, both the paroxysm and the interval being of variable duration. The urine was odorless, contained some pus, and was slightly acid. On examination, the right epididymis was found to be swollen, and an incision evacuated tuberculous-looking pus. Examination of the prostate gland through the rectum disclosed the presence of a number of hard, shot-like bodies. For the purpose of placing the bladder at rest, a suprapubic incision was made and a drainage-tube introduced into this viscus. The effect for good was almost immediate. The urine was drained off as fast as it was poured into the bladder, and the tenesmus ceased. In four or five months the man was well, and so continued for four years after the operation. Four other cases of like nature were treated similarly. Two terminated fatally soon after the operation; in these the tuberculous changes in the bladder were extreme; the bladder was contracted and the mucous membrane almost entirely destroyed. One died from exhaustion following the operation; the other a few weeks afterward from general tuberculosis. In both cases the suffering was lessened by the interference. In the other cases recovery ensued; in one after drainage for ten or twelve months; in the other the artificial opening was maintained.

A Diagnostic Symptom of Mastoid Disease.—Okunjew (*Vratch*, Nos. 48, 49) and Gabritschewski (*Vratch*, 1893, No. 52) point out that in case of mastoid disease, auscultation by means of a stethoscope applied over the respective mastoid process discloses the fact that there is impaired transmission through the bones of the head of the vibrations of a tuning-fork placed upon the vertex. —*Centralbl. f. Chirurgie*, 1894, No. 9, p. 200.

THERAPEUTIC NOTES.

Extract of Bone-marrow in the Treatment of Anemia.—Mann (*Lancet*, No. 3680, p. 599), viewing the red matter of bone as the chief agent in promoting the development of red blood-corpuscles, concluded that an extract of this substance, introduced into the human organism while in an anemic state, might act as a stimulant to the formative process, and increase the rate of production of the red corpuscles. As the tissue-forming power is more active in young than in older animals, the bones of the former are to be preferred as a source of the extract. To prepare this the heads of the long bones obtained from recently killed calves, with other portions of bone that contain red marrow, are broken into small pieces and digested in glycerin, with frequent agitation. The extraction is complete after the lapse of several days, when the extract is filtered off and is ready for use. It is red or reddish-brown in color and devoid of unpleasant taste or odor. It may be given in teaspoonful doses once or twice daily. In a series of cases of anemia of varying kind and origin in which the extract was employed encouraging results were obtained.

For the Visceral Complications of Acute Rheumatism. Jaccoud (*Wiener medizin. Presse*, 1894, No. 9, p. 339) recommends the administration of the tartrate of antimony and potassium hourly, in doses of one-twentieth grain, in mucilaginous solution. Care must be observed not to administer a narcotic simultaneously. The treatment is followed by a rapid decline of temperature, the pains subside, and even large effusions grow less. As a rule, diarrhea and vomiting result, but these should not be viewed as contra-indications, unless aggravated. The patient should be under constant observation during the continuance of the treatment.

Guaiacol in Diabetes.—Clemens (*Allg. med. Centr. Ztg.*, No. 12; *Wien. med. Pr.*, No. 10) speaks favorably of the action of guaiacol in the treatment of diabetes. The dose employed was from six to ten drops, three times a day, in a tablespoonful of milk or cod-liver oil. It was found that a distinct influence was exerted upon both the elimination of sugar and the excretion of urine. The remedy was well borne, and its use was followed by improvement in the general condition.

For Influenza.—

℞.—α-Naphthol. . . . . ℥ijss.
Magnesii calc. . . . . ℥j.
Phenacetin. . . . . ℥jss.—M.
Ft. chart. no. xx.
S.—One from four to six times daily.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, APRIL 14, 1894.

THE NEUROSES.

WE are sometimes asked: What is a neurosis? Is a nervous symptom, or only a nervous disease, a neurosis? Is nausea a neurosis? Is flatulence of nervous origin a neurosis? Is epilepsy a neurosis? To all these questions, and to many others like them, we frankly reply that we do not know what is the essential characteristic of a "neurosis"; but we strongly suspect that its essence is a metaphysical quibble which has, or ought to have, no place in the science of the present day. To this a protest may arise; in fact we think that we can hear the voice of the first-year student proclaiming that a neurosis is a "functional" nervous disease. So it may be; but what is a *functional* nervous disease? We do not know, unless it be a disease that once belonged to a class frequently found in old text-books, but now "gone glimmering through the mists of things that were"—a class of diseases without a pathology, not because they had none, but because men had not yet discovered it.

Opening an old text-book (a noble one, too) of fifteen years ago, we find that the list of functional nervous diseases included epilepsy (comprising focal, traumatic, and syphilitic epilepsy), chorea, tetanus, hydrophobia, and mania after acute disease. Will anyone venture to say now that these are mere neuroses—that they are functional as distinct from organic or infectious? If not, why not?

Opening a very recent text-book (and a good one, too) we find under the head of functional nervous disease some striking and sesquipedalian distinctions. We have now the "degenerative neuroses" of which not only epilepsy but also paramyoclonus, paramyotonia, and akinesia algera are frightful examples. Next we have the "acquired neuroses," as chorea, tetanus and exophthalmic goiter. When we look critically into these refinements we are amazed. *Mirabile dictu.* We ask ourselves: Is not epilepsy acquired, as well as chorea? Does not chorea sometimes promote degeneration, as well as epilepsy? Is not tetanus due to a microbe, and chorea, probably, to some infection? Whither has the old metaphysics gone? Is there no longer any difference between a function and an organ? If, now, tetanus is due to a microbe, how is it merely functional? If epilepsy is degenerative, or produces degeneration, in what does the degeneration consist? Is it conceivable that the degeneration of epilepsy is not in the organic basis? In fact we know better in part, thanks to recent investigations into the finer histologic changes that occur in the sacred disease. It is probably as truly an organic disease as is cirrhosis of the liver. But when we come to the later degenerative neuroses, and find the class reserved for paralysis agitans, and recall how the accomplished author of these distinctions has himself laboriously endeavored to prove that this disease has a pathology that can be demonstrated under the microscope, then, indeed, do we realize that the metaphysical life has quite gone out of the term *neurosis.*

From the psychologic standpoint, too, the term must look to itself; and this applies of course to its kindred term—psychosis. Hysteria is the great example of this metaphysical conception, *i.e.*, a disease of the "mind" without organic basis, a truly functional will-o'-the-wisp; hence "protean," unintelligible, arbitrary, and generally misunderstood. But the critical studies of the modern school have proved that hysteria is a disease of fixed laws; that it accords with all things in Nature, *i. e.*, it is an entity with a certain environment, and that it is not subject to moods and changes without cause. Granted that its pathology is still part of the unsolved problem of the pathology of "mind," who will say in the modern light that it has no substantial basis?

But the worst is yet to come. We have now fallen upon the evil days of the "traumatic

neuroses." We are asked to believe that trauma (the worse the better, so to say) by shocking, banging, wrenching, twisting, dislocating, and harrying generally the delicate nerve-tissue and its enveloping cases produces a neurosis, a functional nervous disease, making a man good for nothing but to receive damages in court.

KRAFFT-EBING has given us the "psycho-neuroses." These are the primary curable insanities and their secondary incurable states. Here is an obvious incongruity. These secondary states, which include terminal dementia, are now known to present evidences of gross disease. An old dement's brain seldom comes to the dissecting-table without showing unmistakable evidence of organic changes. Who will say that with our rapidly improving technique we shall not some day be able to read the story of the psycho-neuroses in the various layers of the brain-cortex?

To conclude, we do not believe that we have such diseases as neuroses, and we do not believe that many others believe that we have them. And yet we and others continue to use the terms "neurosis" and "psychosis" in spite of our unbelief. There must be some reason for this. It may be found in the fact that these terms are convenient, and that this convenience has grown out of the very change in their significance which has here been implied. Very few writers and thinkers use the terms now to indicate what they believe to be "functional" disorders, but rather in a vague way to indicate generalized affections, all-pervading but obscure disease-entities, in contrast with localized, recognizable ones. So long as pathology has her mysteries to explore, so long will some such term, or group of terms, be admissible, even necessary. And if the medical mind will hold them at their proper value, as mere tickets or labels for packages not yet opened, we shall probably experience no greater evil from their use than an occasional neurotic or psycho-neurotic qualm of conscience (a sort of hyperesthetic aversion) when we write them down.

UNCONDITIONAL SURRENDER?

THE MEDICAL NEWS, in advocating rational revision of the Code of Ethics of the American Medical Association, proposed the adoption of a simple set of business-like rules stating in plain and terse language that this was enjoined and the other prohibited. In the rules tentatively suggested by us every injunction and every prohibition of the present Code was preserved, the phraseology being made clearer and shorter.

Quite different is the report of the majority of the Committee on Revision of the Code, which appears in the *Journal of the American Medical Association* for April 7, 1894. That report does not in the least simplify or improve the phraseology of the present Code, while it does tend to break down some of the most important safeguards against unprofessional and dishonest conduct. It has all the faults of the letter of the present Code, and none of the merits of the spirit of that document. It is an emasculated abortion, and should be promptly and indignantly cast out. We cannot now give space to all its inconsistencies and absurdities, but we will cite three examples that should suffice to condemn it utterly.

Article I of Chapter II is entitled "Duties for the Support of Professional Character." In the Code as it stands, this is an admirable chapter. The Committee has, it is true, made few changes in wording, but these few are skilfully contrived to effect tremendous alterations in meaning.

Thus, Sec. 2 prohibits advertising, open or secret. The Committee has let the prohibition stand as written—and then nullifies it by adding:

> "It shall not be considered as a violation of the spirit of this section, however, for physicians engaged in the work of medical education, either singly or associated in colleges, *or for physicians practising in hospitals, whether private or public, general or special*, to announce the fact or allow it to be announced to the profession *in the advertising pages* of strictly medical journals, or for physicians devoting special attention to one of the recognized special departments of medical practise to note the fact on *their signs or private cards*.

The words we have italicized are an absolute surrender to the "professional" (otherwise delicate and proper) advertiser.

In Sect. 3 of the same article, as reported by the Committee, an attempt is made, by the omission of certain essential words, at once to legalize the patenting of instruments by medical men, and greatly weaken the condemnation of nostrums.

We have already expressed our views upon the subject of the patenting of instruments. That subject, however, important as it is, is secondary to the nostrum-question; and we therefore call special attention to the bearing of the words omitted by the Committee in the latter relation. The Code

now says that it is "derogatory to professional character . . . for a physician to hold a patent for *any surgical instrument or medicine or to dispense* a secret nostrum, *whether it be the composition of himself or of others*. . . . It is also reprehensible for physicians to give certificates attesting the efficacy of *patent or* secret medicines, *or in any way to promote the use of them.*"

By omitting the words we have italicized, the Committee surrenders to the nostrum-makers. It removes the stigma from *dispensing* nostrums, or *promoting the use of* nostrums, or giving certificates to *patent* medicines. It substitutes a provision that physicians shall not *patent* nostrums. But nostrums are never "patented," because patenting involves publicity and publicity "gives away" the fraud. Nostrums are "trade-marked." Under the elaborately misleading phraseology of the Committee any scamp of an M.D. can enter into an offensive and defensive alliance with nostrum-makers, and not only go unpunished (as at present such fellows unfortunately do go, through our cowardice), but claim that the Code makes his conduct respectable. The Committee turns a strong and praiseworthy section of the Code into a prohibition that prohibits nothing; making it a stench and an offence in the nostrils of honest men.

It is possible, and, indeed, from the high personal character of the members of the Committee quite probable, that the majority did not realize the full effect of their tampering with this section. But that would furnish even a stronger reason, if stronger reason be possible, for the rejection of their work.

In Article II, "Of Consultations," Sec. 2, the Committee says: "No intelligent practitioner who has a license to practise from some medical board of known and acknowledged legal authority, and who is in good moral and professional standing in the place in which he resides, should be refused consultation when it is requested by the patient."

This is an unconditional surrender to the quacks and "pathists." It needs no comment.

The Committee was appointed to *revise* the Code, not to *destroy* it. The work of the Committee, however, has been destructive. If the report of the majority should be accepted, the formally promulgated ethics of the profession of medicine will be far below the standard that right-thinking and pure-minded men will set up for themselves. Honorable men will then study the Code to see what is permitted, in order that they may not do it. There is but one course open to those who wish to preserve the good repute and honor of the American Medical Association, and that is to vote down the report of the majority of the Committee *in toto*.

EDITORIAL COMMENTS.

Useless and Expensive Adulterations of Food.—We recently watched the unloading of tons of marble chisellings (from a monument-yard) into the bins of a spice-manufactory. It is doubtful if a sample of pure ground pepper or other spice can be obtained in the market. Possibly marble-dust is not particularly injurious to the human economy, perhaps the adulteration may even lessen the noxiousness of the pepper, and perhaps the gravestone-cutter is not increasing his business by selling his waste-stone to the spice-grinder. But it seems at least a stupid waste of money on the part of the community and in the interests of supposed cheapness, and one wonders why it would not be economy to make the holes in the pepper-boxes smaller.

Somewhat the same lesson meets us in reference to oleomargarin. It is estimated that about fifty million pounds of this food-product are annually manufactured in the United States. In many ways as good a food as butter in some respects, and for certain purposes superior to butter, we waste several hundred thousand dollars in taxes in the attempt to restrict its use in the interest of the butter-makers, instead of seeking to rightly utilize it as a proper food.

"Pure Refined Lard" is a trade-mark term well understood to mean the exact reverse of what the words would mean to an unregenerate philologist—*i. e.*, it means that it is not lard, not pure, and not refined—in fact, a mixture of lard-stearin and cotton-seed oil. It is probable that as a cooking-fat cotton-seed oil is just as good in many ways and surely cheaper than hog-fat. As a salad-dressing cotton-seed oil is a nutritious food, perhaps not inferior to olive-oil, and again certainly very much cheaper.

Glucose, again, when properly made is a good food, but millions of gallons of it are annually sold as syrups and honey, the public paying therefor enormous profits to the conscienceless manufacturers for their skill in hoodwinking.

So with almost every prepared food that is sold. "Grandmotherly government" is laughed at by great and wise philosophers, but while "statesmen" wrangle over partisan or peanut politics, the people are cheated out of their money because there is no public analyst or legislative safeguard against food-adulterations that are sometimes dangerous, but at least useless and always expensive.

The Medical Profession and the Pension Bureau.—Our excellent contemporary, *The Philadelphia Polyclinic*, calls attention to the work of physicians and the fitness of those appointed as examiners by the Bureau of Pensions. It is upon the findings and recommendations of the examiners that are annually spent something like one hundred and fifty millions of dollars. There can be no doubt that a large number of the appointments have

been gained through political influence, and that these appointees have often been shamelessly unfit for the position. It may be that the greater number of examiners realize that they have a duty to the Government and to the community as well as to the pensioners, but certainly not a small proportion try to err on the side of "liberality" rather than on the side of justice to the taxpayer. We have knowledge of a case in which an able-bodied man was urged by an examiner to apply for a pension, and assured that it would be easy to secure it, on the ground of a certain scar that was in no way due to military service, and that did not influence or interfere with the most perfect health. Such cases, it was said, were every day favorably passed upon by himself and his colleagues.

It seems strange that these four thousand appointments to positions of such great trust and power should be made without a word of advice either asked of or given by the medical profession. A man without medical experience, a failure as a practising physician, or a student who has just received his diploma, perhaps at a two-term commercial "medical college," importunes his Congressman or Senator and secures an appointment demanding the best medical and surgical training, the soundest judgment, and the ripest experience. It is a gross injustice to the taxpayer and to the Government, as well as to the really deserving soldier disabled in defending his country. A rule should be adopted requiring the indorsement of an applicant by a medical society of good standing.

Convalescent-Homes are most proper objects of interest to those charitably inclined, and there are entirely too few of them. There is often a long period of time after the graver dangers of illness are passed before the organism is fitted to again undergo the strains of work, physical or mental, of the battle of life. During this time the hospital is not the best place for the patient, and a change to different and less painful surroundings well accords with the growth of health and of hope. We think that it should be a systematic plan of treatment, this of transference of convalescent patients from the city hospital to the quiet, the purer air, and the brighter circumstances of convalescent-homes located in the country. A large portion of the money now being expended, and often wasted, upon the recklessly morbid overgrowth of city hospitals should be deflected to this excellent and proper extension and perfection of hospital-work. The stay in the city hospital, as at present, from the beginning to the end of sickness, is often bad for the patient and for the hospital. Every consideration—financial, medical, social—argues against it, and for the establishment of country convalescent-homes. At Summit, N. J., there is a convalescent-home that during the past few years has cared for thousands of convalescents sent thither by the hospitals and charitable societies of New York city. Donations to this perfect charity have been so poor during the past winter that it has not been able to keep open, and there is great danger that it may not be able to open this summer. Full information in regard to the home will be given at the New York office, room 505, United Charities Building. Donations may be sent to Mrs. George M. Grant, Treasurer, Summit, N. J.

Simultaneous Intra-uterine and Extra-uterine Fetation.—A case closely parallel to that detailed by Dr. Hirst in a clinical lecture published in The News of March 31, p. 346, is abstracted by the *Lancet* from the *Revista Médica de Bogotá*. The patient was a young woman who had already borne three children. She complained of pain, weight, and discomfort referred to the right iliac region, and was supposed by the physicians who saw her to be suffering from salpingitis or an incipient uterine neoplasm. After a time it became evident that she was pregnant, and at the seventh month she was prematurely delivered of an infant that lived a month. The pain in the right iliac region, however, persisted, and on examination it was discovered that, although the uterine os had closed, there were unmistakable signs of the presence of a second living fetus, which it was hoped might be retained until term. The woman was for a time lost to observation, and when again seen was evidently dying from peritonitis. Upon post-mortem examination a putrid fetus of about seven months was found in the peritoneal cavity, the uterus being quite normal.

Difference of Presumptions as to Drunkenness and Insanity.—Drunkenness may so becloud the mind as to make it incapable of doing an intelligent act, but the disability ends when the exciting cause is removed. In this it differs, according to a recent decision of the Surrogate's Court of New York County, in the Johnson will case, from insanity, which, once shown to exist, is presumed to continue until there is proof that intelligence and reason have asserted themselves. A drunkard may execute a valid instrument within a day, or even less, from a time when it would be conceded that he was incapable. In each case the question to be determined is whether at the time he was sober, or, if not, whether his mind was so affected by drink that he was not sufficiently master of himself to give expression to his real wishes. A clear mind is needed to conduct a complicated business transaction. A mind partially clouded by drink may execute a valid will.

SELECTIONS.

THE PERILS OF FOOT-BALL.

We printed in our first issue of this year a list of the accidents that had come under our knowledge as having occurred at foot-ball during the last quarter of the year which has just gone. The list, confessedly an imperfect one, though to what extent we do not know, comprised: 1 concussion of the brain, 2 concussions of the spine, 1 fracture of the thigh, 16 fractures of the leg, and 5 fractures of the arm, and in 5 cases death ensued. This roll of disaster, which we recognized might be comparatively insignificant when the enormous number of players was taken into account, we now supplement by a list of the accidents that have so far occurred in the foot-ball field (and come to our knowledge) during 1894: 1 concussion of the brain, 15 fractures of the leg, 6 fractures of the collar-bone, 1 fracture of the arm, 1 fracture of the shoulder-blade, 5 dislocated shoulders, 1 dislocated knee, and 5 undescribed cases necessitating hospital treatment, and 5 deaths have been reported. The factors

which are chiefly at work in rendering foot-ball dangerous are very numerous. Essentially a game, whether the dribbling or running code be in question, where the greatest possible muscular exertion is called into play, and where, though the highest premium may be put upon pace and skill, both strength and weight can be made to tell, it is absolutely certain that dangerous collisions must now and again occur. These dangers are more than of the game; they constitute the game, and cannot be removed without alteration in the rules. But this is not all. Foot-ball is, in particular, dangerous in accordance with the spirit in which it is played. The element of personal conflict is very pronounced in either game, and in the give and take of a scrimmage or *mêlée* loss of temper may lead to the infliction of serious injuries. We do not consider that we are taking up the position of milk-and-water alarmists, and we know that we are expressing the views of many who can justly claim consideration as athletes, when we express an opinion that it is no longer quite a sufficient reply to a protest against the dangers of foot-ball to say that thousands play it. They do, and the fact makes the danger, if a small one, a very general one, and gives to the subject almost a national importance. We hope that those papers whose more especial province foot-ball and the discussion of foot-ball rightly is, will not consider our ventilation of the subject other than reasonable. We have for several successive seasons urged that the game has unnecessary elements of danger, and we may fairly take credit to ourselves for the fact that the increased power which referees now possess, and without which undoubtedly the perils would be still more marked, was loudly recommended in our columns many years ago. We are deeply desirous that those capable of setting the public mind at rest upon the subject should take steps to do so.—*The Lancet.*

AMERICAN QUACK-CURES FOR INEBRIETY.

Further particulars have oozed out about the cases of drunkenness treated in Dundee, several people having written to say that to their certain knowledge in many instances the "cures" had only been very temporary. One of the Edinburgh lay papers has taken up the subject with commendable zeal, and has collected a number of facts intended to show the public what utter frauds these American systems are. Tyson's cure seems to be run by a company, Messrs L. B. Tyson & Co., Limited, of which a Mr. George T. Stephens is an assistant secretary and agent in this country. The latter gentleman is connected with B. W. Hair & Co., chemists, High Holborn, London, whose names will be remembered in connection with a recent prosecution, and who in the present instance, after the first article appeared in the Edinburgh paper, wrote an extraordinary reply to it, in which he tried to explain away the fact that Tyson's agent in Australia was fined under the Colonial Poisons Act for selling without a license a poisonous drug. As we have stated before, a committee of rabid teetotallers in Edinburgh has been gathered together to boom the great discovery in that city; they are to commence work, we believe, this week, if enough sufficiently debased drunkards can be obtained to make it worth while. Some curious details, also, have been published lately about a "Glasgow Metabolic Institute," run by an A. J. Currie, M.D., Cincinnati, Ohio, in conjunction with a Dr. A. Nairne, who is entered in the Medical Directory as L.R.C.P. Edinburgh, 1874, and then in brackets "Currie and Nairne." Dr. Nairne is further stated to have been one of Currie's cures, and his position in connection with an unregistered practitioner is at present, we believe, under the consideration of the Royal College of Physicians. Several cases reported at the time with a flourish of trumpets as having been cured at this Metabolic Institute lapsed in a few days, as we only could expect. It is not known by which method "Dr." Currie treats his patients—some say that it is Tyson's, others Keeley's. The doctor himself does not seem to mind which it is called by, and we do not suppose it really matters. Keeley's people in London have however, written to say that it is a fraud to say that the metabolic cure is the same as theirs, but that they intend shortly to allow the Glasgow people the opportunity of the only true and genuine cure.—*The Medical Press and Circular.*

STATISTICS OF THE ATTENDANCE OF AMERICAN MEDICAL COLLEGES.

Whatever may have been the fact as to the number of students of medicine at some remote period, it has not been true for the last half-dozen years or more that the number is (in relation to population) "relatively diminishing." At the sessions of 1885 the total attendance was 10,891—9245 regular, 1032 homeopathic, 614 eclectic. During the sessions of 1893 the attendance was 18,910—16,759 regular, 1410 homeopathic, 741 eclectic. These figures show gains in eight years of 73.6 per cent. in the total attendance—81.2 per cent. for the regular students, 30.6 per cent. for the homeopathic, 20.6 per cent. for the eclectics—an average annual increase of 9.2 per cent. during the period. The average annual increase of population during the same period was less than 2.5 per cent. So that instead of there being a diminution of students of medicine in relation to population, there is a relative increase nearly four times greater than that of population. As a matter of practical interest to the profession, it may be noted that there is an average increment of nearly 6000 new home-made physicians every year, and that while the population increased 24.8 per cent. during the decade 1881–1890, the number of newly-graduated physicians increased over 50 per cent. during the same period; last year, 1893, the increase was a trifle over 8 per cent.—*Journ. Amer. Med. Assoc.*

REVIEWS.

A Practical Treatise on Medical Diagnosis for Students and Physicians. By John H. Musser, M.D., Assistant Professor of Clinical Medicine in the University of Pennsylvania. Illustrated with 162 woodcuts and 2 colored plates. Philadelphia: Lea Brothers & Co., 1894.

The current works on Medical Diagnosis are of an unusually high average. In a state of sublime ignorance and in blissful unconsciousness of its depths, a man may write such a work as the *Microscopical Diagnosis* of

Ephraim Cutter, but such a condition of mind is happily rare. Diagnosis is not a tempting subject for mediocrity, and the teachers who have of late years tackled it have been men of accurate training and of wide experience.

The books on diagnosis are of two classes: those of Vierordt, Gibson and Russell, Von Jaksch, Eichhorst, Guttman, Spehl, and others, are in reality handbooks of methods of physical examination; while Da Costa's standard work, the best illustration of the second group, embraces as well the special diagnosis of the various disorders. In this second category comes the work before us. With a long experience in teaching, and at an age and occupying positions in which his personal relations with students are still clinical, Dr. Musser has had exceptional opportunities of fitting himself for the task of writing a *Diagnosis*. The work is in every respect worthy of his well-won reputation, and is a valuable addition to our text-books. Method, so essential in the investigation of disease, is evidently the motto of the author, and both in the section on General Diagnosis and in the chapters devoted to a consideration of the special disorders, "the data obtained by inquiry" and "the data obtained by observation" are discussed in orderly sequence and with an insistence which will be itself valuable to the student. An illustration may be given of the way in which the author deals with an important subject in each division; thus sixteen pages are devoted to a general consideration of Fevers—the temperature in health, the variations, the modes of determination, pathologic variations, types of fever, onset, course, recrudescence, symptoms of fever, subnormal temperatures, diagnostic significance of fever. In every one of these sub-sections the question in hand is considered in a thoroughly practical manner and from the standpoint of large experience. The page and a half on the cerebral symptoms of fever, with a description of the differences between the ataxic state and the typhoid or adynamic state, so often confounded, are particularly clear. In the special disorders we turn to Typhoid Fever, as a sort of touchstone indicating a teacher's position. Ten pages are devoted to it, illustrated by seven excellent charts. The bacillus of Eberth is regarded as the cause; but it might have been well, perhaps, had fuller details been given on bacteriologic diagnosis, or, at any rate, some allusion made to the well-recognized difficulties in its differentiation from certain other forms. A note, too, might have been added on the investigation of the bacilli in the stools and urine. But the section, as a whole, is excellent, and no important points are overoverlooked.

A diagnosis should be pictorial, and though the charts are excellent, the figures are scarcely equal to the text, and in subsequent editions many additional ones should be added. There are certain diseases in which illustrations are of greater value than descriptions in giving a student an idea of the affection. In the matter of illustrations, American publishers are still far behind those of France and Germany. In the work before us the figures in the frontispiece, illustrating the various forms of pathogenic bacteria, would have been very much better printed in colors in the text.

The work is compact and well printed, the paper of good quality, and the proof-reading has been done with exceptional care. And, most important, there is a good working index, neither so elaborate as to indicate that it was done by contract-labor, nor so meager as to suggest that it was committed to a friend. The accuracy, the freshness and clearness of description of symptoms, and the presentation of all subjects from an advanced modern standpoint will insure for the work a hearty reception at the hands of students and physicians.

An American Text-book of the Diseases of Children. Including Special Chapters on Essential Surgical Subjects: Diseases of the Eye, Ear, Nose, and Throat; Diseases of the Skin; and on the Diet, Hygiene, and General Management of Children. By American Teachers. Edited by Louis Starr, M.D., assisted by Thompson S. Westcott, M.D. 8vo., pp. xiv, 1190. Philadelphia: W. B. Saunders, 1894.

A critical review of this work within the ordinary limitations of space is at once a difficult and a delicate task. The reason becomes apparent when it is stated that the book is made up of a hundred separate articles prepared by sixty-three different writers. The text is thus a little variable in quality, but even a single author is likely not to write equally well on all subjects, while the impress of the editor is appreciable in all parts of the work. A single instance will illustrate this point. Thus, Forchheimer, in closing an interesting article on Dentition, declares lancing of the gums useless for the relief of symptoms and for facilitating or hastenting the eruption of the teeth, and as harmful and only to be practised for the relief of surgical accidents; but the editor in a foot-note qualifies this expression by pointing out that experience has demonstrated the utility of the use of the lancet in appropriate cases.

The list of contributors includes many names well known in pediatrics as well as in other departments of medicine. Some of the articles are worthy of special mention. Matters appertaining to the clinical investigation of disease, and the general management of children, together with the subjects of feeding, bathing, clothing, and sleep are discussed in the Introduction in a masterly way by the Editor. The article of Osler on Tuberculosis is a perfect one, and faithfully portrays the present status of knowledge upon this important subject. Shakespeare's article on Cholera may be viewed as an authoritative statement of the prevailing conception of that disease. Da Costa contributes a characteristically lucid and interesting description of Rheumatism. Vaughan's article on Diarrheal Diseases is a scientific exposition of a most important subject. In it he considers milk-infection in its acute and subacute forms. The therapeutic indications under these conditions obviously are the withdrawal of milk from the dietary and the evacuation from the gastro-intestinal tract of toxic substances of all kinds by means of cautious irrigation. Ashhurst discusses Diseases of the Cecum and Intussusception in a conservative and scholarly manner. He expresses the opinion that removal of the vermiform appendix after recovery from an attack of acute appendicitis in which suppuration is believed to have occurred, is, as a rule, unjustifiable as a means of preventing recurrence of the disease. He manifests a preference for the word laparotomy rather than celiotomy to designate abdominal section.

A word of commendation for the execution of the neurologic division of the work must not be omitted. Although reference is made to an agreement at the last meeting of the American Pediatric Society to substitute the designation "ileo-colitis" for "dysentery," the latter word is retained for convenience' sake. The section on Diseases of the Blood is fairly complete, but we fail to find any reference to the affection described by v. Jaksch as Anæmia pseudo-leukæmica infantilis. Exophthalmic goiter is likewise not described. In The News of April 16, 1892, p. 430, two cases of this disease are reported in girls fifteen and sixteen years old respectively, in whom menstruation had not appeared; and at a recent meeting of the New York Neurological Society a case was reported in a girl of twelve years. In the illustrations accompanying the article on hereditary ataxia two cases are shown having "increased reflexes and ankle-clonus," and in the text reference is made to perhaps the same two cases, in which the knee-jerk was greatly exaggerated and ankle-clonus was present. It is now almost universally recognized that absence of knee-jerk is distinctive of the hereditary ataxia of Friedreich, and that cases in which this reflex is present or exaggerated belong in another classification.

The book contains a moderate number of illustrations, together with twenty-eight plates, many of which are colored. The former are mostly only of ordinary merit, and are not numbered consecutively, the enumeration of individual articles being distinct. Of the plates, some are excellent, but many are disappointing. Taken all in all, however, we cannot speak of the success of this splendid work in terms of praise too high, and the Editor and his collaborators are to be warmly congratulated on the outcome of their mutual efforts.

CORRESPONDENCE.

ACETANILID AS A SURGICAL DRESSING IN VETERINARY PRACTICE.

To the Editor of The Medical News,

Sir: Attracted by Dr. Francis Harrell's article in The News relative to acetanilid as a surgical dressing, I was prompted to use it as a surgical dressing in the hospital of this ranch (veterinary), and the results have been most happy.

The first case in which it was given a trial was certainly a crucial test—it was upon an extensive fistula of the superior cervical region ("poll-evil") of long standing in a Percheron colt four years old, which had been exsected about ten days previous to my reading the article, and was then suppurating very profusely from the entire wound-surface, about ten inches in length and from two to six inches in depth.

The wound was carefully washed with a 50 per cent. solution of hydrogen dioxid, and packed thoroughly with acetanilid. The following day there were not two drams of pus in the cavity, and at the termination of a week hardly a drop of pus could be discovered. The entire wound healed kindly fifteen days from the commencement of the acetanilid dressing.

I have since used acetanilid after dissecting out three fistulæ of the superior scapular region ("withers"), in one of which immediate union was obtained; in the remaining two slight suppuration continued for a few days only.

In all, I have used acetanilid in about twenty-five surgical cases, with the happiest results; in fact, in all my minor surgical cases only ordinary antiseptic precautions in cleanliness and the acetanilid dressing have resulted in healing by first intention, a result in veterinary surgery otherwise difficult for me to obtain, even under most thorough preparation and scrupulous cleanliness.

I am indebted to the contributors of The Medical News for a number of valuable suggestions easily applied to veterinary medicine; but this of Dr. Harrell I regard as the most valuable of all, and I extend my thanks to him, adding also the expression of satisfaction that The News comes to me every week.

Very cordially,

M. E. Knowles.

Veterinary Hospital, Bitter Root Stock Farm,
Hamilton, Montana.

QUININ IDIOSYNCRASY.

To the Editor of The Medical News,

Sir: The case of quinin idiosyncrasy reported by Joseph L. Hancock, M.D., of Chicago (The News, March 10, 1894, p. 271), reminds me of a similar case seen a short time ago. The patient, a married lady about thirty years old, "tall, with a dark complexion and of rather slight build," was suffering from an attack of intermittent fever. She informed me of her idiosyncrasy, and I prescribed cinchonidin sulphate in three-grain doses. Two doses produced all the symptoms described by Dr. Hancock—erythema, with burning and itching over the entire body, especially severe on the hands and arms, and in addition a severe and distressing palpitation of the heart, with dyspnea. These symptoms all disappeared in three or four hours, leaving no unpleasant effects. Respectfully,

W. J. J. Paris.

Elizabethtown, Ill.

GALVANO-PUNCTURE FOR HYPERTROPHIED TONSILS.

To the Editor of The Medical News,

Sir: Having used the galvano-puncture for hypertrophied tonsils at least five hundred times, permit me to state that I have never had a patient suffer severe pain. From two to four sittings constituted the limit for each tonsil. I never used over from a 4 to a 10 per cent. solution of cocain, and I have never had a bad result from the operation. I consider it bloodless.

Very truly yours,

Frank P. Hudnut,
Ex-Attending Surgeon Throat and Nose Department,
Long Island College Hospital.

Needham, Mass.

NEWS ITEMS.

The Association of American Physicians will hold its ninth annual meeting at Washington, D. C., on May 29, 30, and 31, and June 1, 1894. The following program has been prepared:

President's Address; by R. H. Fitz, Boston. Some Researches on the Significance of Albumin and Casts, especially in those past Middle Life; by Frederick C.

Shattuck, Boston. Some of the Chemical and Bacteriological Characteristics of Milk; by Thomas M. Rotch, Boston. The Chemical Products of the Anaërobic Putrefaction of Pancreatic and Hepatic Tissues, and their Effects upon the Tests for Morphin; by Victor C. Vaughan, Ann Arbor. The Effect of Various Metals on the Growth of Pathogenic Bacteria; by Meade Bolton, Baltimore. Dr. S. C. Martin's Researches on the Bacteria of Vaccinia; by Harold C. Ernst, Jamaica Plain. Note on the Observation of Malarial Organisms in Connection with Typhoid Fever; by W. Gilman Thompson, New York. Experiments in Artificial Melanosis; by George Dock, Ann Arbor. The Mild Character and Diminished Prevalence of Syphilis and the Infrequency of Visceral Syphilis; by John H. Musser, Philadelphia. A Case of Osteomalacia; by George Dock, Ann Arbor. The Treatment of Typhoid Fever; by Samuel A. Fisk, Denver. The Treatment of Certain Symptoms of Croupous Pneumonia, particularly in Adults; by Beverley Robinson, New York. A Study of the Temperature in Cerebral Apoplexy; by Charles L. Dana, New York. Six Cases of Traumatic Headache; by Charles F. Folsom, Boston. Tetany in America; by J. P. Crozer Griffith, Philadelphia. Clinical Report of Two Cases of Raynaud's Disease; by Frederick P. Henry, Philadelphia. A Case of Mitral Stenosis, with Great Hypertrophy of the Right Ventricle; Death from Hemoptysis; by A. McPhedran, Toronto. Stomatitis Neurotica; by A. Jacobi, New York. Gastro-enteric Rheumatism; by Henry M. Lyman, Chicago. Lead-Palsy in Children; by Wharton Sinkler, Philadelphia. A Report of the Ultimate Results obtained on Experimental Eye-tuberculosis by Tuberculin-treatment and Preventive Inoculation; by E. L. Trudeau, Saranac Lake. Modification—Temporary and Permanent—of Physiological Characters of Bacteria in Mixed Cultures; by Theobald Smith, Washington.

Smallpox in Chicago.—The Chicago Commissioner of Health reports that during the year 1893 there were 140 cases of smallpox in the city of Chicago. Cases occurred during every month of the year except March and May. Thirty-five cases occurred during November and 66 during December. There was a total of 25 deaths, none of which occurred in any case that had been previously vaccinated. But few of the cases could be traced to their origin. Some were, however, traced beyond the city and others to immigrants as the most probable source of infection; nevertheless, early in the summer 3 cases were found within two days in three different sections of the city. Careful and extended investigation leads to the belief that during the early summer there were several cases of smallpox of mild character among people who mingle continuously with the public, the disease being so mild as not to demand the attendance of a physician. During the year the disease occurred at 97 different points. From none of these did cases of secondary infection occur after the premises had been disinfected. During January of the current year there were 188 cases, with 29 deaths. Seven of the latter occurred outside of the hospitals and were of hemorrhagic type. Not one of these 7 had been vaccinated, and but few of the 29 fatal cases presented any evidence of successful vaccination. In the month of February there were 233 cases, with 55 deaths. These occurred largely among adults of the lodging-house class, who were greatly debilitated by dissolute habits and dissipation. The death-rate among the unvaccinated was 50 per cent., and was much greater among adults than among children. The disease was found at 93 different points, all of which were thoroughly disinfected. During the month of March there were 305 cases, with about 95 deaths. Vaccination has been pursued with intelligence and vigor. A rigorous house-to-house inspection has been made, with the aid of the police force, in search of concealed cases, but none was found. Children in public and parochial schools have all been revaccinated.

Cases of smallpox are also reported from Chattanooga, Tenn.; Kalamazoo, Mich.; San Antonio, Tex.; Brooklyn, and New York City.

American Medical Association.—The Committee of Arrangements announces that the rate of fare for tickets from Missouri River points, including Sioux City, Council Bluffs, St. Joseph, Atchison, Leavenworth, and Kansas City, to San Francisco and return *via* the Trans-Continental roads, at the time of the meeting of the American Medical Association, will be $65.50. From St. Louis, Cairo, Memphis, and New Orleans, the rate will be $77.50. The going trip must be made within fifteen days from the date of sale of tickets, and the return trip within fifteen days from the day upon which the tickets are signed in the presence of a railroad agent, but in no event later than July 15th. Within the State of California the fifteen-day limit is ignored on both going and returning trips, *i.e.*, the holders of tickets are at liberty to move at will within the State of California within the life of the tickets, and the fifteen-day limit returning is not enforced west of the terminals at Portland, Oregon, and El Paso. If the Shasta route between San Francisco and Portland is passed over on either going or returning trip from Missouri River, St. Louis, or Chicago, the rate will be $15 greater. Efforts are being made to obtain a similar reduction in rates on the Eastern railroads.

The Late John H. Rauch.—At a meeting of the Philadelphia County Medical Society, held March 28th, a minute was adopted expressive of great sorrow at the sudden death of Dr. John H. Rauch, of Chicago, lately Secretary of the Illinois State Board of Health, "a man whose interest in the cause of medical education, and whose efforts in increasing the efficiency of the medical profession and maintaining its dignity and honor, have rendered incalculable service to the public."

Cholera at Constantinople.—It is reported that cholera of a most malignant type has broken out in Constantinople, and is spreading with alarming rapidity. The disease had been prevalent in the poorer and most crowded quarters, but it has now invaded the districts in which the better classes reside. A few cases of cholera are also reported from Belgium.

Dr. Hurlbert Agnew, of Philadelphia, died on April 6th at the age of thirty-two years. He was a graduate of the University of Princeton and of the Medical Department of the University of Pennsylvania. He was a cousin of the late D. Hayes Agnew.

Ollivier, the well-known French pediatrist, died recently in Paris at the age of sixty-four years.

ORIGINAL ARTICLES.

BRIGHT'S DISEASE IN CHILDREN.[1]

BY CLARENCE KING, M.D.,
PHYSICIAN TO THE CATTARAUGUS COUNTY ALMSHOUSE AND HOSPITAL, MACHIAS, N. Y.

BRIGHT'S disease,[2] as you all well know, is a structural disease of the kidneys, either inflammatory or non-inflammatory in character, generally accompanied by dropsy, and the presence of albumin in the urine in greater or less amount. It was first accurately described pathologically by Dr. Richard Bright in 1827, and has received much careful investigation since then, but with the addition of few material facts. Several distinct forms of the disease are recognized, differing widely in many particulars, but in other respects retaining essentially the same clinical characteristics.

Great discrepancy is manifested in the use of the different generic terms employed to designate these various disorders of the kidneys. Formerly the terms albuminuria and Bright's disease were used synonymously, but it is now well known that albumin may appear in the urine from other causes than structural kidney-disease. Thus, for instance, we sometimes find albumin in the urine in typhoid fever, in diseases of the heart, or following the use of certain drugs, as salicylic acid, or the ingestion of an exclusive albuminous diet for some time. It is true that Bright's disease has albuminuria as an almost constant symptom, but unless there are structural changes in the kidneys no case of albuminuria can properly be called Bright's disease. Again, we find in the writings of some of our leading authorities the terms nephritis (without qualifying adjective) and Bright's disease used interchangeably. Da Costa has described a simple inflammation of the kidney, occurring mostly in old men, as the result of cold, which is ushered in by chills, high fever, and great pain in the renal region, generally of one side. These symptoms are soon followed by vomiting, and at times diarrhea and retraction of the testicle, with or without hematuria or albuminuria, but unaccompanied by dropsy, and generally terminating in resolution in about two weeks, in other cases leading to suppuration. I cannot believe that such cases are very rare, as I have encountered at least two of the kind within twelve months, although they both occurred in young adults. It is manifestly improper to call these cases Bright's disease, as this would be extending the term beyond its proper limits and including pathologic conditions not embraced by the original description of Bright.

This disease, like many others, may be either acute or chronic, primary or secondary. In childhood by far the greater number of cases occur secondarily to scarlet fever; later in life the affection is generally primary. In the adult the acute form of the disease is seldom met with except when it occurs as a complication of and secondary to pregnancy, but in childhood the acute is many times more common than the chronic form. Holt maintains that Bright's disease is not rare in infants, and if physicians would make it a practice to examine the urine of their young patients more often many obscure symptoms occurring in the course of other diseases could be easily explained. Undoubtedly exposure to cold and wet is also sufficient in some cases to produce it. Goodhart, of London, suggests that exposure may play a more prominent rôle in the causation of the disease in childhood than is generally supposed. It is possible that many cases may occur from this cause which are never recognized as such, and recovery take place or a fatal termination follow which is assigned to other causes; and the kidneys never being suspected, the diagnosis is not corrected by the autopsy. In infants the primary symptoms point more particularly to the brain or the digestive system, thus making an error of diagnosis easy. Bright's disease is sometimes produced by the poisons of other diseases circulating in the blood, as that of measles, diphtheria, pyemia, or pneumonia; or it may arise from poisoning with phosphorus or arsenic, or from cantharides, or it may occur intercurrently with pulmonary tuberculosis or lardaceous disease. However, all these are much less potent factors in producing the disease in children than scarlet fever and exposure to cold or wet.

We are all more or less familiar with the various

[1] A paper read before the semi-annual meeting of the Cattaraugus County Medical Society, November 14, 1893.

[2] I consider the term "Bright's disease" very unfortunate, as it expresses nothing in regard to the nature of the disease, yet I have chosen to retain it in lieu of any other, as it is the only term which usage has applied to the pathologic conditions covered by this paper. We need a new term, yet it would be difficult to frame one exactly synonymous with "Bright's disease," as this embraces so many essentially different forms of nephritis (but not all of them, as I have shown in the text of this article), and is attended by such a variety of symptoms, none of which is constant.

signs indicating Bright's disease in the adult, but in infants the disease is often attended by symptoms which are very irregular and misleading. Thus, in some cases, dropsy is not a prominent feature at any time during the disease, and generally it is absent entirely during the first few days. Nervous symptoms are frequently conspicuous, and often the first indication the mother has that her babe is sick is a convulsion. By careful inquiry we are sometimes able to ascertain that this was preceded by restlessness and irritability, by slight pyrexia and scanty secretion of urine. In other cases gastro-intestinal irritation, as manifested by obstinate vomiting and diarrhea, is the principal feature and serves to divert attention from the real seat of the malady. Again, a high fever, with rapid pulse, may usher in the disease, or rapid respiration with dyspnea, independently of pyrexia, may cause us to suspect the lungs; these, however, upon careful examination are found to be sound. I allude to these irregular initiatory symptoms for the purpose of calling attention to the importance of a careful examination of the kidneys in all cases of convulsions, persistent gastro-intestinal disturbance, or unusual prostration without obvious cause.

In older children the symptoms of the disease approach more nearly those of Bright's disease in the adult. Following some exposure to cold or an attack of scarlet fever the child becomes ill and may have a moderate elevation of temperature. This is usually not sufficient to excite notice, but sometimes it is accompanied by headache and vomiting and the child is taken from school. Convulsions may occur at this time, but they are much more rare as initiatory symptoms in children than they are in infants; later in the disease, especially if proper treatment has not been followed, convulsions are frequent. The amount of urine passed is diminished in nearly every case, although the decrease may be so small as to escape notice unless the total amount for twenty-four hours is collected and measured; in other cases the urine is nearly or entirely suppressed. An examination of the urine shows it to contain albumin, generally in great quantity, and the microscope reveals the presence of blood-discs. In color and specific gravity it varies greatly according to the quantity of urine passed and the amount of blood which it contains. Casts are also present, frequently in great number, mostly of the epithelial or granular variety. Dropsy generally develops early and increases in amount. It is first noticed about the face, after which the body and extremities become edematous, sometimes to such an extent as to make the wearing of the ordinary clothing impossible, while the face is enlarged and changed beyond recognition. With these symptoms we find pallor and dryness of the skin, an accelerated pulse, which is frequently intermittent, and the heart-sounds muffled and indistinct. Some authors believe that dilatation of the left ventricle is common, which, however, in some cases is only temporary, while in other cases it may be permanent or become the direct cause of death. Great restlessness, disturbed sleep, and even delirium occasionally occur in the Bright's disease of childhood, as likewise of infancy, and may contribute to a fatal issue by inducing exhaustion. All these symptoms vary greatly in severity in different cases, and their association in different degrees is susceptible of an almost infinite number of combinations.

Before proceeding to a consideration of the treatment of the disease as it occurs in childhood, let us review the clinical features by the narration of a case:

A boy, nine years old, strong and healthy, had never had scarlet fever or any severe disease. One day, while running and jumping, he became tired and sweaty and sat down to rest in the open air. During the next day or two he complained of feeling tired and lame in all his muscles, but especially those of his back and sides, and his parents thought he had strained himself by jumping. This soon passed away, but was followed a week later by dropsy of the face and hands, vomiting, and headache, both occipital and frontal. His parents then consulted a physician, who prescribed for him, but the dropsy continued to increase, and by the end of another week had involved the whole body, face, and limbs, and he took to his bed. Up to this time he passed a moderate amount of urine of a very high reddish-brown color. His bowels were somewhat constipated. He had a dull, heavy pain in the lumbar region and also through his bowels, but the headache was less. Soon after taking to his bed he began having convulsions, and had twenty-nine in about ten hours, the majority of only moderate severity. He became semi-conscious only between the convulsions, and tossed and moaned a great deal. I saw him for the first time on the day of these convulsions. As he had then passed no urine for twenty-four hours, I introduced a catheter and drew off about two ounces of very dark urine, which, upon boiling, threw down a deposit of two-thirds its bulk. I advised a hot pack to induce perspiration, to be followed by flaxseed-poultices over the kidneys. I also advised a cathartic and an opiate. The boy had but one more fit after this and soon sank into a quiet sleep, from which he awoke four hours later perfectly conscious. About a week afterward he began again to have convulsions, and I was called and given charge of the case. I found him nearly the same in all particulars as when I saw him before; his fits, however, were not so severe, and there was a longer interval between them. The urine was somewhat increased in quantity, but continued high-colored, almost brown, and contained much albumin. He complained of being sore and lame in one shoulder and side and through his bowels. I instituted the same treatment as before, and directed him to drink freely

of water and to have an exclusive milk-diet. Under this treatment he improved somewhat, the urine increased in quantity, became of better color, and contained less albumin; the dropsy also diminished. Finally, a diarrhea set in, which was accompanied by severe griping whenever his bowels moved, and morphin was required to give him any rest. Notwithstanding our efforts to check this diarrhea it persisted until his death, about a week later and about six weeks from the onset of the disease. His mind was perfectly clear to the last and his dropsy much diminished. His urine, however, while it varied within narrow bounds from day to day, continued albuminous and of a deep-red color from admixture of blood.

There is probably no disease that requires more care and judgment in its treatment than acute Bright's disease. Being universally recognized as a very serious affection, the tendency is toward active treatment by drugs, and this often means increased mischief to the kidneys. At least three important fundamental principles underlie the successful treatment of this disease: 1, to remove the transuded fluid from the tissues and cavities of the body, together with those products of destructive metamorphosis which are usually excreted by the kidneys, but which, owing to their diseased condition, are retained in the system; 2, to restore the functions of the kidneys to their normal condition; and, 3, to do no further injury to the already damaged organs. Many of us have undoubtedly striven assiduously in many cases to carry out the first two indications, but have neglected to heed the third. And what has been the result?

Ordinarily Bright's disease is an inflammatory disorder. Indeed, it is a question if every case of Bright's is not inflammatory at some stage. A cardinal axiom of medicine, as of surgery, is that an inflamed organ requires rest and not stimulation. Hence, when the kidneys are inflamed, any treatment which stimulates their excretory function, or which increases their blood-supply, cannot fail of doing harm. During this stage I believe the best results will follow the stimulation of *other* organs to do the work normally required of the kidneys, so far as they are able, together with restriction of diet and the use of bland diluents. So long as the patient has fever, a rapid pulse, and pain through the loins and back, we may know that the kidneys are in a state of engorgement, if not actual inflammation, and we had better let them alone. The presence or absence of blood in the urine can be no trustworthy guide to our treatment. Dickinson in his valuable work on *Albuminuria*, in speaking of scarlatinal nephritis, says: "The worst cases are those in which no blood makes its way into the urine." But blood when present in quantity is an additional indication of engorgement, and calls for delay in the use of active diuretics.

During the inflammatory or congestive stage the urine is scanty, and as a result dropsy develops, often with symptoms of systemic poisoning. Here, obviously, we should seek to remove the cause by inducing a vicarious discharge of water from the economy, which at the same time will carry away some of the retained poisons. There are two principal channels by which we can do this—by the skin and by the bowels. For purgatives we may employ croton-oil, elaterium, jalap, or Rochelle salts, according to the urgency of the case. To induce perspiration we can make use of pilocarpin, liquor ammonii acetatis, or pulvis Doveri. By far the best way, however, is by the use of the hot pack, or prolonged hot-water or vapor baths. A convenient way to give a vapor bath is to seat the patient, stripped of his clothing, on a stool, and envelop him to the chin in a heavy blanket, which shall reach to the floor on all sides. Under the blanket place a pail of water, and drop one or more hot bricks into it, as required to produce steam sufficient to fill the blanket. If the patient is unable to leave the bed, we can still make use of the vapor bath. Water can be boiled over an oil-stove or a large lamp placed on the floor beside the bed, and the steam conducted beneath the covers by means of a tube made by rolling up a piece of builders' paper.

In case eclampsia has developed, or seems imminent, we may have to resort to chloral hydrate, morphin, or chloroform. On theoretic grounds I would object to morphin, as tending to lock up the secretions, which we are seeking to increase. It is very important in these cases of uremia that the foregoing treatment be promptly instituted and thoroughly carried out, whatever other treatment may seem called for. Some cases may demand stimulants to tide over this crisis, despite the fact that alcohol is an irritant to the kidneys, but they should be used cautiously and withdrawn as soon as possible.

As soon as the stage of renal engorgement is passed diuretics are indicated. These, following Smith, we may divide into three classes: (1) those which act by direct stimulation of the secreting structure of the kidney; (2) those which increase the amount of water in the bloodvessels; and (3) those which increase the general vascular tension. The first class includes the salts of potassium, squills, spirit of niter, cubebs, etc., and can be, in my opinion, discarded with advantage in nearly every case of acute Bright's disease. In the chronic form of the disease they may be admissible and, possibly, in some cases of acute Bright's, after the stage of engorgement has subsided, when we may choose to assume the risk of inflicting further damage upon

the kidneys for the sake of obtaining prompt diuresis to help tide over some critical period.

The second class includes a single substance—water, either plain or alkaline. Drinking freely of water increases the bulk of the urine without causing any irritation of the kidneys, but, on the contrary, allays irritation by diluting the urine. This is accomplished, according to Professor A. H. Smith, by a "process of simple transudation without action of the epithelium, and the effect is soothing, as it washes away irritating material, which would otherwise linger in the half-occluded tubules." If the urine is highly acid, one of the natural alkaline waters may be used with advantage, or an alkali, preferably a carbonate, added to pure water. A patient with Bright's disease in any stage should always be urged to drink freely of water, and the more scanty the urine the more necessary does this become. This will never produce or prolong an inflammation of the kidneys, as the effect is like a soothing lotion to an inflamed surface.

Digitalis is the type of the third class of diuretics. Formerly this drug was used indiscriminately in all cases, but now it is being restricted somewhat in its use. During the stage of active inflammation we should not employ drugs of this class, which includes, beside digitalis, strophanthus and the salts of caffein, as in this state of the kidneys the indication is to lessen vascular tension rather than to increase it. When, however, inflammation is absent, digitalis forms one of our most valuable and harmless means of increasing the urinary secretion. I have frequently used digitalis in combination with the citrate of caffein in the different forms of kidney-disease, and have been pleased with the effects produced.

Diuretin is another drug recently brought into notice as a diuretic, but I have never made use of it, and therefore offer no opinion of its merits. It belongs in the first class of diuretics.

The treatment of the uremic symptoms is sufficiently well set forth in the foregoing paragraphs. The bromid of potassium or sodium, either with or without chloral hydrate, may have some controlling influence on the convulsions, but it does not appear to afford much relief in uremic headache. The same treatment by depletion which we employ for the relief of uremia is also the proper treatment for the dropsy of this as well as of other diseases. The ingestion of fluids should be restricted and the bowels, skin, and kidneys stimulated to increased activity. But we should always have regard for the crippled state of the kidneys and employ the stimulating diuretics only in the absence of engorgement. Paracentesis and acupuncture are seldom, if ever, called for and are always attended with danger.

The diet in Bright's disease should consist entirely of milk if it can be taken in sufficient quantity to properly nourish the patient. If milk is not well borne it may be predigested. Sometimes buttermilk can be taken when sweet milk cannot. Koumyss and other foods made from milk can also be used, either alone or alternately with milk, to give variety to the diet. The white of an egg stirred in the milk makes an important addition, if the loss of albumin from the system is great, as indicated by its presence in great quantity in the urine. Milk contains alone sufficient albumin to replace any ordinary loss in this way, besides its other important constituents, all of which are easily digested and leave but little residue in the bowels. Milk is also diuretic by virtue of the water which it contains, and is, therefore, a great aid to our other treatment. When convalescence is fully established we may add other articles to the dietary, beginning with the various animal broths and increasing the amount and variety gradually. Above all we should use decision in treating these cases of Bright's disease, especially with regard to diet, and should not fail to impress the parents or friends of the necessity of a strict compliance to orders.

GASTRO-INTESTINAL HEMORRHAGE IN THE NEWBORN.

By W. B. KONKLE, M.S., M.D.,
of Montoursville, Pa.

In a white female infant born at noon, March 8, 1893, gastro-intestinal hemorrhage manifested itself on the evening of the following day, first by hematemesis, and during the twenty-four hours thereafter by several copious evacuations of blood from the bowels, the depletion occasioning a condition of profound shock. The accident could be attributed neither to inherited diathesis nor to dyscrasia, to circumstance connected with birth, to unusual feature of body, nor to neglect or impropriety of care. The treatment consisted in the administration, by the mouth, of ergot and vegetable astringents, and in the general application externally of dry heat. The child recovered rapidly and completely, a year having since elapsed, during which no incompetency of the digestive system has been discernible, nor any other untoward symptom exhibited permitting of any association whatever with the grave mishap cited.

The utter absence of tangible cause in this case and in others of the same class renders their investigation and explanation in the domain of theory necessary and interesting. Eliminating then, from this discussion, those cases of *melæna neonatorum* to which may be assigned immediate causes like hemophilia, syphilis, and gastric ulcer, to what adequate factor may we refer that list, proportionately numerous, as testified by the results of post-mortem examination, for the existence of which no

such palpable interpretation is available? The prevailing opinion among writers on the subject is that in these otherwise inexplicable instances the hemorrhage is due to congestion of the gastro-intestinal tract. Vogel, quoted by J. Lewis Smith in his exhaustive research of the subject (*American System of Obstetrics*), while clearly asserting the occurrence of increased arterial pressure in the mesenteric system, also points significantly to the closure of the umbilical vein as a possible cause of congestion. Loranchet, quoted from a French journal (*American Journal of the Medical Sciences*, January, 1894), considers a slow and progressive refrigeration of the body as the operative influence effecting a passive congestion. Indeed the dominant idea seems to be that the congestion, the presence of which is unanimously conceded, assumes preëminently the passive or venous form. That there obtains in these cases an overstrained condition of the capillary system of the surfaces involved will likely be acknowledged upon the most superficial reflection. But whether this strain be produced by an augmentation of the *vis a tergo* or by a suspension or reversal of the *vis a fronte*, whether due to an increase of active arterial tension or to the development of passive venous obstruction, constitutes another problem.

To my mind the congestion cannot be venous. To tie a vein is to empty it on the cardiac side of the ligature. The tying of the umbilical cord, instead of engorging the portal circulation should, on the contrary, unburden it commensurately with the amount of blood that formerly was thrown into its current through the umbilical vein. On the other hand, to tie an artery is to produce turgescence on the cardiac side of the ligature. Hence constriction of the umbilical cord tends immediately to increase the pressure on the abdominal arterial circulation.

But, this element alone considered, one should expect any resultant hemorrhage to occur very soon after the ligation of the cord; whereas, in fact, the bleeding nearly always appears several hours subsequently, in some cases after days. Thereby another causal factor is indicated. Where may it be found? I believe that the explanation of the accident under discussion is involved in the relation which the closure of the ductus arteriosus bears to the closure of the foramen ovale. Let the obliteration of these blood-channels proceed harmoniously, and the consequent forcing of an increased volume of blood through the lungs will compensate for the recoil upon the abdominal arterial system occasioned by the tying of the umbilical cord. Let the ductus arteriosus close more slowly proportionately than the foramen ovale, and the abdominal arteries, already subjected to heightened pressure, will be further distended at the expense of the pulmonary circulation. Should the obliteration of the lumen of the ductus arteriosus progress with disproportionate rapidity, the arterial vessels of the abdomen would be relieved of strain, and a corresponding active congestion of the lungs occur. Obviously such congestion of the pulmonary structures either does not happen as often as the analogous abdominal congestion, or, if it does supervene with comparative frequency, it does not imply the same risk. But that arterial congestion of the lungs may so occur and with disastrous results, is indicated by a case recently reported to the Lycoming County Medical Society by Dr. J. P. Connelly, a careful and trustworthy observer, in which death within two hours after birth took place with profuse hemoptysis presenting all the characteristics of such hemorrhage.

CLINICAL LECTURE.

THE TREATMENT OF NEPHRITIS.[1]

By J. M. DA COSTA, M.D., LL.D.,
of Philadelphia.

Gentlemen: I shall show you a series of cases of nephritis this morning. They are peculiar in some respects, as they display phenomena which are not always present in this affection. They are also of interest, as you will presently see, from a therapeutic point of view.

Recurrent Acute Parenchymatous Nephritis, with a Musical Heart-murmur.

Case I.—This patient, W. H. J., a colored fish-dealer, thirty-three years of age, came into the hospital on the 15th of January, a very ill man. He told us on admission that he is of temperate habits. He had an attack of gonorrhea twelve years ago, but denies other venereal disease. He has never had articular rheumatism. He had not been feeling well this winter, and, being exposed, caught cold repeatedly. He says that in October last, thirteen months after he first noticed symptoms of failing health, he quit work. Dropsy in the legs and ankles developed on several occasions after exposure to cold and wet. The man then had no appetite; had lost flesh and strength; had palpitation of the heart; and with this he noticed that his urine had gradually become less in quantity and smoky in color. Finally, the urine decreased to such an alarming degree that he decided to come into the hospital for treatment.

The last statement is confirmed by a study of the urine after admission, for during the first twenty-four hours he passed only five ounces of urine. The nature of this case is clear enough from the history. It is that of a man who, not being robust, has been much exposed to bad weather, and in whom unusual exposure was followed on several occasions by shortness of breath, palpitation, dropsy coming on gradually and slowly subsiding, to again return after exposure. But the point which does not show very clearly is rheumatism. Has there, or has there not, ever been in this case an attack of acute articular rheumatism? The man replies, "No."

[1] Remarks made in the course of a clinical lecture delivered January 27, 1894, at the Pennsylvania Hospital, Philadelphia.

You will see presently why I ask this question so pointedly.

On examining him we found this state of things: Upon admission he was very short of breath; there was dropsy of the legs, abdomen, and face—in fact, general dropsy, we might say; but his shortness of breath is what particularly attracted our attention. We found—and this is a point to which I shall return presently—a curious, musical murmur in his heart. His lungs were congested and full of fine râles. We also found albumin in the urine. In this scanty urine, of a specific gravity of only 1012, there was 8 per cent., by bulk, of albumin, and also hyaline and granular casts in abundance. In this connection it is important to note whether or not, at the time of his admission, he exhibited any cerebral symptoms. Did he have headache, or delirium, or any other symptom of nervous disorder? After coming into the ward he was subject to nervous spells at night, a curious delirium with confusion of ideas, during which he would sit up and scream violently, and sometimes fall backward in bed. In truth, he had attacks of temporary nocturnal delirium, although during the day his mind was clear. He had no delusion. This delirium occurred only immediately after admission, while the urine was extremely scanty; it was, in fact, a uremic delirium. There is no record of headache or convulsions. You have now heard the history of this case.

Now, gentlemen, the progress of this case well illustrates the effects of treatment, which I will briefly review, leaving some points for further discussion until I have given you the outlines of the case.

This man, with his nocturnal delirium, short breathing, rather irregular heart, feeble pulse, and annoying cough, was put upon tincture of digitalis, ten drops every three hours, and ten grains of ammonium carbonate every second hour. This was done on account of the very evident pulmonary congestion, indicated by râles in the chest and rapid breathing, and in order to stimulate expectoration. But while the action of the digitalis proved valuable to the general condition, the heart becoming steadier under its control, the total quantity of urine passed on the 16th was only five ounces. Realizing the necessity of stimulating the kidneys to action—for the digitalis while strengthening the heart had in this case very little action upon the kidneys—I gave what has become rather a favorite remedy of mine, the lactate of strontium, in thirty-grain doses in solution, four times a day, so that he received from a dram and a half to two drams daily. The result has been a striking one. From five ounces, noted on the 16th, we find the total urinary excretion rising in two days to thirty-five ounces. At the same time, the dropsical symptoms began to decrease, his breathing became less embarrassed, so that he could lie down, and, in truth, a general amelioration of the morbid phenomena took place, and particularly those connected with the dropsy. The man also slept better. He never complained of headache, and the nocturnal delirium did not recur during the course of this treatment. The lactate of strontium was continued in conjunction with digitalis until the 24th instant, when the latter was stopped, as the heart's action had become satisfactory.

Under this treatment the patient's uremic condition and his cough were much relieved, and he is now really in a much improved state. How much of this to attribute to the digitalis, and how much to the strontium, may come to us from the fact that for the first forty-eight hours, while under the digitalis treatment exclusively, he did not greatly improve, and also from the subsequent observation that after the digitalis was stopped the urine did not decidedly diminish in quantity again. We have now got it up to forty-eight ounces in twenty-four hours, and I attribute this mainly to the lactate of strontium, in connection with a restricted milk-diet and rest in bed.

Let us now proceed to examine the present condition of the patient, partly with reference to the heart and partly with reference to the kidneys. The pulse is jerky, slightly tense, and receding. The cardiac impulse is diffuse, rather lacking in force, certainly lacking in force if we take into account its diffuse, extended character. Percussion over the cardiac region shows that the heart is increased in size, and particularly in its transverse diameter. We have, therefore, a case in which there exists enlargement of the heart, not so much due to hypertrophy as to increase in size of the cavities; there is a moderate hypertrophy, but a considerable amount of dilatation. When you have a want of correspondence between the size of the heart and its impulse, and a weakness of the pulse in proportion to the area of cardiac percussion-dulness, you probably have to deal with a stretching of the cavities rather than with an hypertrophy from actual increase of the muscular elements in the walls of the heart.

Now, with regard to the valvular apparatus of the heart. I wish that you could all listen with me, for this is a very peculiar heart. When I apply the stethoscope over the cardiac region I hear a strange, half-musical, half-purring murmur, which has its site of maximum intensity at mid-sternum. It is aortic in situation. This murmur is associated with a purring tremor conveyed to the hand placed lightly on the chest. It is the kind of sensation which the French have described as *frémissement cataire*. It is a curious purring; you can feel it as well as hear it. This murmur I do not hear clearly at the apex of the heart, but it grows distinct toward the base, and particularly the right base; the purring sensation conveyed to the hand corresponds in locality with the intensity of the murmur. This murmur is systolic in time, at the aortic cartilage, and is followed by a second murmur which is not of a purring character.

This is a case of aortic regurgitation, the first sound having associated with it a peculiar, musical, purring murmur. Now, as I go down toward the mitral valve, I hear this purring murmur gradually becoming less distinct, although it is evidently transmitted; but I also hear another murmur, of a softer character, which I think denotes the independent existence, or rather coexistence, of mitral disease. However, the preponderance of the murmur here is evidently aortic, and especially the half-musical sounds. Therefore, while we recognize the mitral lesion, the fact of the double murmur, heard at the base and at mid-sternum, indicates aortic disease, and especially aortic regurgitation.

Now, what is the explanation of this peculiar murmur here, and of its musical character? Gentlemen, the cause of this musical sound is that there is a narrowing of the aortic orifice, a stenosis, which at the same time, as I have already said, permits of some regurgitation.

The orifice is not only narrow, but is especially narrow at one portion, where there is a free edge of membrane vibrating in the blood-current, or a fragment of a valve flapping to and fro. Simple obstruction would never give you a murmur like this. A pure aortic obstruction would give you a systolic murmur, as we have a distinct systolic murmur here, but the musical murmur is due to irregular narrowing, with projection of some tense band or fragment into the current. This musical murmur I can also hear along the course of the aorta at the back. I may say that, in the majority of instances, these musical murmurs of the heart have their origin at the aortic orifice.

With regard to the lungs, I now report that the congestion has disappeared. Yesterday the man was sitting up and was not dropsical. To-day there is slight edema of the dorsal aspect of the feet, but it is very slight indeed. The abdominal dropsy has disappeared. The tongue is slightly coated. The abdominal organs present nothing special; the liver, which was large and swollen, is now reduced to its normal size. As regards the condition of the kidneys, the urine is here and it will now be tested. It is neutral in reaction, with a specific gravity of 1018; amber in color, clear, and contains no albumin or casts. This is the same result as the examination of the 25th inst.—two days ago. The temperature has been normal since admission, and, indeed, part of the time has been subnormal.

Now, what is the condition of this man's kidneys? He came in with scanty urine, which was very distinctly albuminous, and which contained casts—some granular and some hyaline. It did not contain blood. That he had some form of nephritis is evident; but what form was it? Now, gentlemen, look back upon the history which is given us from the time of its beginning. The symptoms came on after cold and exposure; the dropsy afterward decreased; then it returned after another exposure; the man again recovered, and was well until the final exposure brought on his present attack. There can be only one explanation. He has had a series of attacks of acute nephritis, but there has been little if any persistent structural disease of the kidney. Of course the inflammation may have been added to by the disease of the heart, which I am satisfied has always existed, or at least for many years. How did the disease of the heart itself begin? I am not sure of this. The history would suggest that it started just as the disease of the kidneys did—as an acute affection following exposure, or it might have been a latent endocarditis. Which it was I cannot say, but we have no evidence of any previous attack of rheumatism. Considering his mode of life this in itself is rather remarkable.

Coming to the question of treatment, what agent has been most useful in promoting recovery? The strontium undoubtedly had the most effect upon the kidneys. The digitalis had a decided effect upon the heart, but the strontium had an excellent diuretic effect. This man's diet was one of milk for the first six days; he was then allowed to have bread, eggs, and vegetables in addition. He shall continue this diet, but may have besides oysters and broths. The strontium shall be kept up for a few days. For his slight bronchial catarrh he may take wine of ipecac 5 minims, solution of ammonium acetate 3 drams, and of syrup of tolu enough to make a tablespoonful, to be given every third hour. This is an expectorant which will promptly cause the catarrh to disappear. As regards his kidneys, they appear to have resumed their normal condition—at least there is at present no evidence of failure to perform their function properly.

ACUTE NEPHRITIS IN A CASE OF CIRRHOTIC KIDNEY.

Case II.—Here is another case from the men's medical ward. It is in a car-conductor, thirty-nine years of age, who came into the hospital on the same day as the preceding case—January 15th. His history is as follows: He had influenza in 1889, and this was followed by renal disease and dropsy, for which he was treated in a hospital for a period of four months. Last spring, or about a year ago, he had an attack which appears, from his account, to have been rheumatic in character. On the 5th of July last he had a third attack of illness, which was accompanied by dropsy, and he was taken to the Orthopedic Hospital, where he was treated for renal disease. He was discharged and returned to work, but has not felt well. In December he had loss of appetite, nausea, pain in the back, a slight hacking cough, and dimness of vision. When he was admitted to this hospital there was no marked swelling of any part of his body, but there was some slight edema of the feet and legs.

On admission his urine was found to be acid, with a specific gravity of 1008, cloudy, of amber color, and contained 8 per cent. of albumin, by bulk, and a few granular casts were found. He was then passing thirty ounces of urine daily. He has been under treatment for twelve days. He has been taking the lactate of strontium only since the 18th, in the same dose as the preceding case, two drams daily, in plain solution. He passed, on the 16th, twenty ounces; on the 18th, twenty-four; and on the 19th, fifty-seven. Note this increase after taking the strontium only one day; the quantity is almost doubled. The strontium, therefore, had a very happy result here as in the previous case. He is now passing forty-one ounces; somewhat subnormal, but still a larger quantity than it was before. There is now no albumin, and no casts have been detected after repeated examinations. The specific gravity has risen from 1008 to 1018, even with the greatly increased excretion of urine. In testing for albumin my favorite method is to acidulate the urine with acetic acid, and then to boil thoroughly; but I always confirm this by other tests, either by overlaying nitric acid with a layer of urine, or by the use of metaphosphoric or of picric acid.

You will see presently why I am so particular about this. If this report is borne out by subsequent examinations, the man is now free from renal affection. Furthermore, he has no disease of the heart. The first sound is somewhat dull and indistinct, but I cannot say that I find a murmur. The second sound is well marked, but it lacks accentuation; it is not what would be called an accentuated second sound.

Now, gentlemen, what has happened to this man? At first, it appears a case exactly like the other one, with attacks of acute nephritis recurring at intervals. But whether it is in reality so or not I would hesitate to-day to give an opinion. This will require at least another week of observation. I hesitate to say whether it is simply a case of acute nephritis, or a case of

acute nephritis superadded to a chronic contracted kidney. I cannot decide this until I have had further opportunity for observation. The low specific gravity (1008) suggests the latter view, and we know that in contracted kidney there is frequently a temporary disappearance of the tube-casts and albumin. In such a case it is only after long observation and repeated examinations have proved the permanent absence of albumin and casts that we can say that the patient has recovered from his renal disease.

There is another thing that suggests this view of the chronic character of the disease. It is the persistent edema. It is true, there is no accentuation of the second sound of the heart, which usually accompanies contracted kidney, nor is there any increase in the size of the heart, which we see in chronic forms of nephritis; the tension of the pulse is, however, somewhat increased.

What shall we do for him at present? The dropsy has nearly gone, the albumin and casts have disappeared. I will give him Basham's mixture (solution of iron and ammonium acetate), half an ounce three times a day. This will act as a tonic and keep up the urinary secretion.

CIRRHOTIC KIDNEY.

I will now show you another case of chronic nephritis:

CASE III.—This man, John D., a hostler, is fifty two years of age. He had typhoid fever in 1869. One year ago he had dropsy, with suppression of urine, with headache, and other uremic symptoms. He was under treatment in the German Hospital for five months last summer. He then returned to his work, and two months ago noticed that his legs were again swelling; his face also was swollen at times. He had indigestion, slight cough, was constipated, and had scanty urine, which was dark in color. It had a specific gravity of 1007 on admission; no tube-casts were found, but there was 46 per cent. of albumin by bulk. He had the characteristic pale, puffy face of a victim of nephritis. To be brief, I will say that he was put on the lactate of strontium, thirty grains four times a day. The amount of urine, which on admission was only forty ounces, was soon greatly increased; the albumin has decreased 40 per cent. He has been under treatment only for ten days.

There can be no doubt, from the history, the man's appearance, the low specific gravity of the urine, and the large amount of albumin, that he has a chronic form of renal disease, and not, as in the other cases, an acute attack. I also point out to you the fact that there is very little dropsy in this case, and what there has been has disappeared since he came under treatment. The man also had the strontium in the same dose as the other cases. He has cardiac palpitation, a certain amount of increased tension of the pulse, and a decided accentuation of the second sound of the heart, which, taken in conjunction with the other symptoms, leads me to conclude that we have here a case of contracted kidney. In this case there has been less improvement under the remedies employed than in the others.

I must confess, in the main, that what I have shown you to-day of the effects of the lactate of strontium in cases of nephritis only confirms my previous observations with this agent. The salts of strontium are valuable as diuretics in renal affections, and they are particularly valuable in the acute forms, but do less good in the chronic forms. They do not, according to my experience, act so much upon the structure or tissues of the kidneys as they do upon its secreting function. They are admirable diuretics. The claim that has been made by some French clinicians that strontium salts markedly reduce the amount of albumin in the urine has not been fully confirmed in my experience, except that the relative proportion of albumin is greatly reduced by the great increase in the quantity of the urine secreted. There is, however, some slight diminution in the amount of albumin, as well as increase in the quantity of the urine, especially in the acute forms. Whether in the parenchymatous and interstitial renal diseases these salts act beneficially upon the diseased or degenerated structures, or simply act as diuretics, has not been finally settled; but they certainly accomplish more good in the acute than in the chronic forms of nephritis.

To return to our patient, in treating this case we need pay less strict attention to restricting the diet than in the other cases. This man may have meat and vegetables, and a nourishing diet, avoiding indigestible and highly seasoned articles of food. For his treatment now he shall take bichlorid of mercury, grain $\frac{1}{30}$, in a wineglassful of water three times a day, as a tonic to improve his tissues. This will be the treatment in this case, except that we will see with the aid of the lactate of strontium that the urinary secretion is kept free.

I have shown you this morning, gentlemen, cases illustrating different stages and forms of nephritis, which also show the effects of a valuable remedy in the treatment, especially of the acute forms of the malady.

CLINICAL MEMORANDA.

A CASE OF HERPES ZOSTER SHOWING ERYTHEMATOUS, PAPULAR, AND VESICULAR STAGES.[1]

BY J. ABBOTT CANTRELL, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE SKIN IN THE PHILADELPHIA POLYCLINIC; DERMATOLOGIST TO THE PHILADELPHIA AND ST AGNES' HOSPITALS.

IT is in rare instances only that the physician has the opportunity of witnessing herpes zoster other than in the vesicular stage, and in still more rare instances that he has the opportunity of following the eruption through the stages seen in the report of the following case, which appeared at my clinic, and which showed an erythematous, a papular, and a vesicular stage.

On March 22, 1894, W. M., a female, sixty-six years of age, an Italian by birth, had been in this country for the past two years. She is a small, aged-looking person, and apparently not in the best of health. She received a fall about ten years ago, hurting the right knee, since which time she has been unable to flex the joint. She had six children, the youngest of whom is thirty-three years of age and the eldest in his forty-eighth year. She

[1] Read before the J. M. Da Costa Medical Society, April 6, 1894.

states that they are all in good health. The disease for which she applied for relief began one week before. The lesions were confined to the right arm and forearm and over the scapular region. About one week before her visit she had complained of shooting pains in the arm, which were followed by an erythematous eruption which occupied the same points as were then attacked. Upon examination I found that slightly above the right thenar eminence, at the bend of the elbow, and on the antero-external face of the upper third of the arm, the lesions seemed to be distinctly vesicular, with a decided inflammatory border far beyond the vesicular lesions. Slightly below the elbow-bend—for instance, two inches—and the same distance above this point, directly in the median line, there were patches decidedly erythematous, with one vesicle in the center of each. On the antero-external face of the upper third of the arm there was a patch, two inches in diameter, which was erythematous, pinkish-red in color, in which the lesions had not as yet shown any vesiculation, although on passing the finger across them there seemed to be elevations and depressions as though the lesions were still *sub cutis*. On the external surface of the scapular region just below the spine there was another patch about 1.5 inches in diameter, which was erythematous, although not as red as the foregoing lesions; there were no lesions apparent in this patch, although when passing the finger across it there seemed to be three or four points that resembled papular formations, which also appeared to be as yet beneath the cutis. On the inner face of the upper third of the arm, just below the axilla, and not affecting the axilla proper, there was a patch three inches in diameter, of a yellowish-pink color, the feeling being about the same as that upon the general surface of the unaffected skin. This patch was not raised above the surrounding skin, and was somewhat irregular in outline.

The patient complained of great pain over the affected region, and especially if she happened to lie upon the arm of that side. An interesting point is that while the eruption had lasted one week the severe pains had not been present until three days before, although she had had slight stinging sensations prior to the appearance of the eruption. All the lesions followed the outer branch of the brachial plexus from the shoulder to the wrist.

On March 23d the patch over the thenar eminence remained about the same, those near the bend of the elbow and those above and below this region also remaining the same. The patch on the upper inner third of the arm just below the axilla seemed to be approaching the color of the normal skin. The patch on the upper antero-external third of the arm was covered with decided vesicular lesions, apparently as yet raised but slightly above the surface of the skin. The patch near the shoulder and just below the spine of the scapula did not appear to have the peculiar halo of inflammation witnessed the day before, the lesions of this patch remaining papular. The inflammatory condition of all the lesions did not appear so distinct as then. The pain seemed to have more of an itching character than of a neuralgic nature.

On March 24th the patch below the axilla, and which was at the last note approaching the normal color of the skin, had now entirely disappeared. Those immediately above and below the bend of the elbow were very much better. The lesions which were in the center of each of these had dried and become flattened, apparently without contents. The patch over the scapula had lost all of its heightened color, but the papules could still be felt on passing the finger over the region. The patch on the antero-external aspect of the upper third of the arm was covered with characteristic vesicles. The lesions in the other patches were more dry and seemed to be very much better. The pain was not present, and the patient slept during night, which she had not done for about one week.

On March 25th the pain was more severe than on the previous day. The lesions on the patch on the anterior lateral face of the upper third of the arm appeared to be fading; those at the bend of the elbow were still more dry; those on the scapular region were papules as yet, though tipped with vesicle-like formations. The patch on the upper outside of the arm was crusted. The lesions on the patch directly in front of the humerus were umbilicated and resembled very much the wheals of urticaria, although possibly not so reddish in color. The lesions elsewhere were also umbilicated and some were covered with a blood-crust at the summit.

The lesions near the thenar eminence contained a sero-purulent fluid, instead of serum, as usually found in lesions of this character. The halo of redness approached the normal color of the skin—that is, more of a yellowish-white. The pain followed the course of the ulnar nerve. The lesions were as yet distinct in places, and in others appeared to have coalesced, looking as if they had run together.

On March 28th the pain had entirely stopped and the patient was perfectly comfortable, and could sleep at night without danger of rolling on the affected parts. The lesions have almost dried up in their entire extent; those at the bend of the elbow were the only prominent ones; those on the anterior outer lateral face of the upper third of the arm looking more like enlarged papillæ (the so-called lichen pilaris) than anything else. The lesions of the thumb have entirely disappeared and the other lesions have likewise become indistinct. On March 31st the patient appeared at my office, at my request, and it was found that the lesions had entirely disappeared.

We thus have a condition of the skin prior to the formation of either papules or vesicles. This condition, properly an erythematous or macular stage, was shown in all the conditions prior to the visit of the patient, and, at her visit, in that portion of the arm on the inner surface just immediately below the axilla. Upon examination, this patch was found to about three inches in diameter and not raised above the surrounding healthy skin; the edges, while showing a distinct line of demarcation, were irregular in outline. To the touch, the parts felt exactly like that of the normal and unaffected skin; the color was not of that pinkish-red observed in the other lesions, but was more of a yellowish-pink.

Following the writers of to-day, I am unable to find but one reference to a condition of this kind as having existed with or being noticed prior to the formation of papules or vesicles; this is by Dr. James Nevins Hyde, quoting Fabre (*Text-book*, 3d ed., 1893, p. 246) in the following words: "The essential lesion, always present even when the vesicles are not seen, is the first macular

efflorescence of the disease. This appears in the form of vivid and brilliant-red erythematous macules, groups of which, from six to ten in number, appear in the tract supplied by the affected nerve. The vesicles (which are generally regarded as more characteristic of the disease) appear afterward in from a few hours to a day or more, spring from the macules, and are accompanied with a sensation of heat."

Previous to the foregoing, I find that the works of Anthony Todd Thomson (*Text-book on Diseases of the Skin*, 1850, p. 250) contain the following, which I here quote in the author's own words: "Heat, tingling, or acute pain, which continues for hours, days, and occasionally weeks, when it suddenly vanishes with the appearance of several red, irregular-shaped patches, at a small distance from one another, scarcely elevated above the skin, and upon which are rapidly developed numerous minute transparent vesicles, the greater number clustered together, but a few distinct."

Taking the words of these two writers, therefore, we do not find that the conditions present in the case I report are thoroughly brought out by them, and that the following description of the disease would perhaps come nearer stating the appearance of the disease throughout its entire course:

Herpes zoster appears at first as an erythematous redness, scattered in macules of irregular size over the course of the affected nerve; this remains for an indefinite time, when it is followed by the formation of papules upon these erythematous bases, which in turn, quickly or slowly, completely change into vesicles; the condition may or may not be preceded by any sensation of pain.

In further search through the literature of the subject I find that in my case there is a difference from the statements of Hebra (*Text-book: New Sydenham Society*, vol. i, p. 374, div. 1), who says: "I may also remark in this place that the first-formed clusters of vesicles are always nearest the nerve-centers, and that those which subsequently develop lie more toward the remote peripheral distribution of the corresponding nerves." The same writer also, in speaking of herpes zoster brachialis, states that the vesicles first appear opposite the fifth, sixth, or seventh cervical vertebra, and then so on down the arm. In my case the first-formed vesicles were remote from the center of the affected nerves—that is, the vesicles first formed were at or near the elbow, and the later lesions were in or about the locality mentioned by the preceding writer, namely, the fifth, sixth, or seventh vertebræ.

One other question arises in the study of this case, put by Thomson (*Text-book on Diseases of the Skin*, 1850, p. 251) in the following words: "Is it inflammatory or nervous?" In answer to this, he states that Rayer (*Text-book*, 1845), from having observed that it follows the direction of the intercostal nerves, regards it as nervous, and that he accords in the same opinion. Of late years it has been customary with writers to give this credit to Bärensprung, but it appears that this writer, while he did more to connect this disease with the nervous system, did not complete his observations until 1861, sixteen years after the time of Rayer.

Another interesting point in the case here reported is that the disease did not at every point go on to the formation of vesicles, but that at some places it seemed to abort at the erythematous stage and others in the papular stage, while still others went on to the vesicular stage. Of the many writers on the subject of herpes zoster, only two, namely, McCall Anderson and Allen Jameison (*Text-book*, 1892, p. 146) speak of the condition aborting in the papular stage, and not any that I am able to find speak of the condition aborting in the erythematous stage.

SPONTANEOUS RECOVERY FROM CONGENITAL CLUB-FOOT.

BY JAMES K. YOUNG, M.D.,
OF PHILADELPHIA;
INSTRUCTOR IN ORTHOPEDIC SURGERY, UNIVERSITY OF PENNSYLVANIA.

So rarely does spontaneous recovery occur from congenital talipes equino-varus that the history of the following case, related to me by Dr. J. Wellington Byers, of Charlotte, N. C., is worthy of recording.

The case was one of severe double talipes equino-varus. From an examination of the case, April, 1892, the following history was elicited:

"The patient is a male negro, thirty-six years old, with congenital double complete talipes equino-varus. At birth, the toes of both feet touched the heels. The child walked first at five years, and wore its first pair of shoes—heavy, thick ones—at thirteen years of age. He walked on the sides of his feet, the toes being still in the same position as at birth. Up to the age of twenty years he continued to stand and walk on the sides of his feet, lifting one foot over the opposite. At the age of twenty-six years spontaneous improvement was noticed in the right foot, which has gradually progressed until now, when the entire foot and leg are normal in size, shape, position, and function. The left foot is still slightly turned in—pigeon-toed—though the man stands flat on the foot, the only abnormal features being a small leg and slight contracture of the extensor tendons on the dorsum. Improvement is yet constantly going on, and a complete cure appears to be only a question of time."

After a careful and painstaking research, extending over a period of two years, but one similar case of spontaneous recovery has been discovered, and that is the unilateral case referred to by Baron Dupuytren, in his "Lectures upon Clinical Surgery." [1]

"This deformity," he says, "is sometimes cured without the assistance of art. A case is related by Dr. Holtz, of a boy, born of indigent parents, with a very well-marked inversion of the foot. Without any attempt at treatment he was perfectly free from the deformity at twelve years of age. He endeavored himself to turn his foot outward, and as he was obliged to work hard and carry heavy burdens, he was forced to lean heavily on the ground. Exercise restored the equilibrium of muscular action, and now, at the age of twenty years, he would not be supposed to have ever suffered from club-foot."

It is the rule, almost without exception, for cases of congenital club-foot (talipes equino-varus) to grow progressively worse without treatment, and every surgeon knows how prone cases of club-foot are to relapse unless

[1] "Lectures upon Clinical Surgery," Register and Library of Med. and Chir. Sci., p. 201. Washington, 1835.

carefully treated subsequently to operation. So well recognized is this fact that the rule is now established to always slightly over-correct the deformity in manual, mechanical, or operative methods, so as to allow for this tendency to return to the deformed position after the curative means have been removed. The most important factor in preventing relapse is walking with the sole of the foot firmly planted upon the ground, and it is interesting to observe that in both of these instances recovery did not commence until the patients walked.

In the first case the occupation and efforts of the patient were favorable toward recovery, but in the second case the recovery appears to have occurred spontaneously. Moreover, the former case was unilateral, so that the patient was at a great advantage in setting the foot flatly and applying his body-weight and the weight of heavy burdens upon it. With this advantage it will be observed that the first case "was perfectly free from the deformity at twelve years of age," whereas, at twenty years the second case walked with one foot over the other, and recovery did not begin until twenty-six years of age. It is possible that in this case there was an inherited (racial) tendency to relaxation of the plantar fascias, plantar muscles, and the peroneal muscles; and what, had his feet been normal at birth, would have resulted in a condition of acquired valgus, in the event of the occurrence of double congenital equino-varus, resulted in restoring the feet to their normal relations.

Both cases illustrate forcibly how slow to overcome deformity Nature is, in that as many years were required to accomplish what the surgeon could have accomplished in so many minutes by operative means, or in as many months by mechanical means.

It also illustrates that treatment should begin very early, as Dupuytren pointed out before, referring to this case. It is my belief that treatment should commence at birth, and be continued until a perfect cure has been accomplished.

A CASE OF CHOREA DURING PREGNANCY.

By THEO. G. DAVIS, M.D.,
of Bridgeton, N. J.

As so few cases of chorea are met during pregnancy, especially of the grave character called by Osler *chorea insaniens*, I am led to report the case of C. B., twenty years and ten months of age, physically healthy, mentally deficient, but not an imbecile or idiot.

There is an uncertain history of slight chorea during infancy, but none since. The woman has menstruated regularly since fourteen; she was married four months ago, and menstruated once since.

I was consulted at about the third month because of constipation, nausea, vomiting, sleeplessness, and nervousness. I found the patient irritable and surly in disposition, with choreic movements of the body, arms, and head; the urine scanty, very albuminous, and containing phosphates and urates in great excess. There was a slight rise in temperature, and slight edema of the feet and eyelids.

Proper diet, purgatives, and rest in bed were prescribed, but the chorea became rapidly worse. She could not stand or sit, nor could she feed herself or drink; when drink was offered the cup was seized by the teeth and the contents swallowed with difficulty. The head, face, eyes, lips, arms, hands, body, and legs were constantly in motion. She beat and pounded her body and abdomen, thrashed about on the bed, and excoriated and bruised her extremities. The urine was passed in bed from inability to sit on the vessel or commode, even with help, so violent were the movements.

Gelsemium in large doses did some good. Arsenic was not given on account of the renal complication. Cimicifuga, bromids and chloral were used without effect, and hyoscin proved useless. Morphin in quarter-grain doses hypodermatically would cause sleep for a time, with cessation of the movements, but they were renewed on awakening. The woman would try to answer questions, but was unable to control the vocal apparatus except to blurt out monosyllables. The heart was regular during sleep, but rapid and choreic during waking, and the pulse rose to 120, the temperature to 102°.

Medication being without effect and the patient growing rapidly worse, seeming like an insane person at times, abortion was advised, and after consultation, and with the assistance of Dr. Mailly, chloroform was administered, the os forcibly dilated, and the uterus emptied, proper asepsis being observed.

Ergot and morphin were given hypodermatically. The flow from the vagina was normal and without odor. The patient now rested more quietly, took nourishment, and seemed better; the choreic movements were much less, but during an attack of chorea the woman expired by syncope, twenty hours after the abortion. No post-mortem was allowed.

MEDICAL PROGRESS.

Rupture of the Uterus, with Recovery.—Dohrn (*Centralbl. f. Gynäkologie*, 1894, No. 11, p. 250) has reported the case of a multiparous woman, forty-one years old, in which in labor at term, the child occupying a transverse position, rupture of the uterus occurred in the course of attempts to bring about version, external pressure being conjoined with the internal manipulation. A dead child was finally extracted, and the woman, with the placenta unexpelled, sent quite a long distance in wintry weather to a hospital. Here the external genitalia were thoroughly disinfected with a 5 per cent. solution of carbolic acid, the vagina swabbed with mercuric chlorid, and finally well irrigated with a 4 per cent. solution of boric acid. Examination now disclosed the existence of a large tear involving the left side of the cervix and the vaginal vault, and in which lay loops of intestine and the placenta. The latter was removed without inducing noteworthy hemorrhage. The vagina was then packed with iodoform-gauze and an abdominal bandage firmly applied. The hemorrhage now ceased entirely and the patient revived under the use of stimulants. There was no evidence of internal hemorrhage and further interference was deemed uncalled for. Six days later the iodoform-gauze was cautiously removed; though saturated with lochial discharge it was free from odor. The anemic condition improved from day to day, and after temporary and moderate elevation of temperature and an attack of pneumonia, the woman was dismissed in good condition thirty-eight days after the un-

fortunate occurrence. A large cicatrix remained on the left side of the cervix and the vaginal vault, in consequence of the traction exerted by which the uterus was fixed and deviated to the right.

The Relation of Phlegmasia Alba Dolens in Typhoid Fever to Typhoid-bacilli.—HAUSHALTER (*Rev. Méd. de l'Est*, Sept. 1, 1893; *Rev. Int. de Bibliographie*, 1894, No. 2, p. 17) notes that the point of departure of venous thrombosis is to be found in an alteration of the lining membrane of the vessel, and that in some diseases this alteration may be due to microörganisms constituting a secondary infection. A case is reported that goes to show that phlegmasia may be due directly to the action of typhoid-bacilli. A girl, twenty-one years old, died in the sixth week of an attack of typhoid fever, and upon post-mortem examination a fibrinous clot was found in the left crural vein, extending from the apex of Scarpa's triangle to the iliac vein. Bacteriologic study of the walls of the vein and of the clot, as well as of the liver and spleen (which contained two small abscesses), disclosed the presence exclusively of typhoid-bacilli. The phlegmasia was thus the seat of an unusual localization of the bacilli, either from the formation of a bacillary embolus at the time of resolution of rose-spots or from infection of the walls of the vein by direct contact with an adjacent lymphatic gland, itself contaminated by the backward stream from the lymphatic glands of the abdomen.

Menstruation and Ovulation.—From a rather extended histologic study, LEOPOLD and MIRONOFF (*Archiv für Gynäkologie*, B. xlv, H. 3, p. 506) conclude that menstruation, *i. e.*, the periodic discharge of blood from the uterine mucous membrane, is usually accompanied by ovulation, although the former not rarely occurs without the latter. The hemorrhage depends upon the presence of the ovaries and an adequate degree of development of the uterine mucosa, and not upon the maturation and rupture of ovisacs. Ovulation occurs as a rule at the same time as menstruation; the process requires an increased afflux of blood to the generative organs for several days, and results in the formation of a typical corpus luteum. Ovulation may also occur independently of menstruation, though under physiologic conditions but rarely. At times ovulation, with the formation of a typical corpus luteum, is replaced by an afflux of blood to an ovisac that has not matured and does not undergo rupture, resulting in the formation of an atypical corpus luteum. Normal ovisacs may be present at a time when the ovaries are undergoing senile contraction, and they may undergo physiologic rupture and form typical corpora lutea.

Phenol-elimination in Disease.—As a result of a clinical and analytic investigation into the elimination of phenol in disease conducted at the clinic of v. Jaksch, at Prague, STRASSER (*Zeitschrift f. klin. Medicin*, Band xxiv, Hefte 5, 6, p. 543) has reached conclusions that agree essentially with those arrived at by previous investigators, the amounts found, however, being greater. Thus, an increase was found in the course of acute infectious disease (*e. g.*, in the first and second weeks of typhoid fever, pleuro-pneumonia, pneumonia in the stage of resolution); also in all cases of local suppuration or gangrene (*e. g.*, pyo-pneumothorax, putrid bronchitis, gangrene, peritonitis); finally in diabetes mellitus. Normal amounts were found in cases of cystitis, leukemia, and typhoid fever eight days after defervescence; diminished amounts in cases of chronic anemia, of typhoid fever during the period of defervescence, of intestinal obstruction attended with persistent vomiting, of acute phosphorus-poisoning, and of hypertrophic cirrhosis of the liver. The elimination of indican, as well as the variations in the relation between the ether sulphuric acids and the preformed acids, showed no correspondence with the variation in the amounts of phenol.

Relapses in Typhoid Fever.—From a careful study of fifty consecutive cases of typhoid fever with relapse, obtained from the records of Guy's Hospital and from other data, STEWART (*Practitioner*, No. 309, p. 184) arrives at the conclusion that so-called relapses are genuine second attacks, presenting all the phenomena of the first attack and due to reinfection of the large intestine from the small. This reinfection is believed to generally take place at a definite period in the original attack and is probably effected by the passage of sloughs over healthy lymphoid follicles. Constipation was found to be an important predisposing cause of relapses. The opinion is expressed that the prognosis of relapses is good because a certain degree of immunity has been acquired by reason of the first primary attack, and fatal complications are less common.

THERAPEUTIC NOTES.

The Treatment of Carcinoma with Thallin Periodid.—MORTIMER GRANVILLE (*Lancet*, No. 3680, p. 639) maintains the utility of periodotetrahydroparamethyloxychinolin (thallin periodid) in the treatment of carcinoma. He has given the drug in doses of four grains, in pill-form, with a grain of musk, or one-twentieth of a grain of pilocarpin hydrochlorate, if the skin was dry and inactive, every second or third hour, and nothing else. One of the earlier signs of improvement noted has been a better color of the skin. In some instances there was darkening of the urine, but in none disturbance of the stomach or debility. It is theorized that the effect produced is a destruction of the locally proliferating and the wandering leukocytes.

For Pulmonary Tuberculosis.—

HYPNOTISM AND SUGGESTION IN PRACTICE.

Whether hynotism be itself a hysteric manifestation and adapted only to a restricted class of cases, as taught by Charcot and his followers, or a pyschic condition physiologic in character, and therefore capable of therapeutic application in many diverse conditions, as believed by Bernheim and the Nancy school, it remains a fact that the instances of its successful clinical use are rapidly increasing in current medical literature. Nearly a generation ago, Esdaile in India employed hypnotism as an anesthetic agent, and reported some twelve hundred surgical operations performed with its aid. It is probable that the introduction of ether and chloroform diverted attention from this valuable resource by rendering it unnecessary under ordinary circumstances; but from time to time cases are reported which show that under unusual conditions or in exceptional cases it still remains a resource which is not to be despised.

It is probable that the method of producing temporary anesthesia by rapid respiration, as introduced by Dr. Bonwill, may be explained, in great measure at least, by hypnotic suggestion. Even in the administration of ordinary anesthetics, operators occasionally see instances of rapid anesthesia which are clearly hypnotic in character. Some years ago, a physician of Philadelphia, Dr. Barr, described a method of administering ether in obstetric cases in which he succeeded in inducing a state of partial unconsciousness, during which he would describe an imaginary excursion or a drive in the Park, which the patient would afterward refer to with expressions of pleasure, and also with astonishment that she had felt none of the pangs of labor. This was undoubtedly a mixed anesthesia of ether and hypnotism, and is analogous to other instances reported from Europe, in which hypnotism alone was used in parturition with the same happy effects.

To the instances of use in surgery and obstetrics must be added numerous medical cases in which equally good results have been obtained.

A case in point is furnished by an article in the *Australasian Medical Gazette*,[1] furnished by Dr. Creed, in which the symptoms of asthma were entirely relieved by hypnotic suggestion. The patient, proving rebellious to ordinary treatment, all the ordinary remedies being tried without relief, was hypnotized daily for ten days and appropriate suggestions made. On the third day he was much relieved, and after the tenth, became entirely free from dyspnea, and he could then walk with considerable speed, without respiratory distress. It was found that he still had occasional modified attacks of asthma, and he was accordingly provided with a written order to sleep when he read it, and to wake up after five minutes, breathing freely. The report states that this was entirely successful; that the patient always carries his prescription with him, and that it never fails him. What makes the case of still greater interest is the supplementary statement that there are numerous polypi in both nostrils, which have not been removed for fear of making the cure by hypnotism questionable. Such an instance of therapeutic devotion and self-denial on the part of the attending physician is remarkable, and would hardly be matched in this country, where the polypi would undoubtedly have been removed early in the history of the case, and certainly before concluding that "all" the ordinary methods of treatment had been employed without affording relief.

Therapeutic suggestion has also been used in overcoming bad habits and vices, and some valuable results have been recorded. The noteworthy report of Dr. Bushnell (The Medical News, March 31,

[1] Abstracted in Boston Medical and Surgical Journal, April 5, 1894.

1894) is a valuable contribution to this aspect of the question. It is possible in the cases in which genuine and lasting reformation of inebriates has been obtained through the so-called "gold-cures," that suggestion has been called into play with good effect. It is indeed very probable that, among those persons who are addicted to alcohol, many of whom are degenerates and of highly neurotic character, hypnotic suggestion may have a very fruitful field to work in, especially as results have been reported of its successful application in such cases, in which a distaste for liquor has been produced by this means, in subjects who had previously been confirmed drunkards. Sexual abnormalities, such as onanism, spermatorrhea, and impotence, have been successfully treated in this way, and erotic dreams have been banished. BRAMWELL has reported a case of anemic amenorrhea in a young woman, in which the menstrual function was restored upon the day appointed during a hypnotic séance. A very excellent review of the subject was made by DR. FREDERICK H. GERRISH, in an address read before the Maine Medical Association last year, in which his experience in nearly fifteen hundred instances of the remedial applications of hypnotic suggestion is detailed with much discretion and judgment.

Finally, the minor applications of suggestion are of daily utility in practice. DR. RUSH said that he had always stopped to explain to his patients the results which he expected to obtain from the medicines that he prescribed, and that he had found great benefit from this course. We know, at the present day, that expectant attention exerts powerful physiologic effects, and by adapting this in his therapeutics the careful physician is frequently able to score a decided advantage over the mere routine prescriber.

EDITORIAL COMMENTS.

To "Elevate to a Pure and Ethical Plane," etc.—We have before us a remarkable circular which well deserves the notice of the American medical profession. It is called a *Prospectus of the American Physicians' Sanitarium Association*, and sets forth a scheme that it says is *under the charge and indorsement of the regular profession, and on purely ethical lines*. It would, perhaps, more properly be termed "Keeleyism within the Profession," or, "The Commission-business in Medicine."

The circular is signed by nobody, and the composition of the company or association is in no way indicated. But the anonymous company assures us that it has acquired "by purchase of hitherto secret" (the *hitherto* italicized—the synchronous "wink" not shown!) "but thoroughly tested and proven remedies, etc." But this is not enough! Each physician "in good standing" (why the restriction?) who shall send a patient is to receive a ($100.00) share of the capital stock, etc. The object, to be sure, is "to reap the rich harvest of profit now almost wholly diverted to quackery," "to rescue from disrepute and consequent 'unfaith,' and to *elevate to a pure and ethical plane* the virtuous principles underlying the successful treatment of narcotic and alcoholic inebriety, etc." "Science," "scientific principles," "afflicted humanity," and the customary glittering generalities are, of course, liberally used.

We advise our readers to secure a copy of this delightful and richly humorous contribution to medical ethics, and to put it under their pillows to dream over. Perhaps the spirit of the Boss Tweeds of medicine may appear to them in their nightmare, asking, with characteristic leer, Well! what are you going to do about it?"

Catalogue of a Good Library.—Physicians are interested in popular libraries, not only as good citizens, but as special conservators of the mental and moral health of the community. A well-chosen collection of books, arranged in a well-ventilated and well-lighted room, and with proper facilities for general use, in and out of the library-hall, is a hygienic establishment of the first importance. We therefore commend to the earnest attention of our readers Document No. 200 of the U. S. Bureau of Education, issued from the Government Printing Office at Washington, 1893, copies of which may be obtained upon request, addressed to the HON. W. T. HARRIS, U. S. Commissioner of Education. This is a catalogue, or, as the learned Commissioner humanely spells it, this *catalog*, of 5000 volumes for a popular library, selected by a committee of the American Library Association, MARY A. CUTLER, chairman. The collection was shown as part of the U. S. Government Exhibit at the World's Columbian Exposition.

The catalogue is of great value, not only for the titles, but also as a model of clear arrangement; and the directions given for choosing, purchasing, arranging, and indexing books will be useful in private collections as well as in public ones. Naturally we should have desired a larger representation of good, popular health-books, such, for example, as B. W. RICHARDSON'S "Field of Disease," "Preventive Medicine," or "The Common Health," and the admirable series of "Health Primers," edited by W. W. KEEN. However, the few books chosen in this department are good, and the work as a whole, in idea and in execution, confers the greatest credit upon all concerned.

The Home Missionary Society.—Among the most worthy institutions of our city is the Home Missionary Society, the demands upon whose resources have been particularly heavy during the past winter and so continue with little-abated urgency. The society endeavors to afford relief to the unemployed, the poor, the sick, and special cases, and makes visits to children placed under its care. The society has under its guardianship 373 boys and girls, whose natural guardians either could not or would not provide for them. These children are placed with well-recommended families in country homes where they are educated and trained for lives of usefulness. The work of the society is strictly non-sectarian and is

sustained by voluntary contributions. Mr. William H. Lucas, 322 Race Street, is the treasurer, and will be more than glad to receive money, securities, or real estate.

Dr. N. S. Davis on the Code-Revision.—We commend to the thoughtful study of every member of the American Medical Association the letter of Dr. N. S. Davis in the *Journal of the American Medical Association* for April 14th. The veteran leader, with his accustomed clearness, cogency, and consistent logic, reviews the report of the majority of the Committee on Revision of the Code of Ethics, and fully exposes its retrogressive tendencies. We are glad to be in line with Dr. Davis on this question. Let the watchword of scientific and honorable physicians henceforth be: "*Vote Down Revision!*"

SOCIETY PROCEEDINGS.

THE ELEVENTH INTERNATIONAL MEDICAL CONGRESS.[1]

Held at Rome, from March 29 to April 5, 1894.

The Congress was opened in the presence of the King and Queen of Italy, the principal Ministers of State, the Ambassadors to Italy of the courts of Germany, France, Turkey, Holland, Sweden, and Greece; and of an immense number of members of the Congress, and of ladies and other guests. The ceremony took place in the Costanzi Theater, which was filled an hour before the time fixed for the commencement of the ceremony.

Signor Crispi saluted the members of the Congress in the name of Italy, and expressed the pleasure with which Italians saw such an assembly in their capital. "You labor," he said, "in two different directions for the benefit of humanity; in the one you teach us how to prevent evil, in the other how to remove it. Through hygiene, by purging the air and the earth of poisonous miasma, you preserve the health of mankind; through the use of remedies which cure and give hope, you remove diseases. Thanks to you, cities once unhealthy have become flourishing, and districts once deserted and insalubrious have been transformed into gardens. Rome, the mother of all, gave to the ancient world civilization and law. To-day, thanks in no small part to you, there will go forth from Rome a fertile promise of peace—peace which is the necessity and hope of the modern world, peace which will be made the more sure by this International Congress, which is a sign of the brotherhood and of the oneness of nations."

Prof. Baccelli, President of the Congress and Minister of Public Instruction, then spoke in Latin. Among other things he said:

The great difficulties which necessarily attend the civil and political new-birth of a nation render the dearer to Italy the pledges of good-will and of honor which she has received since she has attained her unity and reconquered her rights. Last year to the festival at Genoa the peoples of nearly all the world sent their navies to render a well-merited honor to Christopher Columbus, an Italian citizen. To-day they have sent to Rome men learned in the biologic sciences in order that the bonds which unite us may be drawn the more tightly in the interest of the public good. The learned who have come to Rome will remember that in ancient times the most distinguished public men cultivated *medicina politica* (hygiene), which the ancients esteemed highly, to which Cicero and Cato bear abundant witness. I greet you, then! You are welcomed with joy by this classic land, where the breath of liberty has survived the memory of the ancient greatness of its people. Here no one is a stranger; here, where every country finds some remembrances of its past, where all the human race forms one great family, may each one of you in thought and act seek the preservation of nations and the health of mankind. Then will the maxim of our ancestors shine through you with a new brilliancy: "*Salus populi suprema lex esto*," et "*nulla re magis homines ad Deos accedere quam salutem hominibus dando.*" . . . I am proud to be able, in the name and by the wish of the King, to declare the Eleventh International Medical Congress open in Rome—*Undecimum omnium gentium de medicina conventum, hodie, Roma auspicatur.*

Prince Ruspoli, syndic of Rome, then welcomed the Congress in the name of the city of Rome. In all ages, he said, physicians had been treated in Italy with universal respect. Augustus decreed that they should be Roman citizens, and at court, in the army, and in the communes a distinguished place was reserved for them. The earliest scientific congress met in Rome, and it was then that the conflict between science and prejudice began. In the time of Cæsar a great scientific congress met in Rome to discuss a proposal for altering the course of the Tiber. The governing class then rejected all proposals with the famous epigram of Pisonius: "*Nil mutandum.*" Since that epoch circumstances and habits of thought had changed, and Rome welcomed this Congress of scientific men with heartfelt gratitude.

Prof. Virchow, speaking in Italian, referred first to the history of the struggles by which Italy had attained to unity. The last Congress, in choosing Rome as the place of meeting of the Eleventh, had desired to pay homage to the ancient traditions and the new glories of Rome. The members had come to Rome as friends and brothers; accustomed as they were always to subordinate their own personal convenience to the wants of others, physicians were the true messengers of peace and humanity.

Prof. Maraglino, the Secretary-General, then made a report on the organization of the Congress, and announced that the total number of papers announced was 2700, and that the number of foreign members was as follows: Germany, 900; England and British Colonies, 700; Austria-Hungary, 700; France nearly as many; 200 from Spain, Russia, Switzerland, and the United States of America, and some 500 others from Portugal, Sweden, and Norway, Holland, Belgium, Turkey, Roumania, Servia, Greece, Mexico, South America, Japan, and Borneo. Thirty-two governments and 425 scientific bodies were represented. There were also a large number of guests, including many ladies. He then called upon the representatives of the various countries, who each spoke a few words: For Austria, Professor Nothnagel; for Belgium, Professor Crocq:

[1] Prepared from advance sheets kindly furnished by the British Medical Journal.

for Egypt, Hassan Mahmoud Pasha; for Denmark, Dr. Salomonsen; for France, Professor Bouchard; for Germany, Dr. von Köhler, of the Army Medical Department; for England, Sir William MacCormac; for Norway, Professor Laache; for Holland, Professor Stokvis; for Ireland, Sir William Stokes; for Portugal, Professor Roche; for Roumania, Professor Severeano; for Russia, Dr. Sklifossovsky; for Spain, Dr. F. Caro; for Sweden, Professor Holmgren.

On the proposition of Prof. Virchow, the President and members of the Provisional Committee were formally elected as president and officers of the Congress. The ceremony, which had lasted an hour and a half, then came to an end.

In the afternoon the Sections assembled in the rooms assigned to them at the Policlinic, and elected their officers.

On the second day, Prof. Rudolph Virchow, of Berlin, delivered an address on "Morgagni and Anatomic Thought." Prof. v. Babes, of Bucharest, delivered an address on "The Position of the State in Respect to Modern Bacteriologic Research."

On the third day Prof. Michael Foster, of Cambridge, Eng., delivered an address on "The Organization of Science." Prof. H. Nothnagel, of Vienna, delivered an address on "The Adaptation of the Organism to Pathologic Changes." Dr. S. Laache, of Christiania, Norway, delivered an address on "Idiopathic Hypertrophy of the Heart, and on Degeneration of the Heart-muscle."

On the sixth day Prof. Giulio Bizzozero, of Turin, delivered an address on "The Growth and Regeneration of the Organism."

On the seventh day Prof. A. Jacobi, of New York, delivered an address entitled "Non Nocere."

Section of Internal Medicine.

Prof. Baccelli was unanimously elected acting President, and Prof. Gerhardt, Prof. Bouchard, Prof. Ziemssen, Dr. Grainger Stewart, and Dr. Dreschfeld were amongst those appointed Honorary Presidents.

Warfringe read a paper upon "The Arsenical Treatment of Pernicious Anemia, Leukemia, and Pseudo-leukemia." In all of these diseases he had obtained excellent results.

A. Murri read a paper upon "Cold as a Cause of Chlorosis," which he considered to be due to some disturbance of the vasomotor centers in the medulla and cord.

Dr. Baccelli announced the death of Prof. Brugrioli, of Bologna.

Prof. v. Ziemssen read a paper upon "The Intravenous Transfusion of Undefibrinated Blood." He stated that the operation was not an easy one, although in experienced hands there were no serious difficulties to be overcome, and the results obtained were excellent. In cases of chronic anemia he considered the repeated injection of small quantities of blood a most valuable mode of treatment.

G. De Luca read a paper, in which he stated that he had produced jaundice by the injection of toluol-diamin.

P. Castellino advocated the treatment of anemia with corrosive sublimate.

L. Carrieri described the supervention of purpura hæmorrhagica in the course of a case of chronic articular rheumatism.

L. Cantu discussed gastric disturbances as a cause of chlorosis.

Section of Pathology.

Prof. Virchow presided.

Prof. Bonomo read a paper on "Glanders," in which he dealt with investigations on the biologic action of the products of the bacillus of glanders. These products varied in their action according to the animals used and the mode of cultivating the bacillus. Rabbits infected with the bacillus of glanders, even when the latter was attenuated, were extremely sensitive to mallein, even when the animals were to all appearances in good health. These poisons gave rise to nodules scattered throughout the organs, and the same results might be obtained in guinea-pigs. Twenty-four horses out of 32 suspected of infection with glanders reacted to mallein, and 17 were found to be infected whilst 6 were not, so that the reaction was not an absolute proof of the presence of glanders. Very small doses of mallein injected in a man suffering from glanders produced typical symptoms of reaction lasting from six to thirty hours, as well as great amelioration of the symptoms and even cicatrization of the nodules. In horses good results were obtained with a mallein prepared from the blood and organs of cats. A cure was effected in one horse which was suffering from typical glanders. The same result was obtained in dogs, whilst the control-animals not inoculated with mallein all died from glanders.

Prof. Virchow spoke of the excellent results obtained in Germany by using a dried preparation of mallein for the diagnosis of glanders.

Dr. Julius Donatti and Dr. Gezza Gara read a paper on "Fever-producing Substances." The fever depends on the kind of microbes which are used, whilst some do not produce any fever at all. With anthrax-products the fever appeared in rabbits on the second day, and lasted four to five days. The same result was produced on sheep, whilst similar results were obtained in horses with the products secreted by the streptococcus. The fever-producing action of the chemic products of the bacillus pyocyaneus discovered by Charrin and Ruffer was confirmed. Extracts of the spleen of animals which had died from infectious disease—for example, swine-fever—proved extremely toxic, and their injection was followed by fever.

Dr. Salomonsen (on behalf of Mr. Frissen) read a paper on "The Treatment of Smallpox in a Red Room." The author stated that suppuration was prevented by this treatment, and no scars were produced. He based his treatment on the fact that in 1830 Picton showed that darkness had a favorable effect on the course of smallpox, and also on the experiments of Charcot and Hamer, Unna, Malakoff, and others. Four physicians tried the treatment, and only one (Juhel Rénoy, of Paris) was dissatisfied. Four non-vaccinated children, at Bergen, by this method showed no fever and no suppuration. At Copenhagen, eleven patients were so treated, with similar results. Another physician obtained the same effects, whilst the vesicles which had not yet dried at once began to suppurate when exposed to normal light. The paper was illustrated by several extremely interesting photographs. Great care must be taken that

the treatment should be complete and continued right through the course of the disease.

Babes referred to certain diseases prevalent in Roumania, especially a disease which he calls entero-hepatitis suppurativa, which is not dysenteric in character. It begins by the appearance in the lower part of the ascending colon of small pustules which rupture. There was well-marked edema of surrounding parts which might go on to the formation of retroperitoneal abscesses perforating the intestines, or gangrene of the bowel might follow. This enteritis was always accompanied by an abscess of the liver or necrosis of certain parts of this organ. Amebæ were found in the intestines, but had also been found in ordinary diarrhea, but he did not meet with them after death or in the abscesses of the liver during life or after death. As a rule, the abscesses were sterile, but in some cases various ill-defined microorganisms were present.

Prof. Cornil called attention to Zancarol's work in Egypt, who did not find amebæ in all cases of abscesses of the liver. He considers that no organism has been proved to be the cause of dysentery.

Dr. Kauffmann found amebæ in dysenteric diarrhea in a large number of cases of dysentery, especially when the stools contained blood. He considered that amebæ were the cause of dysenteric diarrhea, and he had also seen them in one case of abscess of the liver. He had noticed that abscesses of the liver might appear one year or more after the dysentery is cured, and an epidemic of dysentery was always followed by an epidemic of abscesses of the liver.

Prof. Virchow said that he had himself showed amebæ in cases of dysentery, but that their etiologic action was uncertain.

A discussion on Carcinoma took place.

Prof. Pio Foa stated that the idea that carcinoma was an infectious disease was as old as medicine itself, but lately facts had been accumulating which placed this idea on a more secure basis. He referred to the observation that in many places carcinoma occurs with startling frequency, and that the mortality in such places sometimes amounted to 15 per cent. of that of the whole population, whilst in other places it fell as low as 7 per cent. Although the cases of actual contagion were few and far between, yet such cases undoubtedly existed. Carcinoma-grafting had also been successful, for, although it was impossible to graft the carcinoma of man on animals, yet the experiments of Hanau and others proved that carcinoma of animals could be successfully inoculated in another animal of the same species. He would now limit himself to the question of the existence of protozoa in carcinoma. This was, in his opinion, an extremely complicated question, as different observers had described as parasites things which had nothing in common with each other. He was of opinion that the parasites described by Darier, Wickham, Podwyssozki and Sawtchenko, Korotneff, and others were simply invaginated cells or products of degeneration. On the other hand, he was of opinion that the structures described by himself, Ruffer, Plimmer, Soudakewitsch, and others had the characteristics of parasites. These parasites all gave the same reactions, and consisted of a central corpuscle or nucleus which did not stain with basic anilin dyes, surrounded by a variable amount of clear protoplasm, the whole being enclosed in a distinct capsule. He confirmed the observations of Ruffer and Plimmer as to the distribution of these parasites in carcinomatous tumors, and called attention to the fact already detailed by the same observers, namely, that the larger and more cystic forms occurred in the center of the carcinomatous tumor, and the smaller ones at the periphery. He had seen several such large parasites form together, and he thought that the multiplication of parasites might occur by the breaking up of the nucleus into small round bodies, though he did not consider this interpretation to be absolutely certain. He had seen the figures of division as described by Ruffer and Plimmer, but was not satisfied that their interpretation was the correct one. He concluded by saying that there undoubtedly existed in carcinoma certain well-defined bodies which were easily recognizable, which had characteristic staining reactions, and which could be easily distinguished from cellular invaginations and degenerations. The lecture was illustrated by some beautiful specimens stained with saffranin, hematoxylin, and orange.

Prof. Trasbot spoke from the veterinary point of view. Carcinoma was fairly common in dogs and horses, but less frequent in cattle; the tumors previously described as carcinoma and sarcoma of cattle having lately been proved to be actinomycotic processes. In dogs carcinoma was common enough, but in a great many cases tubercle of dogs had been mistaken for carcinoma, and hence the so-called successful inoculations of carcinoma in dogs must be regarded with the greatest skepticism, unless controlled by accurate histologic examinations. Personally he had made numerous inoculations of canine carcinoma into other dogs, and had only once obtained a positive result. But in that case even the tumor grew for a few months only, and was then reabsorbed without any metastases forming in internal organs. He was of the opinion, therefore, that carcinoma could not be inoculated from one animal to the other.

Prof. V. Cornil said that he had been working at this subject for some considerable time, but that he was unable to agree with the conclusions contained in Prof. Foà's and Dr. Ruffer's published papers. According to his observations, the nucleus of the carcinoma-cells consisted of two substances which had different chemic affinities: (1) The nuclein, which stained intensely with the ordinary nuclear dyes; and (2) the paranuclein, which stained with protoplasmic dyes. He described how in certain nuclei the hypertrophy of the nucleus was accompanied or preceded by a multiplication of the paranuclein bodies normally present in the nucleus. Parts of the nucleus were then cut off, and formed bodies which, in Dr. Cornil's opinion, were identical with the parasites described by Foà and Ruffer. Dr. Cornil showed a few sections to illustrate his opinion and a large number of beautifully-executed drawings. He did not deny that in all probability parasites were present in carcinoma, but thought that at present they had not been satisfactorily demonstrated. He pointed out that, clinically, there were a great many facts showing that carcinoma could be propagated from point to point by auto-inoculation, as, for instance, from one side of the labia majora to the other or from the lower lip to the upper. He also referred to cases in which, after an exploratory

puncture, carcinoma developed along the track of the needle. He thought there was evidence showing that in certain cases carcinoma could be communicated from one person to the other. He concluded by saying that at the present moment the discussion ought to be narrowed down to the explanation of certain well-defined structures found in carcinoma cells.

Dr. Cazin spoke of the inoculation-experiments which he had performed on dogs suffering from carcinoma. Inoculations into animals of the same species had hitherto proved unsuccessful, except in three cases of non-malignant tumors of the penis. In these three cases he had been able to reproduce the same tumor by grafting it into other animals; but all cases in which he had grafted epithelial tumors had uniformly proved unsuccessful. Graftings from the tumor of a dog to another part of the same animal's body had always been attended with success. He had also performed experiments on rats, which were not yet ready for publication.

Prof. Schrön said that he could confirm the opinions expressed by Prof. Foà, Dr. Ruffer, and others as to the parasitic character of the bodies described in carcinoma, but he was of the opinion that besides these one could trace the evolution of these undoubted coccidia into an adult gregarine. He also thought that in some cases he had seen falciform bodies, and insisted on the necessity of examining fresh specimens.

Morpurgo and Galliotti made references to the minute structure of the carcinomatous body.

Dr. M. Armand Ruffer said that he regretted being opposed to MM. Cornil and Fraenkel, and many other eminent observers, but his researches in collaboration with Drs. Walker and Plimmer had led him to precisely the same conclusion as his friend M. Foà. In all the cases of carcinoma that he had examined he found the bodies which gave distinct staining reactions differing entirely from those of the nuclei of carcinomatous cells. He, with his collaborators, had frequently observed the appearances described by MM. Cornil and Fraenkel, and had even illustrated some of them in his published papers, but he maintained that these appearances differed essentially from the parasites described by Prof. Foà and himself. The reactions of the paranuclein of M. Cornil much resembled those of the nucleus of the carcinoma-parasite; but this parasite, like many protozoa studied by Dr. Ruffer, never contains real chromatin, and he believed that in the pathologic human cell there was no nucleus which did not contain chromatin. Some of the figures of MM. Cornil and Fraenkel resembled very closely those described by Martin Heidenhain in the epithelial cells of the triton helveticus. Dr. Ruffer had also studied phagocytosis in carcinoma, and it was indubitable that the leukocytes penetrated into the epithelial cells, and carried off the parasites which they found there. He had observed this occurrence a number of times in young metastases of the liver and of internal glandular organs. He had not studied the inoculation of carcinoma into animals, but believed that, in order to obtain positive results, it would be necessary to inoculate the metastases, and not the primary tumor; for the grafting of sarcoma only succeeded when one inoculated metastatic tumors. He quite agreed with MM. Duplay and Cazin that the coccidia of Wickham, Korotneff, Podwyssozki, and Sawtchenko, and other observers, were only invaginated and degenerated pathologic cells; he believed that to be admitted now by most observers. With regard to the multiplication of the parasites, Dr. Ruffer had nothing to add to the notes published a year ago by Dr. Plimmer and himself. He believed that little result would be obtained by the usual methods of fixing and coloring, and that recourse must now be had to a new method. He and Dr. Plimmer had for some months past studied fresh preparations mounted in carcinoma-juice; on taking care to lower the condenser and to use an oblique light the parasites could most clearly be seen in the cells, and even the nuclei were distinct. He had even observed movements, which he hoped to be able to photograph later on. If such a preparation be stained with Loeffler's blue, with the addition of a few drops of methylene-green, a very characteristic reaction was obtained; the carcinomatous cell took a dark-blue color, the nucleus of the parasite a pale-pink, with a clear part in the middle, and its protoplasm a light-blue. If one daily examined a carcinoma after removal one could follow all the stages of the degeneration of these parasites, and also certain phases of the life-history of these protozoa, on which Dr. Ruffer hoped to speak on a future occasion. Loeffler's blue was not the only reagent which gave differential staining, for very beautiful preparations had also been obtained with anilin stains, such as eosin, for example.

Dr. Hanau said that with reference to the frequency of carcinoma in dogs and horses, as described by M. Trasbot, the reason for this was probably that horses and dogs were allowed to live to an advanced age, and only killed when age or infirmities rendered them useless; whereas cattle, sheep, and other animals were destroyed for food at an early age, and hence it was not likely that one could have many opportunities of seeing carcinoma in them. He would not give an opinion on the histologic appearances of carcinoma-parasites. He was of opinion, however, that his own successful experiments on rats had shown that it was possible to inoculate carcinoma from one animal to another of the same species; though he did not consider this as a proof of the infectiousness of carcinoma, but rather in the light of a successful transplantation of tissue. He thought there were a great many difficulties in the explaining of carcinoma by the assumption that it was an infectious disease, chiefly owing to the peculiar localization in certain parts of the body, and to the fact that the metastatic growths of carcinoma presented exactly the same structure as those of the parent tumors. He agreed with Dr. Ruffer in thinking that histology had done all it could be expected to do in this question, and that for future work we must trust rather to experimentation and to the observation of fresh specimens.

Dr. Cornil, in summing up, congratulated the Section on the interesting discussion to which the members had listened. He thought it was valuable not only for the facts which had been adduced for and against the parasitic origin of carcinoma, but also because this discussion would serve for future workers as a guide to the points which still remain to be investigated.

Section of Diseases of Children.

The President of the Section, Dr. Blasi, opened the proceedings by giving an address in which, after indicat-

ing the scope of the Section, he sketched the history of pediatrics in Italy. After mentioning some of the earliest observations on embryology, which dated back to the sixteenth century, he referred to the observations of B. da Carpi, who in the early part of the sixteenth century recognized the existence of hereditary syphilis, and of di Aquila of de Vizo, of Genoa, who had discovered the specific treatment; of Curzio, who had studied the phenomena of malaria in children; of Montany, of Venice, who in 1560 had described tetanus neonatorum; of Cortesi, of Bologna, who had first described hydrocephalus; of Carnevale di Rapoli (1620), who had written one of the earliest known descriptions of diphtheria; of Martino Chigi, of Bologna, who had written a stupendous monograph on croup. The list of Italian physicians who from early times had given attention to diseases of children, would, he said, occupy too much time, but he mentioned the names of Bagellardo, of Venice, who in 1481 published a work, *De Ægritudinibus Infantum*, now very rare; and of Mercuréale, who in somewhat more recent times had printed a work entitled *De Morbis Infantum*. Altogether Italy might well be proud of the contributions made to the study of disease in children, and to their relief through the establishment of hospitals, which had been established in most of the principal cities by public or private charity.

A discussion was held on "Diphtheria and Croup."

Prof. T. Escherich observed that there were two factors to be considered in the pathogeny of diphtheria: the resistance of the tissues and the virulence of the bacillus; but that secondary infections by pyogenic organisms frequently determined the clinical character of any particular case. The successful treatment of diphtheria might be grounded on the destruction of the bacilli, on the reduction of their virulence, or on some method of rendering the individual immune.

Prof. Baginsky related the results of a systematic examination of the kidneys in cases of diphtheria complicated by albuminuria and nephritis. This research had shown that the morbid process in the kidneys was a glomerular nephritis attended with considerable desquamation of the epithelium and the appearance of cylindric, epithelial, and hyaline casts in the urine.

Prof. Heubner gave some statistics of diphtheria during three periods, first without the use of anti-diphtherial serum, second with it, and a third period again without it. His general conclusion was that the serum had no influence on the course of the disease.

Prof. Mya read a paper on "The Occurrence of Mixed Infection in Diphtheria," which he had found to be an extremely frequent occurrence. His researches showed that the presence of streptococci did not exercise any apparent influence on the course of the general toxic symptoms, but they had an effect in increasing the rapidity of the process, and in determining the production of albuminuria. The diphtheric infection predisposed the tissues to become the seat of septic pneumonia.

Dr. Luigi Consetti said that for the production of true diphtheria the presence of the bacillus of Loeffler was necessary, though membranous affections due to streptococci might give rise to croup and general symptoms of a severe type. As to the relative frequency of diphtherial laryngitis and non-specific croup, he stated that in 22 children affected with primary croup he had isolated the bacillus of Loeffler in 19. Antiseptic medication was most to be relied upon, especially a spray of corrosive sublimate, which might be used in solutions as weak as 1 in 10,000. Boric acid spray, 2 in 100, was also valuable; also nitrate of silver, 1 or 2 in 30, thymol 5 per cent., and many other antiseptics. A thorough douching of the mouth and fauces with an antiseptic solution was to be recommended when the case was first seen. Mercurial preparations were also of use for internal administration.

Prof. Ranke said that Behring's serum had been tested by himself and Prof. Oërtel in the Children's Clinic at Munich in cases of diphtheria of the pharynx with laryngeal complications necessitating intubation. During recent years the average mortality of such cases had been 37 per cent. The strongest serum was used. The first case recovered, but in the six following cases pneumonia supervened, apparently of a special type and led to a fatal termination.

Prof. Soltmann considered it important to recognize that though under the local treatment recommended by Escherich, the membrane might diminish in quantity, the temperature must be taken as the safest guide, and that the patient must not be considered to be convalescent until the temperature had become normal. He referred to the necessity for disinfection of the mouth, which should be continued after convalescence for at least a week before the patient was allowed to associate with others.

Prof. Malinowski said that he had employed intratonsillar injections with excellent results. Recently he had used aqua chlori, and all the cases so treated had recovered; but when symptoms of croup were present injections did not give good results. Intercurrent pneumonia he looked upon as due to an infection taking place perhaps contemporaneously with the diphtherial infection.

Prof. Heubner had not observed pneumonia after injections with Behring's serum. He referred to the importance of mixed infection in determining the clinical character of an attack of diphtheria, and expressed the opinion that personal predisposition was an important factor.

Prof. Escherich expressed the hope that the treatment by serum might yet be proved to give good results.

Profs. Mya, Baginsky, Rehn, Fede, and Consetti also made some brief remarks.

Dr. Raffaelle Sarra read a paper on "The Local Treatment of Diphtheria by Methyl-violet," which in his hands had not yielded satisfactory results, the rate of mortality being 66 per cent.

A paper on "Intubation and Tracheotomy" was read by Dr. Francesco Egidi, who recommended intubation on the ground that it might be performed at an early date, and that it did not at all prevent, but rather facilitated, the subsequent performance of tracheotomy, should that become necessary.

Prof. Pietro Masucci read a paper on "The Spread of Diphtheria through Schools, Day and Boarding." He thought that every boarding-school should be provided with an observation-ward as well as isolation-wards, and dwelt on the importance of isolating also the attendants on suspicious cases. He spoke in favor of compulsory notification.

Short papers on "The Treatment of Diphtheria" were read also by DR. SZILLAI and DR. GUELPA, and PROFS. COMBY and MASUCCI made some remarks upon them.

A discussion was held on "Rickets and its Relation to Spasmodic Affections."

DR. J. COMBY discussed the relation of rickets to convulsive attacks in children. He found that in every 100 rickety children about 10 had suffered or were still suffering from convulsions more or less serious, and either general or involving only the glottis. The occurrence of general convulsions or glottic spasm did not stand in any special relation to cranio-tabes or rickets. The digestive troubles which preceded and accompanied rickets were responsible for the convulsions which were due to the absorption of toxins from the alimentary canal.

PROF. A. GAMBA, in discussing the "Etiology and Pathology of Rickets," expressed the opinion that the disorder was a constitutional malady dependent on a vice of nutrition, associated especially with an imperfect assimilation of calcium phosphate. Treatment should be mainly hygienic.

DR. CHAUMIER made an elaborate communication founded upon a special mission which he had undertaken at the direction of the Minister of Public Instruction of France for the purpose of studying rickets in Italy. He had arrived at the opinion that rickets was a specific disease produced by a microbe as yet undiscovered. It was contagious, endemic in towns, and sometimes epidemic. It was met with as a spontaneous and epidemic disease among young swine, the osseous lesions being identical with those observed in children. The germs of the disease seemed to be able to exist in houses for a long time, and it was probable that cases of apparent heredity might thus be explained.

DR. NICOLO FEDE had been led to the conclusion that rickets was to be attributed to a disturbance of assimilation, traceable to the absorption of toxins produced by putrefactive changes in the intestinal canal.

PROF. ADOLPHE D'ESPINE considered that the remarkable researches of Escherich on tetany in infants had proved the frequent existence of nervous hyperexcitability, in spasm of the glottis, and in many other conditions produced by digestive disorders in infants under one year. He, however, objected to the employment of the word "tetanie" as synonymous with reflex hyperexcitability.

PROF. FEDE was led by his experience to accept the views advanced by Prof. Comby.

DR. MENSI, from a study of the gastric contents in rickets, had found that the total acidity was excessive, that hydrochloric acid was deficient, and that abnormal acids, the product of fermentative processes, were present.

PROF. BORELLI considered that the conditions of intra-uterine life had an important share in the production of rickets, in predisposing the infant to develop the disorder after birth.

DR. G. B. VIALI, from observations made in Constantinople, had come to the conclusion that rickets was a predisposing, but not a determining cause of laryngismus stridulus.

DR. PAVONE thought that it was easy to exaggerate the importance of gastro-intestinal disturbances as causes of rickets. Common as rickets was, such digestive disturbances were far more common.

Profs. Escherich, Baginsky, Rehn, Soltmann, and Ranke also took part in the discussion.

Subsequently papers were read by Prof. Rehn on "Congenital Myxedema;" and by Prof. Soltmann on "Cyclic Hemoglobinuria." Dr. Sophie Bakunin read an elaborate paper on the "Comparative Embryonic Anatomy of the Genito-urinary System in Man and other Animals;" and Dr. F. Cerna made a communication on the "Diagnostic Value of Indicanuria in Children."

DR. A. MOUSSOUS read a paper on the "Infantile Form of General Paralysis." The lesions, both naked-eye and microscopic, in a case recorded by him in 1891, were in every respect similar to those observed in the adult. Since that date he had observed a second case. The cases, taken together with observations made at Bicêtre, had convinced him that general paralysis would come on in childhood. Development went on normally until the age of two, three, four, five, or six years, but convulsions were often observed indicating an undue excitability of the nervous system. The onset of the disease was marked by symptoms of meningitis, of apoplectic symptoms, or severe convulsions. The manner of the patient was subsequently changed, and characteristic symptoms developed with greater or less rapidity —vertigo, tinnitus, epileptic fits, partial or complete, with or without paralysis. Next ensues, slowly or rapidly, the stage of dementia, which becomes absolute. Death ensued in from one to four years, determined sometimes by an attack of meningitis, sometimes by an epileptic attack, with hyperpyrexia, sometimes by marasmus.

SECTION OF DERMATOLOGY AND SYPHILOGRAPHY.

PROF. KAPOSI, of Vienna, presided.

DR. TOUTON made a communication on the gonococcus of the blennorrhagic process. He insisted that the gonococcus was the cause of blennorrhagia, and that the diagnosis of the disease can only be made sure by the microscope. The gonococci are usually most abundant at first, but if at later periods the microscopic examinations are negative, the microörganisms can be made evident by a provocative irritation. Sometimes cultures by Wertheim's method may be necessary for diagnosis. He maintained that the tissues beneath the epithelium are invaded, as well as the softer epithelial cells, but not the horny cells. The infection extends by the lymph-channels.

Other papers on genito-urinary subjects were read by the following members: DR. PADULA, on the "Infective Fever of the Blennorrhagic Virus"; DR. GRÖNFIELD, on the "Present Position of Urethroscopy"; Dr. ROCA, on "Lemon-juice in the Treatment of Blennorrhagia"; DR. BARRUCCO, on the "Local Treatment of Urethritis with a New Form of Syringe."

Messrs. Barduzzi, Mibelli, Bröse, Neisser, Jullien, Wahrschewski, v. Petersen, Mange, and Casper took part in the discussion.

DR. NEISSER doubted the invasion of connective tissue by the gonococci, except rarely. He considered that frequent examinations for the microörganisms were necessary, and if, after repeated trials, none was found, the case might be regarded as non-infective, and the

individual allowed to marry, even though abundant secretion be present. He did not think that the clinical conditions alone, the presence of flocci, etc., were of so much importance.

Dr. Savill communicated his researches on a new form of "Epidemic Skin-disease," occurring in London, and exhibited a large series of photographs and drawings.

An important discussion on the present state of the lichen question was then opened by Dr. Neisser, who maintained that the term "lichen" should be confined alone to the disease known as "lichen ruber," which presents two principal forms: "lichen (ruber) planus" of Wilson, and "L. ruber acuminatus" (Hebra, Kaposi).

Mr. Malcolm Morris read a paper in which, after reviewing the literature that had appeared on the subject of lichen since the Dermatological Congress in Paris in 1889, he said lichen had no more right to be created into a group than pityriasis or purpura. After sorting out of the lichen group those elements that belonged to definite diseases, such as eczema, syphilis, etc., the only affection left was the lichen planus described by Erasmus Wilson. He summed up his conclusions as follows: 1. Lichen is not a disease, but a type of lesion. 2. The term should be reserved for the clinical entity described by Erasmus Wilson under the name of lichen planus, which is the same as Hebra's lichen ruber. 3. The affection described by Kaposi under the name of lichen ruber acuminatus is identical with that described by Devergie and Besnier as pityriasis rubra pilaris. 4. Other forms of lichen—obtusus, hypertrophicus, verrucosus, etc., are variants of the typical form, the Hebra-Wilson lichen ruber planus. 5. The group of symptoms to which the name of lichen planus is applied is probably caused by a variety of factors, but at present we are almost entirely in the dark as to its pathogeneis.

Drs. Majocchi, Ehrmann, Oro, Schwimmer, Schiff, Hallopeau, and Tomassoli joined in the discussion, Dr. Schiff maintaining that "L. ruber acuminatus" is identical with Devergie's "pityriasis rubra pilaris," and that the affection is quite distinct from L. ruber planus. The present confusion is caused by employing the term "lichen" for all these conditions.

Among the papers read was one by Dr. Alfred Eddowes, on the "Treatment of Ringworm," giving statistics of a large number of cases treated by Una's method, and detailing the modifications he now employs. He strongly disapproved of epilation, and thought that, with proper care, children might be allowed to attend school while under treatment.

Dr. Abraham communicated a "New Method of Treating Obstinate Parasitic Diseases of the Scalp by the Application of Parasiticides under Pressure," and exhibited an apparatus which he had constructed for the purpose. During the past few months he had successfully employed the method in several cases which had long resisted other treatment.

Section of Laryngology.

The following were the officers elected: *President*—Prof. Massei. *Honorary Presidents*—Drs. Fraenkel, Schmidt, Chiari, Semon, Gougenheim, Moure, Ruault, Schmiegelow, Botey, Sajous, Lowman, Heryng, Sokolowsky, and Onodi. *Secretaries*—Drs. Nuvoli (responsible secretary), Egidi, Trifiletti, Karis, Flatau, Bronner, St. Clair Thompson, Rougé, and Roquer y Casadesus.

The President delivered a stirring inaugural address, in which he made a sympathetic reference to the late Sir Morell Mackenzie.

Papers were read by Prof. Chiari on "Pachydermia of the Larynx and on the Nature of Fibroma of the Vocal Bands." In regard to pachydermia he excluded Virchow's verrucose form, which he considered to be only the clinical papilloma. Pachydermia diffusa was, in his opinion, a phase of some other diseased condition of the larynx, and not a particular disease *sui generis*. He distinguished the primary or idiopathic form, the result of simple chronic catarrh, and the secondary or accessory form, which was part of some other disease such as perichondritis, tubercle, or syphilis. Potassium iodid was occasionally beneficial, but in some cases was injurious to the general health, and was often powerless, even in cases of undoubtedly syphilitic origin. The treatment he recommended most strongly, when called for, was electrolysis, which he believed to be the most efficacious in preventing the recurrences which were too apt to take place.

Vibratory massage of the mucous membrane of the upper air-passages was recommended very highly by Drs. Braun, Dionisio, and Garnault, but decried by Dr. Chiari. Good effects were claimed for it in the treatment of ozena.

A paper on "Intubation of the Larynx in the Adult" was read by Dr. Schmiegelow, and a good discussion took place, especially with reference to its use in cicatricial contractions in the larynx and upper part of the trachea. Several speakers referred to the excellent results obtained from thyrotomy and excision of the cicatricial tissue, and also from dilatation from below upward through the tracheotomy wound.

Section of Otology.

The following officers were elected: *President*—Dr. Emilio Rossi. *Honorary Presidents*—Drs. Calladon, Gellé, Moos, and Politzer. *Secretaries*—Drs. Ferreri, Dundas Grant, Ludewig, Garnault, and Sartori.

The President's Address was followed by the description of a case of otitic thrombosis of the lateral sinus, by Prof. Moos. The mastoid process was trephined, and after death from pyosepticemia, lateral sinus disease was found, in spite of the absence of the characteristic temperature and rigors. Prof. Moos advises bacteriologic examination of the blood as an aid to diagnosis in such obscure cases.

Dr. Moure described a case of latent cerebral abscess due to ear-disease in which sudden death took place. No necropsy was obtained. Several similar cases were related by others.

Dr. Rheinhardt read a paper on "The Treatment of Cholesteatoma by Operation." He recommended in the operation the transplantation of flaps from the back of the ear, and the leaving of an opening in the mastoid region, especially in women, where it could be hidden by the hair. There was freedom from recurrence in those cases in which the opening was left.

Prof. Gradenigo dealt with the subject of auricular affections in hereditary syphilis, which might be either

suppurative or non-suppurative, and might occur even in advanced life.

DR. GELLÉ reported cases in which anti-syphilitic treatment produced rapid benefit after other means had quite failed.

DR. CALLADON read a paper on "Fixation-abscesses in Otology," meaning thereby the derivative action of an abscess in the external ear in effecting the cure of middle-ear inflammation. He employed applications of thymol as being an antiseptic irritant.

The pathogenesis of Ménière's disease was discussed by PROF. GRADENIGO, who considered most cases to be of the spurious or reflex type, and due to disease of the tympanum.

DR. AVALEDO described a case in which Ménière's symptoms were well marked, and in which recovery took place after the performance of Stacke's operation.

Papers were further read by DR. KIRCHNER on "The Value of Gymnastics of the Ossicles," and on "Necrosis of the Cochlea;" by DR. GELLÉ, on "The Osseous Casing of the Facial Nerve and its Lesions," directing attention to a case in which the extraction of an ordinary aural polypus was followed by facial paralysis. PROF. POLITZER described a new form of disease of the ear, with progressive deafness, in which a kind of inflammatory hyperostosis took place round and in the fenestra ovalis. It occurred chiefly in the later years of life, and sometimes was associated with the arthritic or syphilitic dyscrasiæ. PROF. MOOS showed and described some beautiful sections illustrating disease of the inner ear. PROF. GRAZZI read a paper on "The Injurious Effects of Railway Signals of a Noisy Nature on those Employed among Them," and insisted on the necessity for examining the ears as much as the eyes of railway servants. DR. CONRADI, in some studies on the influence of asymmetry of the cranium on Weber's tuning-fork experiment, arrived at the conclusion that the influence was *nil*.

(To be concluded.)

PHILADELPHIA ACADEMY OF SURGERY.

Meeting March 5, 1894.

THE PRESIDENT, DR. WILLIAM HUNT, IN THE CHAIR.

DR. JOHN H. PACKARD presented a verbal report of three cases of left inguinal colotomy:

By some surgical writers, notably the elder Gross, the opinion has been expressed that the making of an artificial anus by opening the colon placed the patient in a condition so distressing that death itself would be preferable. My own experience with these operations warrants me in upholding a very different view. My first case occurred in 1873, and I had the advantage of the presence and assistance of Prof. Gross and of Dr. Levis; the patient, whose rectum was occluded by a uterine carcinoma, lived in comfort for eight months, dying then from exhaustion due to the advance of the disease. In this instance, and in other cases for many years afterward, I made the opening in the left loin, thinking the access more ready, and preferring to avoid encroaching upon the peritoneum. There is, however, one great objection to the method, that the point of exit for the feces is so placed as to be only with difficulty reached by the patient, and to require the assistance of others in attending to it.

For the operation in the left groin, I think the best rule as to the incision is to make it, just as on the right side in appendicitis, an inch and a half from the left anterior superior iliac spine, and at right angles with a line between this process and the umbilicus. With scrupulous asepsis the opening of the peritoneum is made with safety; the operation is one of no more difficulty than that in the loin, and the artificial anus is entirely under the patient's control. The directions given in some of the books for the finding of the bowel seem to me to be needlessly complex; if the large intestine does not immediately present itself in the wound, a portion of the small intestine will, and must be pushed aside, when the sigmoid flexure, especially if distended, will be seen, and may be recognized by the longitudinal muscular bands.

My own opinion is that it is a matter of but little moment whether the bowel is opened at once or after the the lapse of several days.

I do think it important that the gut should be well drawn down into the wound until the portion above this point is slightly tense, so as to avoid subsequent prolapse through the artificial anus. Even with this precaution it sometimes happens that the inner wall will pouch out and be a cause of some annoyance.

For suturing the edges of the peritoneum to those of the skin it is well to use black silk, so that these stitches may be readily distinguished from those by which the bowel itself is fastened in the wound; these latter should be of white silk, and should penetrate beyond the muscular coat, but not through the mucous membrane.

It is not always easy to judge how large an opening should be made into the bowel. In a child, or when the wall of the gut is very thin, a small orifice will suffice; and I do not think more than three-quarters of an inch is ever necessary.

CASE I.—J. B., a mulatto, aged fifty-five years, but looking much older, was admitted into my ward at the Pennsylvania Hospital, November 26, 1892, on account of epithelial carcinoma of the rectum. His condition was most deplorable; there was a mass of disease stiffening the wall of the bowel and discharging from its ulcerated surface a very offensive pus, which, mixed with fecal matter, flowed away constantly through the wide-open anal orifice. Hence he not only suffered agonizing pain, but the intolerable fetor made him loathsome to himself as well as to all about him.

He had, moreover, a left inguinal hernia, which he ascribed to the kick of a horse in January, 1891. This did not in any way interfere with the operation, which was done four days after his admission. The opening into the bowel was not made until December 4th, or four days later.

Immediately after the operation his temperature fell to 97.6°, but he soon rallied and did well. The artificial anus gave no trouble, but was cleansed once daily. By means of washing out with a solution of potassium permanganate or other detergent, the rectum was rendered inoffensive. A portion of the diseased mass was curetted away about four weeks after the colotomy, but no more radical procedure seemed to be justified.

The patient lived in comfort until April 18th, nearly five months, and then died painlessly from exhaustion.

At the autopsy it was found that the morbid growth extended five inches above the anus, and had involved the posterior wall of the bladder; there were abundant deposits in the pelvic and mesenteric glands.

A somewhat noticeable fact was that the serous covering of the gut was adherent to the parietal peritoneum for a long distance above the point of operation.

Case II.—Ellen B., aged fifty-two years, was admitted under my care in the Pennsylvania Hospital, October 24, 1893, suffering from extensive carcinomatous disease of the uterus, involving the rectum; she had not had a natural stool for a year. Her general health was not greatly impaired, but she had great distress by reason of the rectal obstruction.

The next day I exposed and secured the sigmoid flexure, and twenty-four hours afterward opened the bowel. Just after the operation her temperature fell to 96.2°, but reaction took place quickly. Regular movements were soon had through the artificial anus, and on the seventeenth day she was discharged at her own request, to return to her home in Sullivan County, Pa.

Case III.—Mrs. M., aged about fifty, living in one of the cities in the interior of this State, was seen by me in April, 1893, on account of almost total obstruction of the rectum by the pressure of a tumor of the womb, which filled up the entire pelvic cavity. To attack this in its then condition seemed to me, as well as to her physicians, unwarrantable; and as her suffering arose mainly from the rectal obstruction, I proposed opening the bowel in the left groin. To this she agreed, and I performed the operation at her residence. Complete relief was afforded, and after some experiments in the devising of a suitable contrivance for keeping control of the contents of the bowel, this lady was enabled to resume her active life, going into society freely, and attending to all her affairs without hindrance.

Should this tumor, probably a fibroid, develop so as to rise out of the pelvis, the question of hysterectomy might be entertained; and if this were successfully accomplished the closure of the artificial anus might, perhaps be undertaken.

Dr. J. M. Barton: I can speak most favorably of inguinal colotomy. It gives us an opportunity of determining what portion of the bowel is involved and making our opening well above the disease. It also permits us to explore the glands in the interior if removal of the rectum is contemplated. In regard to opening the bowel I have preferred to permit it to remain at least four or five hours before opening; by that time the peritoneal surfaces are adherent. It has been recommended to leave the bowel twenty-four hours and then open with the Paquelin cautery. This seems unnecessary. I usually employ scissors and control any bleeding that may occur with hemostats. I have had no difficulty from prolapse.

Dr. John B. Deaver: It has fallen to my lot to have done several colotomies, but only one or two inguinal. My reason for preferring the lumbar method is chiefly that it is an extra-peritoneal operation. Another reason is that if the disease extends it will take longer to reach the opening in the loin than one in the abdominal wall in front. I am free to confess that I have been largely influenced by the views of Mr. Bryant. The lumbar operation is not by any means difficult. I think that it is quite as simple, and, when there is distention, simpler than the abdominal operation. In the anterior operation distention increases the difficulty.

The anterior wound can probably be looked after better than one in the loin, but it is more difficult to keep a pad in position in the former case.

Dr. T. S. K. Morton: Not many days ago I did an iliac or inguinal colotomy, and a most curious feature of the case was an apparent transposition of the colon to the right side. On making the incision in the left side the colon presented, but on making traction it was found that the entire transverse colon and omentum were speedily delivered, and I had considerable difficulty in locating the descending colon. I finally traced it to the right inguinal region. The lumbar operation, I think, would not have been feasible in this case.

There is one point which I think has not been sufficintly emphasized, and that is the importance of making a spur. This cannot be done by suturing the side of the bowel to the abdominal opening. If little pieces of feces pass the opening and reach the diseased surface they cause a great deal of pain. I have seen nothing equal to a bar of glass or other material passed through the meso-colon for securing an adequate spur. When the bowel is cut transversely upon this support you have two openings presenting, one above the other, and it is impossible for feces to pass across. As far as the control of the anterior opening is concerned, in the cases that I have seen it has been almost perfect.

With regard to prolapse, Mr. Allingham has proposed dragging into the wound as much colon as possible, and removing the redundant portion. He claims that this will prevent subsequent prolapse. This method has been condemned by others, and it has been found sufficient to make the upper part of the colon taut before fixing it.

The size of the opening, I think, should be the entire diameter of the bowel. This gives some sphincter-like action to the end. It has occurred to me that we might employ here the operation of Gersung for incontinence of feces from the anus—that is, rotating the bowel a full circle before suturing it. It has been shown that when incontinence is present an efficient sphincter can be made in this way, and one that will control liquid feces.

Dr. John B. Roberts: A limited experience with both operations leads me to strongly favor the inguinal method. I feel, with Dr. Morton, that the important thing is to obtain the spur. I do not see how that can be easily done without using some form of support and bringing the mesentery out of the wound. I think it a most important feature. I prefer when it can be done, to wait a few days for adhesions to take place. In opening the bowel I am inclined to prefer cutting entirely across.

Dr. Packard: With regard to the making of a spur, it has never been necessary in any of my own cases, and I think it can only exceptionally be of advantage. If the opening made is sufficient the feces will escape easily through it, and the lower part of the bowel has been, in my cases, kept quite free from irritation by them. Of course if a spur is to be made the bowel must be drawn clear out.

As stated in the report of my cases, there was, in the third especially, still some tendency to prolapse in spite

of the drawing down of the bowel, and I should be glad to know of some other way of preventing it.

I am aware that Allingham advises complete section of the bowel, but this seems to me to add to the gravity of the operation without adequate advantage.

A properly adjusted pad ought to keep its place without trouble.

DR. JAMES COLLINS detailed "An Observation of the Effects of Erysipelas on Epithelial Cancer": About eighteen months ago my attention was called by Mr. M. to an ulcer on his right cheek nearly opposite the ear. This ulcer was one and a half inches in its longest diameter, one inch in the shorter, and presented an oval outline with irregular edges. The discharge was slightly purulent and tinged with blood. The granulations were soft and bled on the slightest touch.

Mr. M. stated that twenty years ago there appeared at this point a small elevation, which frequently formed a scab, which every ten or twelve days would fall off and then re-form, and, giving but little trouble, received but little treatment.

Nineteen years ago he was treated for a time with ointments and lotions, also some medicine was administered without special benefit. The ulcer gradually increased in size and depth. Some benefit was derived from a lotion of zinc sulphate and salt, dissolved in water to make a mild astringent solution. The ulceration, however, continued giving inconsiderable pain, but much annoyance by its presence.

About November 12, 1893, he suffered from an attack of erysipelas of the face. This ran no unusual course, spreading rapidly from the tip of the nose over the scalp to the nape of the neck. The efflorescence was followed by desquamation. An external dressing of ichthyol and lanolin was applied and afforded relief and comfort.

As the erysipelas faded the ulcer seemed to assume a more healthy appearance. Granulations of a more nearly normal character developed, and in about two weeks the ulcer was entirely healed. The cicatrix on March 1st was slightly indurated, but smooth and firm, presenting the appearance of normal cicatricial tissue.

This case is reported without special comment, as a single case from the practice of a surgeon is but of little value, isolated and alone.

DR. JOHN B. DEAVER: I now have a patient with osteo-sarcoma to whom I have given the toxin of erysipelas, but it seems to have no effect.

DR. ORVILLE HORWITZ: I have had three cases—two of sarcoma and one of carcinoma—treated by the hypodermatic injection of the toxin of erysipelas. In the case of carcinoma and in one case of sarcoma there was no benefit. In the third case the mass involving the side of the neck has become much softened, and it looks as though some improvement were taking place.

DR. PENROSE: My experience is limited to one case of inoperable carcinoma of the right superior maxillary which had existed some two years. Three or four operations had been done, but the disease had finally gotten beyond bounds. Last spring this woman accidentally acquired erysipelas, and had one of the worst attacks that I have seen, but it had no effect on the neoplasm. The progress of the growth has been the same as before. The beneficial effect of this antitoxin is limited almost exclusively to the softer forms of sarcoma—to sarcoma of the soft parts.

DR. JOHN B. DEAVER read a paper entitled "Vaginal Hysterectomy": *Symptoms.* The symptoms of carcinoma of the cervix may at first be so slight that the patient will pay no attention to them, but will attribute the sensations experienced to the change of life or menopause, at which time carcinoma in this locality usually makes its appearance. From the insidious character of the invasion, considerable involvement will generally have taken place ere the case comes to the notice of the attending physician or surgeon. A slight hemorrhage is noticed, following exertion or coitus, and occurring in the interval between the menstrual periods. This usually does not alarm the patient until it becomes a frequent occurrence. It has been compared to the hemoptysis of early pulmonary tuberculosis, but is unlike this from the fact that there is no active, destructive change going on as yet. A leukorrheal discharge is present, although without the characteristic odor. In the first stage the general or constitutional manifestations of carcinoma do not present themselves. Pain, however, is one of the earlier symptoms. There may be disturbance of either the digestive or the nervous system, or of both.

Following this preliminary stage there is usually a period of latency, in which the disease seems to "rest upon its oars," prior to the second stage, when all the symptoms are present in a marked degree. The hemorrhages are more frequent, and at times are profuse. There is also present a sero-purulent, irritating discharge, with a penetrating, foul odor, and by contact with the internal and external genitalia giving rise to irritation and pruritus, which often cause as much distress as the primary disease. The pain is severe and radiating in character, and is felt most in the lumbar region. The uterus may be fixed or movable; as the disease progresses the uterus becomes fixed by extension of the disease to the surrounding pelvic structures. Examination with the speculum is often unsatisfactory, unless ulceration or granulation-tissue be present; the finger more readily detects the changed character of the tissue, recognizing the neoplasm from its consistency.

The general condition of the patient during the second stage undergoes a marked change. The digestion is very much impaired; anorexia, constipation, etc., are present, and give rise to systemic malnutrition. As a result of this general disturbance, what is known as the "cachectic stage" makes its appearance. The skin is dry and rough, and its color is changed to a muddy, yellowish-brown tint.

Diagnosis. The conditions from which carcinomatous disease of the cervix must be differentiated are the following: Lacerated cervix, with cervical catarrh; erosion of the cervix; specific ulceration; mucous patches; papillary growths; vaginitis; myoma; and sarcoma.

The diagnosis of cervical carcinoma is in the main easy, as the cases are usually seen after positive ulcerative and other gross changes have taken place. When there is simply thickening of the mucous lining of the cervix, with infiltration of the walls, and particularly when the cervix has been torn, it becomes somewhat difficult to differentiate the condition from a long-standing case of cervical catarrh. When, in addition to these features, the cervix presents a nodular appearance from

occlusion of the cervical glands, the difficulty is increased. This last condition, however, should not be mistaken for carcinoma, as the nodules are characteristic of malignant infiltration.

If ulceration is present, and the ulcers present a punched-out, ragged appearance, bleeding freely on the slightest touch, suspicion should be aroused. On the other hand, ulceration consequent upon erosion of the cervical mucous membrane is regular in outline and the surface of the ulcer smooth.

Specific ulceration of the cervix, chancral and chancroidal, is rarely seen, and bears little or no resemblance to carcinoma, and in connection with the history of the case, age of the patient, etc., should not cloud the diagnosis.

Mucous patches and papillary growths are more likely to be confounded with the disease than the two preceding conditions; these are, however, distinguishable in that they are more numerous and more widely distributed.

The discharge which accompanies vaginitis in no way resembles that resulting from carcinoma.

Myoma of the cervix might be confounded with a single carcinomatous nodule, but differs from the latter in the absence of infiltration, inflammation, and adhesion of the overlying mucous membrane.

In incipient carcinoma of the mucous lining of the uterus before the body has become involved, the only symptoms are the presence of a sero-sanious discharge, not necessarily accompanied by odor, and the general appearance of anemia, with debility and digestive disturbances. Pain may or may not be a feature of the case. These indefinite symptoms, together with the failure to respond to well-directed treatment, and the absence of disease of the uterine adnexa, should warrant dilatation and curettement for purposes of diagnosis.

In carcinoma of the body of the uterus the presence of a sero-sanious discharge with the characteristic odor, associated with frequent hemorrhage and enlargement of the fundus, would warrant curetting and microscopic examination of the particles of tissue removed. This may be done without anesthesia.

Sarcoma of the uterus is capable of giving rise to symptoms similar in many respects to those of carcinoma. While it is not always possible to differentiate between these affections, each has symptoms peculiar to itself.

The symptoms in favor of sarcoma are the presence of a rapidly growing tumor of the uterus appearing rather earlier in life than carcinoma; hemorrhage, which is more or less constant; and severe pain.

The diagnosis of sarcoma can often be established by a digital examination, when the cervix will be found less patulous than in carcinoma, the tumor presenting the form of a polypoid growth. It may be necessary to dilate the cervix to explore the interior of the uterus, when, if a mass be found, a portion of it may be removed and examined.

Prognosis. As to the probable outcome of vaginal hysterectomy for carcinoma, it is too early in the history of the operation to draw definite conclusions, but the results thus far have proved that especially early and even later operation prolongs life. There is no doubt but that removal of the uterus for carcinoma, if done early, offers a longer immunity from return than does operation for the same disease in other parts of the body.

Complications. Fatal attacks of uremia may follow, though it is rare to have eclamptic convulsions.

By extension of the disease the bladder and rectum become involved, and as a result cystitis or vesico-vaginal or recto-vaginal fistulæ may arise to aggravate the already deplorable condition of the patient. Peritonitis from extrusion would cause a speedy termination of the case, as would an embolus.

Pregnancy is a dangerous complication, as septicemia or fatal hemorrhage is likely to ensue if the case be permitted to go to full term.

Anatomic relations. The relations of the ureters are of so much importance in this operation that I have thought it worth while to describe their course. They extend from the termination of the pelvis of the kidney to the bladder, passing through the laminæ of the subperitoneal connective tissue. Their average length is about twelve inches. At their commencement they lie about three inches apart, but on nearing the base of the bladder they run forward and inward and pierce its wall, and at their termination are separated by a distance of about an inch and a quarter. We may describe them as consisting of three portions—viz., abdominal, pelvic, and vesical. The abdominal portion is in relation posteriorly with the psoas muscle and its fascia, the genito-crural nerve, and the common iliac artery. Anteriorly they are covered by the peritoneum, and the right ureter lies partly under the caput coli and ascending colon, and the left under the descending colon and sigmoid flexure. About the middle of their course they are jointed by the ovarian vessels, which cross them to descend into the pelvis along their outer border. At the brim of the pelvis the right ureter lies just behind the peritoneum, where it can be seen, with the ovarian vessels. The relations of the ureter to the sigmoid flexure depend entirely upon the length of the meso-sigmoid. Thus in one case the ureter may lie behind the sigmoid vessels, and in another directly behind the intestines. After crossing the psoas muscle it passes obliquely over the common iliac artery above its bifurcation, dropping into the pelvis at this point.

The pelvic portion runs in front of the sacro-iliac synchondrosis, then upon the obturator internus muscle and its fascia, finally leaving the pelvic wall to join the bladder. It lies at first usually to the inner side of the internal iliac artery, subsequently to the outside, and is again crossed by the ovarian veins and artery, which leave it at an acute angle. It then descends in the lower cellular tissue to the floor of the pelvis in a forward direction, passing directly under the uterine artery, and through the uterine plexus of veins and beneath the base of the broad ligament. Finally it crosses the upper third of the vagina to reach the vesico-vaginal interspace, and pierces the bladder opposite the middle of the vagina.

The vesical portion, about half an inch in length, runs obliquely downward and inward through the coats of the bladder to open on the mucous surface at a distance of from an inch to an inch and a quarter from its fellow, and the same distance from the internal urinary meatus.

The uterine artery leaves the lateral pelvic wall at a point just above the ischial spine, reaches the vaginal

wall at the level of the os externum, and then runs upward along the side of the uterus to reach the fundus.

Preliminary treatment. Much depends upon the preparation of the patient for operation. The most careful antisepsis of the vulva and vagina should be carried out. It is the practice of some surgeons to have the hair covering the soft parts removed; I do not believe this necessary if this region be thoroughly scrubbed twice a day with some good detersive soap for two or three days prior to the operation. The vagina should be cleansed with soft soap, and then both the external genitals and the vagina irrigated with a 1 : 60 carbolic acid solution containing an amount of mercuric chlorid to make it equivalent to 1 : 4000. The bowels should likewise be carefully regulated, and a mild laxative administered for a few days before operation, to thoroughly clean out the lower end of the alimentary canal. If there be present granulations covering the cervix or occupying the uterine canal, or should the cervix be eroded and there be a fetid discharge, it would be wise at first to curet away the granulation-tissue exciting the discharge, and subject the vagina to mercurial irrigations twice or thrice daily, the frequency depending on the character of the discharge.

Methods of operation. In the operation of vaginal hysterectomy one of three methods is practised—the clamp, the ligature, or enucleation (Langenbeck's). There is no doubt but that the method by enucleation is the ideal one, and should be adopted when the case is suitable for it.

The enucleation-method consists first in liberating the cervix by carrying two elliptic incisions through the vaginal wall in front of and behind the cervix, or by a circular incision carried around the cervix, the dissection being made close to the cervix. This should be the rule whatever method be employed. In the removal of tumors of the neck in the immediate neighborhood of large vessels, or, in fact, of any tumor occupying important vascular relations, the surgeon follows the practice of dissecting close to the tumor. The second step in the enucleation-method is in making a subperitoneal dissection of the uterus. I think this should be the operation of choice, in the early cases at least.

Between the clamp-method and the ligature-method there is in my mind no doubt of the superiority of the latter. I grant that there are a few cases in which the clamp-method is probably the better operation, but these constitute the exception. The ligature-method of vaginal hysterectomy is as much superior to the clamp-method as is the dropping of the stump in the supra-vaginal method after having tied off the uterine appendages and ligated the uterine arteries over that of the *serre-nœud*. The ligature is surgical, while the clamp compared to it is unsurgical.

In the selection of any operation, that which will leave the patient the most comfortable, not, of course, exposing her to a single additional risk, should in my judgment be the one of choice. I am frequently confronted with the argument: "Why, the clamp-method can be done in fifteen minutes and less." In answer to which my reply is: The ligature-method can be done in from thirty to forty minutes. The question of a few moments in doing the operation is of no import, as, if the case is suitable for hysterectomy, there will be no shock. The loss of blood in the ligature-method, if done properly, is no greater than in the clamp-method, and the security against secondary bleeding is much greater. The ligature-method is one that can be made a strictly aseptic one, and maintained so throughout, while in the case of the clamp there is always some suppuration following, thus exposing the peritoneum to infection from without.

The question may arise: Why not close the wound in the vault of the vagina? The wound closes itself. I have observed, and have demonstrated after the removal of the uterus, the almost perfect apposition of the cut surfaces; and have, therefore, never been able to see the necessity of introducing sutures. If bleeding follows reaction from the anesthetic, and the wound in the vagina has been closed by sutures, the closure may be the cause of a subsequent abscess, while in allowing the edges of the wound to appose naturally, and introducing a little packing of iodoform-gauze into the vagina, not carrying it into the pelvic cavity, the blood finds its way into the vagina and is taken up by the gauze. By the time reactionary or consecutive bleeding, if you see fit to call it such, would occur, the wound in the vagina would not yet have been sealed off; therefore it finds its way out of the pelvis.

In either the ligature-method or the clamp-method, when the cervix is entirely destroyed, thus making it impossible to grasp it with a vulsella or pressure-forceps to pull the uterus down, my practice is to introduce a tenaculum into the uterus, by which I am able to make slight traction, and thus steady the organ; this allows me to free the vaginal walls and expose the supra-vaginal portion of the cervix, which I grasp with the vulsella, and thus command the uterus through the remaining steps of the operation.

Operation. The bowels and bladder having been emptied, the patient is anesthetized and placed in the lithotomy-position, with her limbs held by assistants. A Sims' speculum is introduced and the cervix uteri exposed. The cervix is then grasped either with a vulsella or a pair of pressure-forceps, the latter being less likely to slip or tear out. Traction is made upon the uterus, drawing it downward and forward to expose its under surface. An incision is carried across the exposed surface to the situation of the internal os, or as far away from the eroded tissue as possible, and with the fingers the posterior wall of the vagina and the areolar tissue are freed, from the uterus down to the peritoneum. The forceps holding the uterus is then carried downward, and the incision continued to make it encircle the organ. The structures in advance of the uterus are dissected away in the manner described, great care being observed to keep close to the body to prevent injury to the bladder; having reached the vesico-uterine folds of the peritoneum, the vagina is thoroughly irrigated. The recto-uterine and vesico-uterine folds of the peritoneum are now broken through, and, if the operator so desires, a small piece of gauze or sponge may be introduced to prevent prolapse of the intestine; this I do not believe, however, to be essential. The female blade of the clamp is then introduced along the palmar surface of the finger, which acts as a director. The blade of the clamp is made to hug the under surface of the broad ligament, and the end of the blade is made to pass beyond its upper limit. The handle is depressed to make the end

appear above the upper surface of the ligament, the other blade introduced, and the clamp locked. The opposite side having been treated in the same manner, the attachments are severed and the uterus removed. Should difficulty be experienced in applying the second clamp, the attachment of the side already clamped may be severed, and the body of the uterus loosened and delivered, when the clamp can be easily applied.

A piece of sponge or gauze is introduced, and the vagina is irrigated; gauze is loosely packed around the clamps to prevent ulceration of the soft parts from pressure, and a light packing is placed in the vagina to act as a capillary drain.

The clamps may be removed at the end of the second or third day. In removal of the uterus by the ligature-method the early steps are the same as in the clamp-operation. Having freed the uterus from all its surrounding tissues except the broad ligaments and the peritoneum covering the fundus, the vagina is thoroughly irrigated. The broad ligaments are now to be ligated. An aneurism-needle, curved on the flat and set at right angles to the handle, is threaded with a silk ligature and passed through the base of the right broad ligament a short distance from the cervix; this secures the uterine artery. Successive ligatures are then applied until the entire ligament is tied off. As each ligature is tied the included portion is cut free from the uterus. Having ligated and secured the right ligament, the left is treated in the same manner.

If there be an elongated body, as is often found in uterine carcinoma, great difficulty may be experienced in ligating the entire ligament upon one side without tying off and removing a portion of the ligament of the opposite side. By adopting this course the organ can be pulled down and the remaining ligatures easily applied. As the ligatures are being tied down the traction of the uterus should be relaxed. The uterus having been freed from its ligamentous attachments, the peritoneum is broken through and the organ removed.

After the uterus has been removed, it is the custom of some surgeons to close the opening in the vagina. I do not practise this. The cut surfaces approximate themselves, and further favor drainage if we simply pack the vagina and do not stitch.

Report of Cases.

Case I.—Mrs. C., aged thirty-five years, was admitted to the German Hospital with an extensive carcinoma of the cervix, which had recurred after a previous curetting and now demanded the removal of the whole organ. The patient was carefully prepared for operation, receiving several antiseptic douches daily for a few days, and also boric-acid baths. The anterior and posterior walls of the vagina were carefully dissected up, and the uterus freed and its broad ligaments tied off in sections. The ovaries were removed with the uterus. A light packing of iodoform-gauze was introduced into the vagina.

The patient made an uninterrupted recovery, and was discharged in three weeks.

Case II.—A. B., aged forty years, and unmarried, was admitted to the German Hospital with the following history: For some time past she had been suffering from profuse uterine hemorrhage. The menstrual flow was excessive and painful. A diagnosis of carcinoma of the uterus was made, and total removal of the organ advised.

Operation. The mucous membrane of the anterior vaginal wall was dissected up until the fundus of the uterus was reached. The posterior wall was treated the same way. The broad ligaments were tied off in sections—four on either side of the uterus, which was now removed with the ovaries and tubes. The ligatures were cut short. A light packing of iodoform-gauze was introduced into the vagina, and a pad placed over the vulva. The packing was changed on the fourth day; on the seventh day a slight odorous discharge was noticed, which disappeared on the twentieth day after the operation. There were no signs of peritonitis.

The patient was discharged on the twenty-fourth day. Microscopic examination of the specimen proved the correctness of the diagnosis—carcinoma at an early stage.

Case III.—Mrs. K. G., aged thirty-five years, was admitted to the German Hospital with a history of curetting at another institution for carcinoma of the cervix. At the time of admission a granular mass was found involving the entire cervix. She was again curetted. Six days later vaginal hysterectomy was performed.

Operation. The cervix was drawn down by means of a tenaculum, and a silk thread introduced through both lips. The anterior vaginal mucous membrane was carefully dissected up from the exterior surface of the uterus. The posterior surface was similarly treated. The smallness of the vaginal cavity complicated the enucleation considerably. After the uterus had been freed of the vaginal mucous membrane, clamps were applied to the broad ligaments. The organ was removed by cutting between the uterus and the clamps. The part was irrigated with a boric-acid solution, and the vagina packed with iodoform-gauze. An antiseptic pad was applied to the vagina. The clamps were removed on the fourth day. Recovery was uninterrupted.

Case IV.—Mrs. K., aged thirty-four years, was admitted to the German Hospital with a granulating mass of the cervix. An attempt was made to curet the mass away, but it was found to be too extensive.

Operation. The cervix was firmly held with a vulsella-forceps. The anterior vaginal mucous membrane was dissected away from the uterus. The posterior surface was treated similarly. The broad ligaments were tied off in sections—three ligatures upon either side of the uterus, which was now removed; the vagina was irrigated and packed with iodoform-gauze. The dressing was removed on the eighth day, the parts irrigated, and another dressing applied. The patient made a successful recovery, being discharged upon the fourteenth day.

Dr. C. B. Penrose: In the diagnosis of doubtful cases I have found dilatation and curetting unsatisfactory in most cases. We may be obliged to rely on these in carcinoma of the fundus, but in suspected carcinoma of the cervix I think that it is better to cut out a wedge-shaped piece. I have done this in fifteen or twenty instances, and in many of them have recognized carcinoma in its early stages.

I prefer removal through an abdominal incision in all cases, if necessary making a preliminary incision in the anterior and posterior vaginal fornices in order to be

sure that all infiltrated tissue in the vagina is removed. By this method you can more readily deal with any complications that may arise.

DR. DEAVER: I quite agree that the removal of a portion of the cervix for diagnostic purposes is more reliable than curettement; but this is not applicable in all cases.

I should like to hear from Dr. Penrose what is the status of removal of the tubes and ovaries in these cases. I always attempt to remove them because I see no advantage in leaving them. I should like to know if this lessens the liability to recurrence. The ovaries, however, do not hold the same relation to the uterus that the lymphatic glands do to other structures.

DR. PENROSE: I think that the chief reason that it is desirable to remove the tubes is that in from 25 to 30 per cent. there is extensive disease of the tubes, not necessarily malignant, however. The ovaries, I think, in young women might be left in order to preserve the ovarian influence.

(To be concluded.)

NEWS ITEMS.

Pennsylvania State Medical Society.—The following scientific program has been arranged for the meeting to be held in Philadelphia, May 15, 16, 17, and 18:

Annual Addresses.—Medicine, W. S. Foster, Pittsburg; Surgery, G. D. Nutt, Williamsport; Obstetrics, E. E. Montgomery, Philadelphia; Mental Disorders, T. M. T. McKennan, Pittsburg; Hygiene, J. H. Wilson, Beaver; Ophthalmology, George E. de Schweinitz, Philadelphia.

Medical Papers.—Charles W. Dulles, Hydrophobia; H. F. Slifer, Dietetics; John M. Batten, Unique Cases in Practice; W. C. Hollopeter, Therapeutics of Whooping-cough; William P. Munn (Denver, Col.), Colorado Climate for Consumptives; R. G. Curtin, Subcutaneous Emphysema; John Aulde, Diarrheal Diseases; Wharton Sinkler, Acroparesthesia; Adolph Koenig, Typhoid Fever; W. E. Hughes, Tapping of Abdominal Effusions as a Therapeutic Measure.

Surgical.—E. Laplace, Radical Cure for Hernia; F. Le Moyne, Modification of Pirogoff's Amputation; X. O. Werder, Surgery of the Gall-bladder; T. S. K. Morton, Section of Tendo Achillis in Fractures and Dislocations; John B. Deaver, Appendicitis; G. G. Davis, Amputation near the Ankle; O. Horwitz, Stricture of the Urethra; Charles W. Dulles, Treatment of Fractures at the Lower End of the Humerus; J. M. Barton, Acute Intestinal Obstruction; Edward Martin, Ocular Exploration of the Bladder and Urethra; John B. Roberts, Thyroidectomy.

Obstetric and Gynecologic.—J. C. McAllister, Puerperal Eclampsia; Charles P. Noble, Uterine Fibroids; J. M. Baldy, Acute Endometritis; Anna M. Fullerton, Studies in Obstetrics and Gynecology; Horace Fox, Symphysiotomy and Other Procedures; B. F. Baer, Cholecystenterostomy.

Eye and Ear.—S. L. Ziegler, Corneal Ulcers; S. MacCuen Smith, Diseases of the Ear; H. F. Hansell, Surgical Treatment of Internal Strabismus; Charles H. Thomas, Eye-strain; Charles H. Burnett, Tympanic Vertigo; Louis J. Lautenbach, Massage-methods in the Relief of Tinnitus; L. Webster Fox, Capsulotomy after Removal of Cataract.

Nose and Throat.—W. H. Daly, Intra-nasal Surgery; William R. Hoch, Naso-pharyngeal Catarrh.

Skin.—J. V. Shoemaker, Clinical Observations; M. B. Hartzell, Epithelioma of the Skin.

Tuberculosis.—Arrangements have been made for a discussion on Medical and Surgical Tuberculosis, and papers will be read on Medical Tuberculosis as follows: S. S. Cohen, Curability and Treatment; J. M. Taylor, Psychic Phases; A. M. Cooper, Contagiousness; L. F. Flick, Prophylaxis; Hugh Hamilton, Medical Tuberculosis; T. J. Mays, Strychnin-treatment of Pulmonary Consumption; D. Longaker, Case of Tuberculous Meningitis.

The following members of the Society have announced their wish to take part in the discussion on Medical Tuberculosis: J. H. Musser, W. B. Ulrich, J. C. Wilson, J. S. Cohen, and W. E. Hughes.

The following papers on Surgical Tuberculosis will be read: C. B. Penrose, Tuberculosis of the Fallopian Tubes; H. A. Wilson, Treatment of Tuberculous Caries of the Spine; E. B. Haworth, Case of Tuberculosis of the Knee-joint.

The following members will take part in the discussion on Surgical Tuberculosis: J. B. Roberts, DeF. Willard, G. G. Davis, J. K. Young, J. M. Barton, and B. F. Baer.

Tuberculous Manifestations of the Skin will be discussed by H. W. Stelwagon.

Besides these, the following papers on general subjects are announced: Hildegarde H. Longsdorff, Christian Science and the Medical Profession; S. S. Cohen, Should the Journal of the American Medical Association be Used to Promote Quackery? E. Jackson, Reasons for the Revision of the Code of Ethics; O. H. Allis, Cramming in Medical Schools.

The committee has obtained the consent of Dr. Benjamin Sharp, of the Academy of Natural Sciences, to exhibit to the Society his beautiful series of lantern pictures of the leper settlement at Molokai, Sandwich Islands, and of lepers in various stages of the disease.

Resident Physicians at the Methodist Episcopal Hospital of Philadelphia.—An examination for two resident physicians at the Methodist Episcopal Hospital of Philadelphia will be held on Thursday, May 3, 1894, at 7.30 P.M., at the Hospital, Broad and Wolf Streets.

One of the officers thus selected will go on duty August 1, 1894, and serve twelve months. The other will go on duty September 1, 1894, and serve for thirteen months.

In accordance with the charter of the Hospital, applicants must have the degree of Bachelor of Arts, in addition to that of Doctor of Medicine. Further information may be obtained from John B. Roberts, M.D., Chairman of the Committee on Examinations, 1627 Walnut Street, Philadelphia.

The Wisconsin State Medical Society will hold its forty-eighth annual meeting at Milwaukee, May 2, 3, and 4, 1894.

Correction.—In the 26th line from the top of the second column of page 389 of THE NEWS of April 7, 1894, the figures "100,000" should read "1000."

VOL. LXIV. SATURDAY, APRIL 28, 1894. NO. 17.

ORIGINAL ARTICLES.

CONCERNING THE HISTORY OF THE DISCOVERY OF REFLEX OCULAR NEUROSES, AND THE EXTENT TO WHICH THESE REFLEXES OBTAIN.[1]

BY S. WEIR MITCHELL, M.D.,
OF PHILADELPHIA.

You are well aware that you touch the general practice of medicine at many points, and very often are most helpful, but, sometimes, because of being satisfied to think only of the eye, you may be quite the reverse of helpful.

Nowadays, except for obvious eye-trouble, you are most likely to be consulted as concerns headaches, and to be asked if they are in this or that case the offspring of disorders of the visual apparatus. Very frequently the patient goes directly to you, so that you become his only adviser, and it is as to this form of undivided responsibility that I shall have to speak before I close; for it is here that you sometimes fail to grasp the truth that he who has correctly glassed the eye may have left undone that without which his work loses much of its value.

Before dealing with more practical matters, I should like to call your attention to the general history of the connection of headaches and other neuroses with eye-strain. I am the more interested in doing this because I had a personal share in directing the attention of the medical public to this matter, and also because it is my firm belief that we of this city were the first to bring this relation into large practical prominence.

I am under the impression that Dr. Ezra Dyer and Dr. J. Haskett Derby, of Boston, were the first Americans to bring us home from Germany modern views as to corrections to be accomplished in disorders of the optic apparatus.

Dr. Dyer came here to live in 1862. From this accomplished oculist I learned a great deal in regard to the treatment of the eyes, and it was through certain cases thrown into his hands by me that I came first to understand more fully the mischief-making capacity of imperfect eyes.

I remember with great distinctness the earlier of the many important cases I saw with Dr. Dyer. Some of them made an immense impression upon my mind. One was that of a young woman whom I had known for many years to have exceedingly disordered eyes, and to be unable to use them for more than a minute at a time without pain. She suffered a great deal from headache, but although she had seen many physicians, neither they nor I, nor Dr. Dyer (whom she consulted as to her eyes), had any suspicion that the eyes were a factor in the product of pain. The headaches were entirely occipital. Dr. Dyer carefully glassed this young woman, merely to aid her vision, and shortly afterward, in some two or three months, she told me that her headaches had entirely disappeared, but that they returned if from any cause she was without her glasses for a few days.

This fact struck me very forcibly. Shortly afterward I met in consultation the late Dr. John F. Meigs, concerning the case of a young widow who had suffered for many years with extreme headache, pain down the spine, and also with what at that time I considered as hysterical retraction of the head. After we had talked the case over, Dr. Meigs said to me that his medical resources were exhausted as to this case, and that he did not know what caused the headaches. I then asked if they might not possibly be due to what at that time I was beginning to call "eye-strain." He said it was possible, but that he had never met with or heard of such a thing. I got his ready consent to refer his patient to Dr. Dyer. Careful correction wiped out these headaches. The stiffened muscles at the back of the neck relaxed, and four months afterward this woman was in better health than she had been since childhood. These, and other cases, at last opened my mind to a distinct conception of the frequency of the relation between disorders of the apparatus of the eyes and headache or other neursoses.

As Dr. Dyer's practice enlarged, and as physicians began to have more and more confidence in methods of correcting the eyes, I, too, learned still more of these interesting difficulties. I think the knowledge that a headache might be due to ocular troubles was becoming pretty well diffused among the more intelligent of the profession in Philadelphia, when, in the *Medical Reporter*, in 1874, in writing of headaches, I described headaches from eye-strain, and gave several cases at length. These cases were corrected by Dr. Thomson. The cases seen with Dyer occurred as early as from 1862 to 1864; I cannot more surely set the dates. I then got the impression,

[1] An abstract of remarks before the Ophthalmologic Section of the College of Physicians of Philadelphia, March 26, 1894.

which I still retain, that hemicrania of the classic type, although it may be increased and made worse by ophthalmic defects, rarely owes its existence to this alone, and that headaches of eye-strain are usually of quite different type.

I did not again write on the subject until 1876. In April of that year I published a paper in the *American Journal of the Medical Sciences*. There I announced the following conclusions, having learned that not only headaches, but vertigo, nausea, anemia, and much disturbance of the general health, might be due to difficulty of the eyes.

Conclusions as to Headaches from Eye-strain.

1. That there are many headaches which are due directly to disorders of the refractive or accommodative apparatus of the eyes.

2. That in some instances the brain-symptom is often the most prominent, and sometimes the sole prominent symptom of the eye-troubles, so that while there may be no pain or sense of fatigue in the eye, the strain with which it is used may be interpreted solely by occipital or frontal headache.

3. That the long-continuance of eye-troubles may be the unsuspected source of insomnia, vertigo, nausea, and general failure of health.

4. That in many cases the eye-trouble becomes suddenly mischievous, owing to some failure of the general health, or to increased sensitiveness of brain from moral or mental causes.—*Am. Journ. Med. Sci.*, April, 1876.

It may be somewhat interesting to carry the history of the subject beyond this point. The knowledge of which I speak is perhaps one of the most valuable contributions to the relief of human suffering that has been made during the century. It is impossible to give the credit of this vast gain to any one man, and say that it was due to him alone. Helmholtz, Donders, and von Graefe made this relief possible by their scientific work, but neither in Europe nor here was there, so far as I know, in 1862, or much later, any practical conception among either oculists or physicians as to the frequent power of bad eyes to create headache and divers other troubles. No general physician then sent headache-cases to an ophthalmic surgeon, and my own paper of April, 1876, was, I think, the first contribution of importance to this subject made from the side of the general practitioner.

In fact, one looks in vain for many a day through the text-books on the eye, and the monographs on headache, for a statement of the imperative need to study the eyes in headache, vertigo, etc. If here and there we find a sagacious ophthalmologist speaking of the distress and pain which manifest ocular trouble occasions, the general text-books are silent as to a practical hint, and the profession at large remains ignorant.

Quite recently, in 1886, there appeared Ernest Clark's book on *Eye-strain*, and here is full confirmation of what I state, and, too, of Dr. Clark's entire failure to make clear our own share in the valuable discovery I am discussing. This author points out that fifty years ago Tyrell, in speaking of asthenopia, very well described its power to cause *headache*, *dyspepsia*, *vomiting*, *diplopia*, *vertigo*, and *palpitation*. He even employed the term *eye-strain*, its first printed use, I suspect, in connection with this subject.

I find in Dr. George Stevens' book on *Functional Nervous Diseases*, published in 1887, information which enables me to carry forward the history of this subject. He says, page 8: "No general principle of sympathetic or reflex irritation had, however, been formulated, and the first *printed* announcement of the existence of such a principle was made by myself, in a paper presented to the Albany Institute in the early part of 1876," ("On Some Results of the Anomalous Refraction of the Eyes"). It is difficult to understand this claim.

The paper to which Dr. Stevens alludes here as presented to the Albany Institute, was read by title before the Institute, May 30, 1876, and placed on file to be presented thereafter, but I do not find it anywhere stated in the *Transactions* or *Proceedings of the Albany Institute* that it was ever read or printed.

Soon afterward a paper, by the same author, was read before the Academy of Medicine in New York, June 15th of the same year ("Refractive Lesions and Functional Nervous Disorders"). This paper deals with the question of chorea chiefly. Dr. Stevens attributes a very large proportion of choreal cases to hypermetropia. As to this matter I shall have more to say before I close.

In the *New York Medical Record*, September, 1876, there is also a paper by Dr. Stevens upon the "Relations between the Anomalous Refraction of the Eyes and Certain Functional Diseases of the Nervous System," with a table showing the refractive condition of eyes in fifty-four cases of epileptic and insane persons. This paper deals with the facts that refractive errors are common in cases of epilepsy and the like, and with the great frequency with which refractive anomalies have been found in connection with recurrent headache. As to this matter, too, we have the later papers of both Drs. Stevens and Ranney, as to which I shall also have a few words to say before I close this present communication.

I find later, in the *New York Medical Journal* for June, 1877, a paper by Dr. Stevens ("Light in its Relation to Disease,") which I presume is the same as one before presented to the Albany Institute, December 19, 1876. It deals chiefly with the question of heredity in connection with faulty refraction of the eyes and other matters.

In looking over the later history of this matter I find that certainly one of the earliest distinct papers on the subject of astigmatism as causing headaches, was written by Dr. William Thomson in 1879.[1] After this, papers began to multiply in the eighties; but long before the general medical public had the least idea of this pathologic relation, these two gentlemen (Drs. Thomson and Dyer) had obtained a clear and practical grasp of the facts in question.

So much for the history of this matter; it has become an old story.

Now, the every-day practitioner called upon to treat a neurosis, especially a headache, habitually refers the patient to an ophthalmologist, and does not know whence came this inestimable lesson. I can remember to have heard it laughed at as utterly absurd.

Before leaving the subject I should like to say a few words as to the more recent claims made by Drs. Stevens and Ranney. Men who run into extremes are often those who in the end teach proportioned wisdom to such as know wisely to profit by the excesses of others. This is going to be the case in regard to the extreme views enunciated by these two gentlemen. There is in them an element of occasionally useful truth. Where they appear to me to have most distinctly failed I have endeavored to point out to the best of my ability.

At my clinic, for two years or more Dr. G. E. de Schweinitz examined with the utmost care the eyes of all of the numerous choreic children who appeared at the Infirmary for Nervous Diseases. The cases extended to one hundred, and although many of them have been given the most careful attention, I do not think that any notable good in the way of cure of chorea was obtained by correction of refractive or other errors. In the disorder I first described as "habit-chorea," glasses have now and then been found to be useful, but not always; nor should we expect to find anything else in regard to chorea proper. It is largely a disorder of seasons in the first place, and secondly it is a disease easy enough to treat. The great mass of cases get well without much difficulty; in a large number of instances the disease is self-limited, and gets well if let alone, nor has it the gravity which one would be led to expect from reading Dr. Stevens' early paper. Dr. de Schweinitz, who is present, will, I am sure, entirely agree with the conclusions I have reached as being his opinion and mine, to the effect that we have gotten no good by correcting the eyes in cases of chorea. I came to this matter with a perfectly free and unbiased mind, but this was the end. Choreal children with ocular defects got well under arsenic alone quite as soon as others who had no like disorder of vision; or the choreas got well, and the hypermetropia remained unaltered and unglassed.

And now as to epileptics I have met with no better fortune. As regards this, I have read with care the conclusions of Stevens and Ranney, and have wished I could have seen some of the epileptic persons whom they so successfully treated. Those who have treated epilepsy know that in some respects it is a very curious disease. If we take an obstinate epileptic case and put it suddenly under new conditions, in a new place, with altered diet and different surroundings, we occasionally find marked changes for the better, which are usually temporary. This is frequently the case at the Infirmary. When an habitual epileptic is put there for the purpose of being watched, in order to determine the quality of the spasm, weeks and even months may pass without the patient having an attack, when before this they occurred every day; and this, too, despite the discontinuance of all drugs. I know of two cases of men who had such attacks before entering the army, and under the new surroundings were entirely freed from them. These are the things which make neurologists careful in concluding for the value of a new agent in this sad malady until the cure has lasted a long while, and been observed with care. Still, there are cases found in Ranney's last contribution ("Eye Treatment of Epileptics," *New York Med. Journ.*, Jan. 13, 20, and 27, 1894) which seem to have ended in cures. I can only say that I have failed to obtain like results in our own attempts to cure epilepsy by the correction of refractive errors or by cutting tendons. I neither believe nor disbelieve. When I can see two or three cases of cure of undoubted epilepsy by tendon-clipping, I shall want to recommence. So far I have had only disappointment, and others here who began to cut tendons with enthusiastic hope, have, like me, got no good for their patients out of an industriously acquired experience in this direction. I shall be but too happy to drop the dubious mood in which I am as to this whole matter.

I believe, as regards tenotomy *versus* prisms, that these gentlemen have taught us a lesson which we may with moderation usefully employ. I have called your attention to the matter because I am well assured that if, as to tendon-cutting, the gentlemen whom I have so frankly criticised have gone too far, you, I think, have not gone far enough.

I have tried as to this whole matter to be fair and courteous, and yet to set the history right. As concerns too positive views of treatment, time alone will entirely settle these.

And now a word or two as to your own relations

[1] The literature before this must have been meager indeed. See American Medical Library Catalogue.

to the disorders in which we see ocular troubles, or as to those in which these are the cause of symptoms.

I trust the day has gone when you will put on prisms, or cut the tendons of ataxic cases without perceiving the spinal source of the defects; but a more lasting evil arises out of the fact that sometimes you do not comprehend the fact I have long tried to teach, that eye-strains lasting through the years of development may make permanent headaches which no glass will do more than partially relieve.

Again, you often see people who owe to ill health a suddenly intensified capacity to feel an eye-strain. You glass them and expect too much. Neither you, nor any specialist, can, or should, escape from a sense of larger responsibility, and if you cannot hold your patient when you have corrected the eyes, it is imperative that he learn from you the fact that he needs more than merely the best correction of the eyes. A careful study would often tell you that a man may have two or three forms of headache, and that it were well to understand that while your glasses may cure an occipital ache, for instance, he may still continue to have neuralgic hemicranial pain, or an occasional attack of gouty headache.[1]

I suspect that our own oculists are far in advance of the English and most Continental surgeons, in the care with which they correct defects in refractions. I fancy that they sometimes fail to get the best possible results because of difficulties due, it may be, to personal peculiarities in patients, or sometimes to the belief that slight muscular defects may be let alone when the refraction has been accurately corrected.

THREE CASES OF CHRONIC TINNITUS AURIUM AND TYMPANIC VERTIGO RELIEVED BY REMOVAL OF THE INCUS.[2]

BY CHARLES HENRY BURNETT, M.D.,
AURAL SURGEON, PRESBYTERIAN HOSPITAL, ETC., PHILADELPHIA.

THE following cases were operated upon primarily to rid the patients of intensely annoying tinnitus and ear-vertigo, dependent upon so-called chronic catarrh (sclerotic) of the middle ear. Incidentally we may learn something about the effect of the operation upon the hearing, which is always reduced to a low point in chronic tympanic vertigo. The deafness in such cases, however, is disregarded by the patients in their eagerness to obtain relief from tinnitus aurium and aural vertigo.

CASES XIII AND XIV.[3]—Mr. W. R. P., of Philadelphia, aged fifty-eight, formerly a sea-captain, now a salesman in this city, was brought to me October 11, 1893, by his family physician, Dr. M. G. Tull. It was stated that the man's hearing had begun to fail fifteen years previously, first in the left ear, and then in the right. A year ago the patient began to have added to his other symptoms of chronic catarrh of the middle ears, more tinnitus aurium and some ear-vertigo. The vertigo was at first not very bad nor very frequent; gradually, however, the attacks became more frequent and more intense, until for three months preceding his first visit to me the vertiginous attacks had nearly incapacitated him for business. He has never fallen, but he has been obliged to sit down in the street and to hold on to objects in the street to keep himself from falling, as these attacks have occurred without warning. The vertigo has usually been followed by more or less nausea.

Otoscopic examination of the ear revealed retracted but not thickened membranæ. The incus was visible through each. Hearing in the left ear was *nil;* in the right ear by means of the ear-trumpet only. The tuning-fork was not heard *per ossa* in either ear. The membranæ were found restricted in their movement under the pneumatic speculum.

Retraction of the ossicles and impaction of the stapedes were diagnosticated as the cause of the tinnitus and vertigo, and removal of the incudes was advised as the only means of liberating the stapedes and overcoming the labyrinthine pressure caused by the stapédial impaction in the oval window. The removal of both incudes seemed advisable, as both ears being similarly affected it was deemed that lesions in both might contribute to the causation of the tympanic vertigo. On October 16, 1893, both incudes were removed, the patient being under ether. By November 1st the right membrana had healed, and the man could hear conversation close to his ear without an ear-trumpet. A little tinnitus existed.

The day after the removal of the incus the patient could hear the voice close to the left ear, which had been impossible before. This ability, however, gradually disappeared before the membrana closed.

Two months after the operations on the tympana the patient reported feeling a little tinnitus in both ears, *but no vertigo since the operations.* The tuning-fork was heard *per ossa* in both ears. He depends upon his right ear for hearing, aided by the trumpet, in business, but at home he uses his ear without this aid much of the time.

When I was a student of otology in Vienna, over twenty years ago, Politzer showed his class a few cases of what he denominated "traumatic catarrh" of the middle ear, resulting from falls or blows. In this affection the deafness, tinnitus, etc., are not considered dependent upon a lesion of the nerve in the labyrinth, but upon trophic disturbances in the middle ear. The treatment recommended was the

[1] See International Clinics, vol. ii, on Permanent Headaches.

[2] Read before the Section on Otology and Laryngology of the College of Physicians of Philadelphia, March 6, 1894.

[3] Cases I–X were detailed in THE MEDICAL NEWS, May 13, 1893, p. 509, and Cases XI and XII in THE MEDICAL NEWS, September 30, 1893, p. 374.

same as that for non-traumatic catarrh of the middle ear. As far as I could discern no relief was ever given these cases by the ordinary routine treatment of chronic catarrhal otitis media. Since the time I allude to I have seen a number of cases of so-called "traumatic" catarrh of the middle ear, which I have failed to relieve of any of their symptoms by the ordinary remedies.

Although the etiology and pathology of these cases of "traumatic" catarrhal otitis media are obscure, I concluded at last that the lesion in such instances must lie in adhesive inflammation in the tympanum and about the ossicula, induced by the traumatism. This condition would be competent to bring about a retraction of the entire chain and consequent impaction of the stapes in the oval window, with pressure upon the labyrinthine fluid. Therefore it seems just to conclude that liberation of the stapes, or even its entire removal, in such cases would afford relief from the tinnitus and vertigo. This supposition has been to some extent justified by the results of removing the incus in the following two cases:

Case XV.—Mr. C. S., of Philadelphia, aged sixty years, was sent to me October 2, 1893, by Dr. Lawrence Wolff, with the statement that four months previously the patient had "fallen down stairs and sustained a concussion of the brain, and probably some fracture about the base. He is since deaf in the right ear, and has great tinnitus and throbbing in it." The patient stated that in his fall he had struck the top of his head, but that there was "no cutting of the scalp." He seemed to have been attacked with vertigo, without any reason assignable on his part, just as he was going to bed, and hence the fall. He was unconscious two weeks. Immediately upon recovering consciousness he noted tinnitus and deafness in his right ear, which, he said, had been perfectly well before the accident. After getting up and walking about he had attacks of uncertainty of gait. Tinnitus and deafness have been constant since the accident.

Examination with the otoscope showed that the membrana in the right ear was crinkled and white. Under Siegle's pneumatic speculum the malleus was found to be immovable, but the posterior half of the membrana was easily movable under this test. The pneumatic suction of the ear caused the ear to "feel better," but did not quell the tinnitus. The opposite membrana tympani was white and lusterless, but the hearing perfect in the left ear.

The case was diagnosticated as one of "traumatic catarrh" of the middle ear, productive of deafness, tinnitus, and vertigo. The removal of the incus was suggested as the only means in my power to relieve him, and this was acceded to by his physician, Dr. Wolff, and himself.

On October 23, 1893, under ether, the posterior superior quadrant of the membrana tympani was cut away from its peripheral attachment, and the incus exposed to view. This was easily detached from the stapes, but it was so adherent to its attachments in the attic and on its outer surface with the inner surface of the tympanic ring that considerable traction was necessary in order to remove it from the tympanic cavity. By October 25th there was no reaction in the drum-cavity, less tinnitus, and the gait was more steady. On October 28th, the man slept much better because of the lessening of the tinnitus, which was scarcely appreciable. The patient walked much better. On October 30th there was a little discharge from the drum-cavity, probably due to the tearing of the adhesions about the incus at the time of its removal. There was no pain in the ear, however.

On October 31st, the patient said that he had had great pain in his head and right ear the night before, with very little tinnitus. There was not much discharge from the drum; the jaw was stiff. Possibly the patient took cold while standing in the street looking at a night parade forty-eight hours previously, or perhaps the inflammation was due to the tearing of the adhesions about the incus at the time of its forcible removal.

By November 7th, the membrana had healed; there was very little tinnitus, and he felt much freer in the head than at any time since his accident.

In this case the tinnitus has recurred at times with severity during the past two months, followed by periods of lessening. There has, however, been no pain in the ears or head. The gait is permanently better, but the tinnitus has not been as much relieved as in the following case. The hearing has not been improved. Suction upon the membrana, which is sunken in the posterior superior quadrant, relieves the tinnitus markedly. The relief may continue for hours. The adherent incus in this case leads to the inference that in the healing of the synechiæ, severed when the incus was removed, the stapes may have become involved and still more or less impacted in the oval window.

The relief now given by the rarefaction of the air in the canal by Siegle's speculum would seem to indicate that there is still some retractive force acting on the stapes, perhaps through the depressed quadrant in the membrana, and mediately thence through the synechiæ still left in the region formerly occupied by the incus, and pressing with varying vigor on the stapes.

So probable do I esteem this that, should the tinnitus and vertigo become as bad as ever, I would advise another opening of the membrana and an inspection of the region of the stapes. If synechial bands should be found in this territory, I would advise their careful exsection.[1]

Case XVI.—William H., fifty-six years old, personally known to me for over ten years, was struck

[1] Since writing the foregoing the patient has informed me, March 10, 1894, that the tinnitus is decidedly less, his ear is more comfortable in every way, and the dizziness far less marked than before the operation.

by a locomotive in December, 1892, and thrown up into the air, landing on his vertex. This happened at a station near Wilmington, Del., and he was conveyed to a hospital in that city. He was admitted as suffering from a compound depressed fracture of the skull. He was unconscious and delirious for two weeks, his life being despaired of.

Immediately upon his discharge from the hospital, January 16, 1893, he perceived deafness and tinnitus in the previously good right ear. He also suffered greatly from confusion in the head, dizziness, and uncertainty of gait. I examined him shortly after the accident, and found the membrana tympani normal in appearance; there was total deafness; and the tuning-fork on the vertex was not heard. The treatment consisted of inflation of the tympana and a spray of Dobell's solution to the nares at intervals for a few months, but without relief. In fact, the noises in the ear and the confusion in the head, with the attacks of vertigo, were by the autumn of 1893 (nearly a year after the accident) beginning to interfere with the patient's ability to attend to business, though his general health and strength had partly improved. The tinnitus in this case was relievable by Siegle's speculum. I advised removal of the incus, which was done under ether on November 23, 1893. The bonelet was not adherent. November 24th, there was hardly any tinnitus, no vertigo, and a great sense of relief in his head. On November 27th, the patient's head was free from confusion and dizziness for the first time after his accident. A small patch of dried blood was present over the seat of the operation in the posterior quadrant of the membrana.

On November 29th, there had been no dizziness since the operation. On December 2d, it was noted that there was a little tinnitus and dizziness on the previous day, but none on this day. He seemed to be able to hear my voice in ordinary tones at six inches.

This patient has continued to feel the relief from tinnitus and dizziness to the present time—March 1, 1894—notwithstanding an attack of influenza in January last. He says his memory and intellect have been much better since the operation. The tuning-fork is now heard *per ossa* in the ear operated on, and his quantitative hearing has certainly increased. He hears quite low tones through the otophone—inaudible before the operation. The operation was, however, not undertaken to improve the hearing, but to relieve the patient from tinnitus and tympanic vertigo, which has been accomplished.

I have operated eighteen times for the relief of *tympanic vertigo* within the past six years. *Seven* of these operations were total excision of the membrana tympani and the malleus, followed by relief in all the cases excepting one—an instance of so-called "traumatic" otitis media. *Eleven* cases were operated upon by removal of the incus, the membrana and malleus being left *in situ;* in one of these the entire stapes was removed, and in another the crura of the stapes in addition to the incus. Of the eleven, nine cases were relieved at once and have remained free; one case slowly improved, and one case, in a neuropathic subject, has experienced little or no relief as yet.[1] Two of the eleven were cases of "traumatic" catarrh, viz., Nos. XV and XVI (in this article), of the series of eighteen cases of tympanic vertigo upon which I have operated.

All of these operations for the relief of aural vertigo were performed upon the etherized subject, the ear being illuminated by a six-volt electric lamp held on the operator's forehead. Removal of the incus is preferable to total excision of the membrana tympani and the malleus in these cases, as the latter operation is invariably followed by more or less reaction, while simple myringotomy and removal of the incus is entirely free from this complication.

CLINICAL LECTURE.

CYST OF THE BROAD LIGAMENT FROM A PATIENT SIXTY YEARS OLD—CARCINOMA OF THE BODY OF THE UTERUS—UTERINE FIBROID.

A Clinical Lecture delivered at the Buffalo General Hospital, Gynecologic Clinic.

By M. D. MANN, A.M., M.D.,
PROFESSOR OF OBSTETRICS AND GYNECOLOGY, UNIVERSITY OF BUFFALO, BUFFALO, N. Y.

CYST OF THE BROAD LIGAMENT IN AN OLD WOMAN.

The specimen I show you is the result of an operation in a decidedly interesting case. The patient was a little more than sixty years old, and she gave the history of having had an abdominal tumor for forty years. Upon examination I found a great distention of the abdomen, and, as the walls were thin, fluctuation was very evident. The fluid was plainly encysted and not free in the peritoneal cavity, as there was dulness anteriorly and resonance in the flanks. I made the diagnosis of parovarian cyst, or a cyst of the broad ligament, for three reasons—(1) the length of time which the tumor had lasted without causing serious symptoms; (2) the sensation communicated to the hand of a thin-walled, unilocular cyst, without the hard distention which an ovarian tumor causes; (3) the history of repeated tappings without evil result, on account of the bland character of the fluid, which was described as being like spring-water.

Since the tumor was first noticed the patient had borne six children, and she had been tapped twenty or thirty times. During each pregnancy the size of the uterus and of the tumor taken together was so great as to interfere with respiration, and tapping became necessary. The tumor would remain collapsed while she was nursing the child, but as soon as the child was weaned it would begin to refill, necessitating tapping, sometimes before she was again pregnant, sometimes not till she

[1] Since the foregoing was written Case XVII has reported great relief from tinnitus and vertigo.

was carrying the next fetus. After the birth of the last child the cyst did not fill again for ten years. After each tapping it has been impossible to detect any evidence of tumor. These facts I learn from Dr. Gould, of Lockport, who has followed the case through its history. The general health of the patient has been good, and she sought operative relief because tapping had become necessary at intervals of only three weeks, and she was tired of the frequent interference.

I naturally expected to find adhesions where the tumor had been tapped, but none was present, not even at the site of the latest aspiration, three weeks previously, when thirty-nine pounds of fluid had been withdrawn. This is a remarkable fact, and it bears additional testimony to the innocuous and unirritating qualities of the fluid of broad-ligament cysts. It is an impossibility to prevent the entrance of some of the fluid into the peritoneal cavity at each tapping, and it is a well-known fact that such cysts do not produce peritonitis, even if they rupture into the peritoneal cavity, unless there is some accidental element of sepsis or irritation.

After emptying the tumor and pulling the flaccid sac out, I found that it had a very broad pedicle, and that it had grown between the folds of the mesentery of the large intestine, so that the bowel was apparently adherent to it. By cutting through the peritoneal coat of the tumor, I was able to enucleate it from its seat in the mesentery. It would have been possible to enucleate the whole cyst, leaving no pedicle at all, but there would have remained a large oozing surface, and I preferred to tie off a considerable part of the tumor. After trimming the cyst away from its adhesions down to the intestine, I puckered together the raw surfaces with catgut, and brought the peritoneum together over them, so as to leave only a line of cut tissue. The ovaries were atrophied. One lay on the tumor and was removed. The other I lifted up and examined, but as there was no disease it was left in place. The uterus was somewhat large.

The patient has had practically no elevation of temperature or acceleration of pulse, and her recovery is assured.

You will notice the thin wall of the cyst, the clear fluid, which is so different from the turbid contents of an ovarian tumor. Here is a little cyst filled with even lighter-colored fluid than the larger one, but there is not the multilocular condition seen in ovarian tumors. I can demonstrate to you on this specimen another characteristic of intra-ligamentary cysts: the peritoneum separates with the greatest ease from the tumor, whereas in ovarian cysts, there being no peritoneal covering, we cannot make such a separation.

CARCINOMA OF THE BODY OF THE UTERUS.

This specimen is probably one of carcinoma of the body of the uterus. The patient from whom it was taken was a woman of fifty-eight, who, for a year or two, had had a discharge from the uterus, accompanied by so much pain that one-grain doses of morphin hypodermatically were necessary to give relief. I had treated her for a year, curetting the uterus, once or twice inserting tampons of iodoform-gauze, and using other local measures without affording relief. Although the duration of the disease made me doubt the existence of carcinoma, I finally decided to remove the uterus, as the patient was losing ground continually, and was praying for anything, even death, that would stop her sufferings.

The operation was rendered difficult by the small size of the vagina, which would not hold a Simon's speculum. The patient had never borne children, and the vagina was already undergoing the atrophy of age. I first made an opening into the utero-vesical pouch through the vagina, and continued the incision entirely around the uterus, so as to free the cervix from its vaginal connections. Then the abdomen was opened, the patient occupying the Trendelenburg position, the advantages of which were never more clearly exemplified. The intestines were all retracted toward the diaphragm, and the pelvis was exposed and found empty. The broad ligaments were ligated and cut away. The ligatures, which were of catgut, were brought down through the vaginal wound, which was left open, the vagina being stuffed with iodiform-gauze, which has not yet been changed. The uterus, as you see, is not very large, and its removal was easy. There was no oozing at the completion of the operation. The patient nearly died of shock on the table, but she rallied, and last night was in fair condition. Whether she recovers or not, and whether the condition proves to be carcinoma or not, I shall still consider that the operation was justifiable.

On pressure, what appears to be pus exudes from many spots in the muscular wall, and there is no distinct tumor. If this is not carcinoma, it must be a diffuse suppuration of the uterus—something which certainly would demand radical treatment. But on examining this substance under the microscope, it is seen to consist of epithelial cells, which perhaps have been squeezed out of carcinoma-nests. (P. S.—The patient recovered.)

FIBROMA OF THE UTERUS.

This patient is forty years old, has been married five years and a half, has never had children, and was perfectly well until six months ago. She then began to have pains across the abdomen, and her menstruation, which had previously lasted three days, was prolonged to five or six days, with a corresponding increase in the loss of blood and with much pain. She complains of having to pass water every fifteen minutes during the day, and very frequently at night, so that her rest is broken. Except for the calls to urinate she says she would sleep well. The urine is clear and light-colored, almost like water, and she does not pass much at a time. Her digestion seems to her sluggish, she feels as if the food remained in the stomach, and there is a tendency to constipation.

As is usually the case, there is nothing distinctive in this history, and an examination will be necessary to reach a diagnosis. I find the cervix in about the normal position, but in following up the uterus it seems to spread out in front, behind, and on both sides. By bimanual palpation it is easy to determine that the uterus is enlarged, and, from the presence of this firm mass, and the history of increased and painful menstruation, I have no hesitation in making the diagnosis of a fibroid tumor, perhaps as large as my two fists. The tumor is hard, smooth, painless on pressure, with a few secondary

nodules—all these items being diagnostic of a fibroid. As to its location, it is not subperitoneal, as the uterus is quite symmetrically enlarged; there is not sufficient menorrhagia to determine that it is submucous, and it is probably therefore interstitial. The passage of a sound would aid somewhat in the diagnosis, but there is no especial advantage in determining the exact location.

We might remove the tumor, tying off the broad ligaments, drawing the uterus into the abdominal wound, and holding it there with a clamp. But, as it is still quite small, the case is favorable for the trial of galvanism. We may diminish the flowing and ameliorate the other symptoms, even if the tumor does not decrease to any extent.

The bladder-symptoms deserve special attention. It is generally supposed that a large tumor pressing on the bladder will cause irritability and a frequent desire to void urine, but it is by no means necessarily the case. The patients from whom I removed a large fibroid of the uterus and an ovarian cyst respectively, and whom you saw at a recent clinic, presented no such symptoms. I have seen the pelvis so completely filled by tumors that there was apparently no room left for the bladder, and yet there were no particular bladder-symptoms. The urine should always be examined in these cases of vesical irritability, for there is usually found an excessively acid reaction, or oxalate of lime crystals, or some other irritating substance. Even when a tumor is present, it is not safe to take it for granted that all the symptoms are due to it alone. Such irritability of the bladder as this patient has is more than an uncomfortable symptom. It interferes with her work, it interrupts her sleep—which is still more important—and it depresses her general health appreciably. Electricity will tend to relieve the local irritability; if the urinary symptoms are due to anatomic conditions, to the encroachment of the tumor, a diminution in the size of the tumor would also be effectual, and this we hope to accomplish with electricity. Certainly I have seen many similar cases improve symptomatically and in the size of the tumor by the continuous use of galvanism.

Note.—The symptoms were not entirely relieved by galvanism, and oöphorectomy was performed later. Even this did not materially diminish the size of the tumor, and I should recommend extirpation of the uterus.

CLINICAL MEMORANDA.

COMPOUND COMMINUTED FRACTURE OF THE FRONTAL AND ETHMOID BONES, WITH INJURY TO THE MENINGES, AND LACERATION AND PROTRUSION OF THE BRAIN-SUBSTANCE; RECOVERY.

By THOMAS J. McLOUGHLIN, M.D.,
SURGEON TO ST. FRANCIS HOSPITAL; SURGEON TO JERSEY CITY CHARITY HOSPITAL, JERSEY CITY, N. J.

The following case is thought to be of interest, not only on account of the severity and extent of the fracture of the frontal and ethmoid bones, but also because of its having been complicated with a rupture and tearing of the meninges, and a laceration and protrusion of the substance of the brain; and, lastly, because of the complete recovery from these severe injuries.

C. A., by occupation a dock-builder, was born in Norway, and is at present twenty-four years of age. While going to his work, on July 15, 1893, he received an injury by jumping from a moving railroad train. The cars slowed up, but did not stop as he expected, and he jumped on a pile of cinders, which he hoped would protect him from the bad consequences of his rash act. Impelled by the momentum of the moving train, he pitched forward after jumping, and his forehead struck with great force against a cross-tie. He was picked up unconscious and bleeding, and after a little delay sent to the hospital. On examining him after admission, I found all the soft tissues torn from the frontal bone from the middle of the forehead to the nose, and hanging down over the face, revealing an extensive compound comminuted fracture of the frontal and ethmoid bones. The line of fracture extended from the inferior and outer border of the left frontal eminence, through the nasal eminence and right superciliary ridge to the right external angular process.

By exploration I was enabled to feel the movement and crepitation of the fractured ethmoid, and to ascertain that the fractured edges of the frontal bone, nearly throughout the line of fracture, were separated half an inch, freely admitting the tips of the fingers. Both the tables of the frontal sinus had been extensively comminuted. The meninges were ruptured and torn, the lower frontal convolutions were lacerated, and brain-substance was seen protruding through the opening. The right eye appeared hopelessly crushed, and from the large size of the chasm all hope of recovery seemed precluded. I removed many small pieces of bone, partly the tables of the frontal sinus, and the whole of the orbital plate of the frontal, which was broken into several fragments and detached. All loosened pieces of bone having been removed, the wound well cleansed of dirt and cinders and thoroughly syringed with bichlorid solution, I put in a strand of catgut for drainage, brought the reflected flaps of soft tissue back to their natural position, as exactly as I could, and united them with carbolized silk sutures. The wound was then dusted with iodoform and dressed with iodoform and carbolic gauze, and bandaged.

Notwithstanding his severe injuries the man was conscious when taken to the hospital, and gave rational answers to the questions asked him; his pulse was good, his respiration undisturbed, his left pupil contracted, the right eye being too much injured to note the state of the pupil.

On the evening of the 15th there was some acceleration of the pulse; complaint of headache; slight delirium; but the man had rested quietly during the night. The temperature was 99°, the pulse 85.

On July 16th, the temperature ranged from 99° to 100½°, the pulse from 76 to 82. The dressings, having become soiled during the night with blood and free serous discharge, had to be changed. The bowels were evacuated during the day. The pupil was contracted, headache was constant, and delirium occurred in the evening, followed by an uneasy rest. His hair was cut short, and an ice-water cap was applied to his head.

On July 17th, the temperature ranged from 99½° to 101°, the pulse from 80 to 88. The patient was delirious and restless all day; the pupil was contracted, and headache was severe and continuous. It was again found necessary to change the dressings. The patient partook freely of liquid nourishment.

On July 18th, the man was drowsy and listless, some paralysis of right arm and leg had set in, and his headache and delirium still persisted actively.

On July 19th, the hemiplegia of the right side was more marked, and the patient used chiefly the left extremities in his movements. The pupil was now dilated, and delirium was unremitting. The discharge from the wound was free and the dressings required to be changed daily.

From July 20th to the 23d the temperature ranged from 100° to 102.5°, and the pulse from 64 to 72. During these four days the patient was in a comatose state, with complete paralysis of sensation and motion of the right side; he lay on his back and right side, the pupil dilated, delirious the greater part of the time, and endeavoring to pull the dressings off his head. All evacuations were passed in bed. The wound discharged freely and the dressings were renewed each day.

On July 24th and 25th, the delirium was less severe and constant; there was some return of sensation, but no improvement of motion was yet appreciable. The wound was doing well.

On July 26th, the temperature was 99¾°, and the pulse 70. Sensation was much improved, and there were evidences of returning motor power; there was no delirium during the day, and the man could be aroused to consciousness, making brief answers to questions.

The next day there was a full return of consciousness and recognition of friends and attendants; the power of sensation and motion was rapidly returning. The wound discharged less, was granulating well, and did not require a daily change of dressing.

On July 28th, the man's condition was still further improving, although he was not much inclined to talk, but did so rationally when spoken to. He had so far recovered from his hemiplegia that he was able to get out of bed and walk to the night-chair close by.

On July 29th, the temperature was 98½°, and the pulse 74. The man was more attentive to his surroundings, giving correct answers freely to questions addressed to him, but his speech and reasoning faculty were not always coherent; he was able to sit up and walk about the room, and his appetite and digestion were remarkably good. The wound was doing well, discharging almost nothing; the bony interruption was rapidly filling up with callus, and cicatrization was progressing favorably.

On the night of July 29th he again gave evidence of deranged intellection by putting on his clothes in the middle of the night and starting down stairs, but the following day his mental faculties were clear. The swelling and inflammation of the right eye, which I feared was so badly crushed that total loss of sight would follow, had greatly subsided, and vision was so much improved that he could discern and count fingers held before the eye.

On July 31st, the wound was healed and the bandages were removed; the chasm in the forehead was filled out firm with ossifying callus, and almost on a level with the rest of the bone. The man sat up all day, had a good appetite and digestion, and declared that he felt well bodily. Notwithstanding his great physical improvement he still at times showed traces of intellectual derangement, manifested chiefly by the performance of irrational actions. During the next four days his sight steadily improved, and he could read large print with the injured eye. Frequent headaches of a severe character across the forehead still distressed him, and he stated that his right side continued to be a little weaker than his left, and that a slight numbness of feeling persisted as well in his face as in his right arm and leg. His mental faculties seemed restored to their normal condition, and his speech and actions were entirely rational.

On August 20th, five weeks from the date of his injury, he was discharged, cured.

On examining the patient on November 8th, nearly four months after the injury, I found a noticeable change in the contour of his forehead; it had lost its regularity of outline. The superciliary ridge was effaced, and at the site of the nasal eminence, in place of the former elevation a marked depression existed. Immediately above the frontal sinus the bone appeared more prominent, and seemed bulged out, but I think the prominence was only relative, and that the appearance was caused by the absence of the sinus of the forehead and by the depression that replaced it. On close inspection and measurement it was found that the right eyebrow was on a plane one-half inch posterior to that of the left brow, the whole right side of the forehead having been driven back by the force of the blow. The sight of the right eye he declared to be good, and from his friends I learned that they perceived no difference either in his mental operations or in his disposition from what these were before his injury.

A CASE OF COLCHICUM-POISONING.

By HAROLD N. MOYER, M.D.,
of Chicago;
Adjunct Professor of Medicine and Chief of the Neurological Clinic, Rush Medical College.

Between four and five o'clock on September 10, 1893, a physician administered an unknown quantity of colchicum to a young woman, twenty-two years of age. The woman was apparently in good health, with the exception of chronic constipation, and colchicum was administered for its cathartic effect. The quantity given was claimed by the physician to have been about a teaspoonful, but he admitted pouring it from a bottle directly into a glass, to which a small quantity of water was added, then giving it to the patient. There is thus some uncertainty as to the quantity that was actually taken. There is also some uncertainty as to the preparation. It was stated, however, to have been the wine of colchicum, but it had remained in the physician's office for many months very insecurely corked, and it is possible that the preparation had become very much stronger from the evaporation of the menstruum. From the physician's office the patient hurried to her home, and reached there about five o'clock, somewhat overheated, from having walked rapidly. Immediately on her arrival home she took a cold bath, and changed her clothing. At about seven o'clock she had a severe chill, followed by vomiting and frequent movements of the bowels, with very severe colicky pains in the abdomen. This

condition continued until 10.30 P.M., the woman being alone in the house. At that time a physician was called, who administered sedative remedies, the exact nature of which is not known. Very early the following morning the pain subsided, the vomiting ceased, and she became quite comfortable. Her condition continued substantially the same until about twelve o'clock of the following day, when the pulse and respiration began to fail. The physician was again summoned, and administered stimulants. Her condition then remained about the same until twelve o'clock the following night, when another sinking spell came on. Notwithstanding that stimulants were freely administered at this time, the respiration and the pulse continued to fail, and death took place at four o'clock on Wednesday morning, thirty-six hours after the administration of the colchicum.

A post-mortem examination was made September 13th, at 2 P.M., twenty hours after death. The body was that of a fairly well-nourished girl, of medium size, in good flesh, and well developed. Rigor mortis was disappearing. The scalp was removed, and was comparatively bloodless, otherwise normal. The skull-cap was slightly adherent; the dura normal. The superior longitudinal sinus contained a long, slender, goose-fat clot; the pia was normal, thin, and with difficulty separated from the convolutions. There was a minute whitish clot in the basilar artery, which was loose, soft, and did not occlude the lumen of the tube. A similar minute clot was found in the anterior communicating artery. The ventricles were quite empty; the brain, as a whole, contained only about the usual supply of blood; the choroid plexuses were more prominent than usual. On the floor of the fourth ventricle, just above and anterior to the striæ albicantes, a minute hemorrhagic spot was found, not larger than the head of a pin. A vein was dilated so as to be readily distinguished a little in front of this and on either side of the median rhaphé. The remainder of the brain was entirely normal. The right heart was moderately distended with clotted blood, the left contracted and empty; a goose-fat clot was found in the right ventricle, extending into the pulmonary artery. The valves and the muscular structure of the heart were intact. The coronary arteries were dissected and found normal, and contained no clot. The right border and the apex of the heart contained a number of hemorrhagic markings; there were slight effusions of blood between the muscle-bundles, which resembled somewhat the appearance produced by dipping a comb into a colored fluid and marking a sheet of paper. These were some thirty or forty in number, and when cut across some fluid blood could be pressed out of the spaces. Ten or fifteen of these small spaces were found at the junction of the left ventricle and auricle, somewhat larger than those described, and round rather than oblong. The left pleural cavity was normal, with the exception of two bands of adhesions. The lungs were hypostatically congested, but floated well upon the surface of water. Very little edema was present, though they seemed to contain more than the usual quantity of blood in the vessels. The right pleural cavity was almost obliterated; the lung was removed with difficulty. The right lung was in substantially the same condition as the left. The bronchi of both lungs contained a small quantity of frothy, bloody mucus; the trachea contained a small quantity of bloody mucus; the thyroid gland was enlarged, each lobe measuring two and one-half by one and one-half inches. The esophagus was normal. The abdominal cavity was opened, and the stomach found enlarged, about ten by five inches, and distended with gas.

The general appearances of the intestines were normal, upon first opening the abdomen. About six ounces of bloody serum were found in the abdominal cavity. The spleen was small and pale. The pyramidal portion of the left kidney was congested, the cortex normal, and the capsule readily stripped. The right kidney was in precisely the same condition, with the exception that the pyramids were still more congested. The colon was quite empty, containing only a white, cheesy-like mass, spread out evenly over the mucous surface. There was no ulceration or disease of the mucosa of the intestines. The small intestines were normal throughout. The stomach seemed a little more deeply red than usual on its posterior surface. It contained nearly a pint of liquid; the mucous membrane was grayish in color, and separated readily from the submucous structures. The liver was unusually pale and glistening, and the proper markings of the organ could not be distinguished. The bladder was empty and contracted, containing a small quantity of mucus. The rectum was empty and very pale; the vagina was dark in color, with its rugæ well marked, and it contained some fluid blood. The body of the uterus was not enlarged. The mucosa was soft, velvety, and a little congested. The spinal cord was not examined. An examination of the contents of the stomach gave no reaction for colchicin. The liver was not examined for that poison.

While there is uncertainty as to the quantity of colchicum taken in this case, the clinical symptoms are quite in accord with those detailed in the few cases that have thus far been published. A very complete post-mortem examination also failed to reveal any adequate cause of death. Therefore, while the colchicin was not separated and identified in the abdominal organs, I think the cause of death was fairly well established. In this connection we would call attention to the hemorrhagic markings found upon the heart, which have been described before in cases of death from colchicum-poisoning.

EPITHELIOMA OF THE SOFT PALATE.[1]

BY A. H. CLEVELAND, M.D.,
OF PHILADELPHIA;
SURGEON TO THE NOSE, THROAT, AND EAR DISPENSARY OF THE PRESBYTERIAN HOSPITAL; INSTRUCTOR IN DISEASES OF THE THROAT AND NOSE, PHILADELPHIA POLYCLINIC.

ON May 16, 1893, Mr. P. C., sixty-five years old, presented himself at the Nose and Throat Clinic of the Polyclinic Hospital, giving a history of having had, early in the winter, an attack of influenza, accompanied by severe cough. The violence of the cough, he thought, had caused the hoarseness and slight soreness then present. The cough and hoarseness soon disappeared, but the soreness still persists, and lately he has felt a lump in his throat. At no time has there been acute pain either on swallowing or talking.

[1] Exhibited before the Laryngological Section of the College of Physicians, March 6, 1894.

As to the family history, we learn that the patient's father died of "cancer" at the age of fifty, his mother of a "stroke," at seventy-three. Four brothers and one sister are deceased, none from malignant disease.

Examination disclosed a large irregular mass, involving the entire uvula, extending upward on the soft palate, and on either side well across the half arches. The margins seemed elevated and well-defined. The entire growth seemed quite dense to the touch, but was covered with superficial ulceration.

A diagnosis of probable epithelioma was at once made, which was verified by the removal of a small portion of the tip of the uvula and its microscopic examination. As immediate excision seemed to offer the best chance to the patient, it was advised and accepted.

Through the kindness of Dr. MacCoy, I was enabled to operate in the hospital on June 6th, Dr. Cleemann, the patient's family physician, being present. In order to avoid hemorrhage, and as the growth was so clearly defined, I decided to remove it under cocain, and with the galvano-cautery knife. The pain from the cautery being so easily borne, the cocain was soon discontinued.

As it was almost impossible to keep the cautery-knives continuously hot, the operation was rather tedious, and recourse was finally had to the smallest point of the Paquelin cautery, with success. At no time was there any hemorrhage until I divided a few remaining fibers with a scalpel; then it was but slight. The patient made an uninterrupted recovery, was allowed to leave the hospital on June 8th, and within two weeks the wound had entirely healed. Since then there has been no indication of recurrence.

Being fully aware that considerable of the soft palate would have to be sacrificed, making practically an artificial cleft palate, I was careful to tell the patient that there would probably be a decided change in his speech. To my surprise, we were unable, after the operation, to detect any change whatsoever.

Malignant growths of the soft palate are not very frequently encountered, but in the comparatively few cases on record a considerable variety in structure has been observed.

Carcinomata, scirrhous, medullary, and encysted, as well as epitheliomata, have all been reported. It is interesting to note in how few of these pain was a prominent symptom.

Mr. R. Perssé White (in the *Irish Hospital Gazette* for 1873, p. 181) describes a case which was curiously like mine, in that a growth of almost exactly similar size and position was removed by means of the galvano-cautery. It is the only instance reported in which that instrument was used.

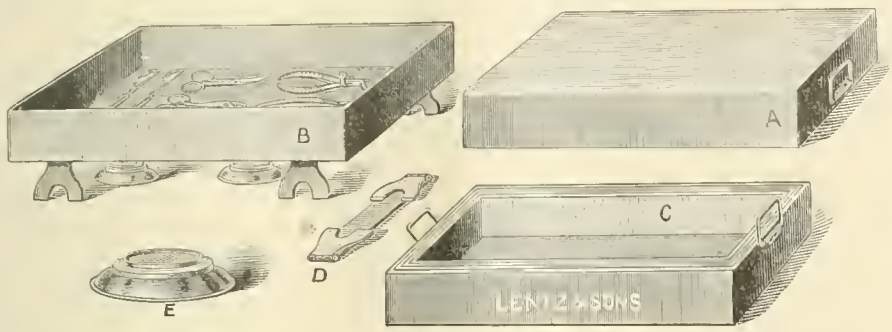
1804 Chestnut Street.

NEW DEVICE.

A PORTABLE TRAY INSTRUMENT-STERILIZER.

By ANDREW J. DOWNES, M.D.,
of Philadelphia.

Nearly two years ago I devised the simple sterilizer here illustrated. It consists of a nest of trays (C, illustration), the largest tray being 13¼ inches long, 6⅛ inches wide, and 1½ inches deep. The next size is just sufficiently less in all measurements to fit inside of and telescope freely but closely with the larger. These two trays, with a pair of simple trestles, as shown in the cut, and two asbestos alcohol lamps, form a complete sterilizer for instruments and trays. The third and fourth trays form a second sterilizer; the nest thus supplying one or two sterilizers, as occasion requires, and always four trays. In use the smaller one of a pair of



trays (B), holding the instruments, silkworm-gut, silk, etc., immersed in water containing 1 per cent. of soda, rests on the trestles; the cover tray, A, is placed over this, and the lamps lighted. Experiments prove that in six minutes a temperature of 212° F. can be obtained in any part of the sterilizing chamber. When ready to work, the surgeon removes the cover and assorts the instruments in both trays, which are also sterile.

The trays are made of sheet-brass, nickelled on both sides. The sizes are arbitrary; those described fit snugly in the bottom of a cabin-bag, 14 inches long, the inner tray of the nest holding conveniently instruments, trestles, and lamps.

For the usual run of gynecologic work this size is sufficiently large. For obstetric operative work and major surgery requiring large and numerous instruments a pair of trays to fit in an 18-inch cabin-bag will meet all requirements. This set should be 17 inches long and 2 inches deep.

A few small shallow trays, ¼ inch deep, will be found useful. They occupy little space and are sterilized with the instruments.

The sterilizer is made by Charles Lentz & Sons, of Philadelphia.

MEDICAL PROGRESS.

Celiotomy for Intestinal Obstruction by a Biliary Calculus.—Gusenthal (*Wiener medizin. Presse*, 1894, No. 12, p. 441) has reported the case of a woman, seventy years old, who for a period of twelve years had suffered with recurrent attacks of intense abdominal pain, without the association of jaundice. The patient came under observation in one of these attacks, not having had a movement of the bowels or having passed flatus for three days, and vomiting. The general condition was bad, the pulse was feeble, and the vomiting became stercoraceous. The abdomen was not distended and not painful. The bladder was empty, and nothing abnormal could be detected by rectal or vaginal examination. High irrigation of the bowel brought away fecal matter and permitted the escape of gas. On the following day the general condition appeared better, but the fecal vomiting continued. Irrigation of the stomach brought away feculent fluid, but a high irrigation of the bowel was without effect. Operation was now determined upon, and the abdominal cavity was opened by an incision extending from the umbilicus to the symphysis pubis. The intestine below a certain point in the duodenum was collapsed, while the small portion above was distended. At this point a hard ovoid mass as large as a walnut was palpable, and to which the intestine was closely applied. The bowel was grasped on either side of this body, which proved to be a biliary calculus and was removed through an incision an inch and a half long. The wall of the intestine presented a normal appearance, and the opening was at once closed by suture. The abdominal wound was closed and dressed antiseptically. Recovery followed without complication, and the patient was dismissed, wearing an abdominal bandage, four weeks after the operation. Six and a half weeks later the woman again came under observation, presenting symptoms similar to those of the preceding attack, but death took place after the lapse of eighteen days. Upon post-mortem examination, multiple encapsulated abscesses were found in the course of the lower portion of the abdominal cicatrix, and containing remains of silk sutures. The omentum was attached to the abdominal wall in the line of the cicatrix. The first and second loops of the jejunum formed an angle and were bound by adhesions, in the midst of which was an abscess communicating by a small opening with the lumen of the bowel. The inner surface of the bowel presented a small, smooth, linear cicatrix. The liver was enlarged and contained numerous umbilicated, carcinomatous nodules. The gall-bladder was contracted and contained a small, pyramidal stone of about the size of a cherry. On the inferior surface of the viscus was a fistula communicating with the adjacent adherent duodenum. The common choledoch and cystic ducts were patulous. The head of the pancreas was the seat of a large carcinomatous formation.

Cerebellar Tumor.—Jalland (*Lancet*, No. 3681, p. 671) has reported the case of a woman who presented progressive weakness, together with pain in the right arm and leg and between the shoulders. The voice had gradually become husky. Vision had gradually failed until there was absolute blindness, with utter inability to distinguish light from darkness. The pupils were rather large, but there was no contraction on exposure to light. The grasp was enfeebled in both hands, the more so in the right. The neck was stiff, and on being bent forward great pain was induced in the cervical portion of the spine. The plantar reflexes were pronounced, but the knee-jerks were absent and there was no ankle-clonus. Sensibility was preserved in the legs. Both optic discs were pale and yellowish; the vessels were distinct; and the margins of the discs faded imperceptibly into a pale retina. There was neither ptosis nor paralysis of the recti muscles. There was deafness of the right ear, while the hearing of the left ear was preserved. The act of winking was but seldom performed, and then but partially. There was lessened power in the right orbicularis palpebræ in ordinary movements, though the eyelids closed tightly when the will was exerted. While under observation headache set in, burning pain through the head and down the neck being complained of. The head was held low in bed, and the neck and spine stiff, attempts at movement inducing pain. The right conjunctiva became anesthetic, though the left maintained its sensibility. Difficulty in localization with the right arm and forearm developed, but the left side remained unaffected. Smell and taste appeared to be preserved. Drowsiness and mental apathy came on, although knife-like pains in the back and legs were complained of. Vomiting appeared late, together with twitching of the eyes and stiffening of the arms. Breathing appeared to cease three or four minutes before the heart stopped beating. Upon post-mortem examination, a tumor about the size of a walnut was found situated upon the antero-inferior aspect of the cerebellum, projecting slightly above the surface. The growth was moderately firm in consistence, irregularly oval in form, and more deeply gray in color than the general substance of the cerebellum. It was distinctly localized, but not encapsulated. It occupied a position corresponding to the anterior portion of the right digastric lobe of the cerebellum. It pressed on the right side of the medulla, which displayed a slight depression. The right optic tract was somewhat flattened and only two-thirds the thickness of the left. The posterior aspect of the internal surface of the petrous portion of the temporal bone was hollowed out from the pressure of the growth. On section the tumor showed slight hemorrhages in its interior. Histologic examination disclosed the structure of a glio-sarcoma. The right optic tract was atrophic.

The Relation of Heart-disease to Menstruation.—At a recent meeting of the Obstetrical Society of London, Gow (*British Medical Journal*, No. 1733, p. 579) detailed the results of a study of the menstrual function in fifty cases of heart-disease in women. In twenty-eight the menstrual flow was unaltered; in seventeen it was absent or scantier than before; in five it was either more profuse or recurred more frequently than before. In no case was there good evidence that heart-disease gave rise to severe menorrhagia. Amenorrhea or scanty menstruation appeared to be a more common accompaniment than menorrhagia. A further analysis of these cases seemed to point to the fact that heart-disease led to relative sterility, and also that it increased the tendency to premature expulsion of the ovum. It was pointed out

that a large number of women suffering from valvular disease of the heart passed safely through the period of pregnancy and labor. Of mitral stenosis there were twenty-two cases; in nine menstruation was regular, and the amount of blood lost unaltered; in five cases menstruation was regular, but more scanty; in four there was amenorrhea; in four menstruation was either more frequent or more profuse. There were fifteen cases of mitral incompetence; in ten menstruation was unaltered, in four more scanty; in one there was amenorrhea. Mitral stenosis and incompetence were present in seven cases; in four menstruation was unaltered, in one more scanty; in one there was amenorrhea, and in one the menstrual loss was slightly increased. There were two cases of aortic incompetence and obstruction; in both menstruation was unaltered. In three cases there was aortic and mitral incompetence; in these menstruation was unaltered. One case presented aortic incompetence and obstruction and mitral incompetence; in this the menstrual loss was scantier than before.

Accentuation of the Pulmonary Second Sound in Typhlitis.—In studying the records of a number of cases of perityphlitis, Mannaberg (*Centralblatt f. klin. Medicin*, 1894, No. 10, 209) was struck by the frequency with which accentuation of the pulmonary second sound was noted—ten times among eighty-eight cases. In a subsequent study, devoted to the determination of this point, among thirteen cases of ordinary acute perityphlitis, the pulmonary second was found loudly accentuated in four, and more distinct than the aortic second sound in seven others; while in the remaining two both the pulmonary and the aortic second sound were accentuated, in one with duplication of the pulmonary sound. In one other case there was duplication of the pulmonary sound; in two there was functional systolic blowing, and in one of these transitory arhythmia of the pulse. The conclusion is thus reached that accentuation of the pulmonary second sound is a frequent manifestation in the course of perityphlitis, but an explanation for the phenomenon is as yet wanting.

THERAPEUTIC NOTES.

The Treatment of Typhoid Fever with Lactophenin.—v. Jaksch (*Centralblatt f. klinische Medicin*, 1894, No. 11, p. 233) reports the employment of lactophenin in eighteen cases of typhoid fever with most gratifying results. Lactophenin is chemically a phenetidin in which the acetic acid yet in combination with the ammonia-remnant is replaced by lactic acid. It is thus lactylphenetidin, and appears as a crystalline powder of slightly bitter—not disagreeable—taste, and is soluble in water. The remedy was given in doses of from 7.5 to 15 grains, enclosed in capsules of starch, the frequency being determined by the degree of pyrexia and other conditions. The cases thus treated were not selected, and were of at least average severity. In no case was any notable unpleasant effect observed. The drug was administered in thirty-three other cases of various febrile kind, making a total of more than a thousand individual doses, and with the same freedom from complication. In one case an initial dose of 7.5 grains was followed by nausea and vomiting, but subsequent doses occasioned no untoward manifestation. In two cases there was slight arhythmia of the pulse, but this could not, however, with certainty be attributed to the medication. The decline of temperature that follows administration of lactophenin takes place gradually and lasts for a considerable length of time, and the subsequent rise, even if it occur rapidly, is not attended with a chill. The quality for which lactophenin is most warmly praised is its sedative action. It dissipates delirium, clears the sensorium, and induces a sense of well-being such as has not been observed in the course of other modes of treatment. The appetite also soon returns. Complications, such as hemorrhage and relapses, are not prevented by lactophenin.

The Treatment of Asphyxia Neonatorum.—Prochownik (*Centralblatt f. Gynäkologie*, 1894, No. 10, p. 225) points out that under certain conditions (such as a low room, bony fracture, objection of the family) the swinging method of Schultze for the resuscitation of asphyxiated newborn children may be impracticable. The requirements to be met are to clear the air-passages, to force air into the lungs, and to stimulate the circulation, in order that oxygenated blood may reach the medulla. To bring about these ends the child is inverted and held by the feet, either by the accoucheur or by an assistant. To prevent slipping, the feet may be covered with soft linen or other material of like nature. The head of the child is gently rested upon some firm surface, in such a way, however, that the neck remains extended. The chest of the infant is now grasped with one or both hands of the accoucheur, and moderate pressure exercised, which, upon the first two or three attempts, is maintained for a short time, and then gradually released; after a certain amount of mucus has escaped from the mouth, the thorax may be given free play following each compressive effort. In successful cases respiration will have been instituted after eight or ten compressions. The child may now be placed in a warm bath, or warm affusions may be made; then another series of eight or ten compressions is undertaken, and these procedures are continued alternately until the resuscitation of the child is permanently assured.

Guaiacol Topically in Acute Tonsillitis.—Raymond (*Medical Record*, No. 1220, p. 364) reports successful results from topical applications of pure guaiacol in the treatment of acute tonsillitis. The application is somewhat unpleasant and attended with moderate irritation, which is not prevented by the previous application of cocain, but the duration of which is, as a rule, but brief. Relief of pain follows almost immediately, and in cases presenting febrile symptoms a slight decline in temperature may be observed. The applications were made with a cotton swab dipped in pure guaiacol. A 50 per cent. solution in oil of sweet almonds is less efficient. The therapeutic effect appears to be more pronounced in cases of superficial or lacunar tonsillitis than in the phlegmonous variety of inflammation.

THE SAFRANIN-REACTION IN SPUTUM AS AN AID TO THE DIFFERENTIAL DIAGNOSIS OF PNEUMONIA FROM BRONCHITIS.

THE affinity of mucin for the anilin dyes, pointed out by FLEMMING, SCHIEFFERDECKER, HOYER, and others, led S. SCHMIDT some time ago to suggest a method of differentiating pneumonic from bronchitic sputum by means of the stain of EHRLICH BIONDI, consisting of a mixture of methylene-green, acid fuchsin, and orange G. According to SCHMIDT, a piece of sputum the size of a pea was shaken in a test-tube with a two and one-half per cent. solution of bichlorid of mercury in alcohol until it was broken up into fine particles; the alcohol was then carefully poured off, and the fixed sputum treated with the diluted triple stain. Sputum which contained large quantities of mucus turned the mixture greenish-blue, while pneumonic sputum changed the color to red, a mixture of the two giving rise to a dirty-violet tint. The reaction has been attributed by RENK, KOSSEL, STARKOW, and others, to the predominance of albumin in pneumonic sputum and of mucus in the sputum of simple bronchitis, and this is probably the correct explanation. The test is a macroscopic one and has been manifoldly confirmed, but it is not always reliable, as the reaction is obscured when there are many cellular elements (leukocytes, epithelium) present.

ZENONI ("Ueber Farbenreaktionen des Sputums," *Centralbl. f. innere Med.*, 1894, No. 12) claims that the method which he suggests does away with this difficulty, and, moreover, is an improvement on the old, as his test adds to the naked-eye appearances the possibility of increased precision by means of microscopic examination.

He spreads out a piece of the sputum to be examined on a cover-glass, leaves it in strong alcohol for a quarter of an hour or more until coagulated, and then stains with a half-saturated aqueous solution of safranin. The cover-glass is examined on a white ground; if mucus (bronchitis) predominates the color will be distinctly yellow, if albumin (pneumonic diseases) is in excess the color will be red. The reaction of safranin with mucus occurs so quickly and sharply that there can be but little doubt that a definite chemic combination takes place.

BIZZOZERO was among the first to observe this peculiar metachromatic action of safranin, when studying the tubular glands of the stomach and intestine. ZENONI has tested the reaction on various mucoid and albuminous substances and finds that among others the mucus of the gastro-intestinal tract and of the vagina, the secretions from nasal polypi, synovia, and cartilage undergoing mucoid metamorphosis, turn yellow with safranin, while blood-serum, fibrin, albumin, and peptone invariably give the red color.

The test, as a means of differentiating sputum as an aid to diagnosis, it seems to us, is well worthy of further trial, and it may be, too, that subsequently wider application of the principle may be found in the differentiation by color-reactions of different substances now grouped together under the generic name of the "nucleo-albumins."

EDITORIAL COMMENTS.

The Medical Profession its own Worst Enemy.—Such is the lesson of every nostrum-advertisement in medical journals, or certified to by medical men, of every attempt to break down the Code, of reading-notices, of our indifference to the patent-medicine humbug, to the charlatans within and without the profession.

But the most amusing proof of the truism comes from Ohio. After a long war, in which "the three schools" had been worsted and jeeringly howled into defeat by the combined forces of the clairvoyants, Indian medicine men, wizard kings of pain, and abortionists, the

medical men arose in their wrath, intimidated candidates, went to the polls *en masse*, and elected a Legislature bound and bonded to enact a medical practice act (in the interests of "the three schools") that should certainly and at last put to utter rout the filthy hordes of the worst sorts of medical harlequins. To the House Committee on Medical Colleges and Universities of the Legislature, a committee made up almost entirely of physicians, was consigned the bill.

And there it died! The committee proposed to report the bill back without recommendation, but this was equivalent to complete defeat, and the responsibility was left where, as Dr. Richardson says, it properly belonged, with the committee itself.

This bit of opera bouffeism is so astonishing that Dr. Richardson's explanation must be quoted in order to render our report believable:

"The division in the committee is entirely on the organization of the board. Under the present arrangement the regulars would have three members out of seven, with five affirmative votes necessary to effect any action by the board. The disaffected members of the committee desired a board of eight, four of whom may be regulars, with an affirmative vote of six necessary to pass any measure. There is no more difference in the practical effects of the two boards so constituted than there is between tweedle-dum and tweedle-dee, and the members of your committee on legislation here have been quite willing to agree to either, but the chairman of the committee in the House is a homeopath, and his school seems to suspect some treachery and something inimical to their interests, and will not consent to the change."

After this, dare anyone say a word as to any deficiency among medical men in a sense of humor, or hint that we need a Jonathan Swift as our historian?

Insular Understandings.—Our English friend, the *Medical Press and Circular*, views as "curiously novel" the suggestion of erecting in New York a large building for the sole purpose of providing consulting-rooms for physicians (with the added comment that "we never seem to hear of 'surgeons' in America"). Our worthy contemporary seems not to be aware that just such buildings as that contemplated for New York are already in most successful operation in Chicago and Pittsburg, and perhaps elsewhere, and that a proposition has been made for the erection of a similar structure in Philadelphia. Our contemporary may not have heard of the American surgeon as constituting a distinct class, but medical literature, past and present, will bear abundant evidence of the ability of the surgeons of America and of the character of their work. The American surgeon is first of all a medical man, and only a surgeon by specialization.

In passing we may call the attention of our friend, who so strenuously objects to the omission of the unnecessary part of the diphthong in such words as "hæmorrhage" and "perinæum" and the like, that in the *Press and Circular* of March 21st, in a prescription written in Latin, the word "ætheris" appears. Even the American orthographomaniac dare not take such liberties with the dead languages.

The Conduct of the Journal of the American Medical Association.—We are glad to learn that at a largely-attended meeting of the Philadelphia County Medical Society, held April 18th, the following preamble and resolutions were unanimously adopted:

Whereas, The Code of Ethics of the American Medical Association declares it derogatory to professional character for a physician to dispense or in any way promote the use of a secret nostrum; and the American Medical Association by a resolution unanimously adopted at its meeting in 1892 forbade the advertising of such nostrums in its *Journal*;

And whereas, The *Journal* of the Association has continued to advertise such nostrums, and in defence of its course in this particular has published an anonymous personal attack on a member of the American Medical Association and of this Society:

Resolved, That the Philadelphia County Medical Society respectfully demands that the Trustees of the *Journal of the American Medical Association* shall, in their public official acts, respect the spirit and letter of its Code of Ethics; and that the columns of its *Journal* shall not be used for the anonymous personal abuse of its members in good standing.

Resolved, That a copy of these resolutions be transmitted to the Medical Society of the State of Pennsylvania, and to the American Medical Association, and to the weekly medical journals.

Resignation of Dr. Pepper of the office of Provost of the University of Pennsylvania.—To those who have had any adequate conception of the enormous labor, physical and mental, carried on during the past thirteen years by Provost Pepper in connection with his duties as physician, professor, and chief administrative officer of the University of Pennsylvania, it has seemed simply marvellous that the human organism could endure such a strain. Dr. Pepper says it has now become necessary for him to choose between administrative work and medical science, and that his devotion to medicine has compelled his choice. The resignation was accompanied by a check for $50,000, in subscription to the fund for the extension of the University Hospital buildings. Dr. Pepper retains his connection with the Medical Department of the University. Dr. Pepper graduated from the Classical Department of the University in 1862, and from the Medical Department in 1864. He was Lecturer on Morbid Anatomy from 1868 to 1870, Lecturer on Clinical Medicine from 1870 to 1876, and Professor of Clinical Medicine from 1876 to 1877, when he succeeded Dr. Alfred Stillé in the Chair of the Theory and Practice of Medicine. In 1881 he was unanimously elected Provost, which position, in connection with the professorship in the Medical School, he has since held with such marked distinction and with incalculable advantage to the welfare and prosperity and advancement of the University. It is with a wholly justifiable and honorable pride that Dr. Pepper, in his letter of resignation, recounts the splendid progress made by the University during the time of his administration. Surely the gratitude of the institution, of Philadelphia, of the State, nay, of Education, are due him for a devotion and self-sacrifice rarely if ever equalled; and to these the profession of medicine adds a most hearty tribute of appreciation and of pride in the achievements and honors of one of its members.

Professional Tolerance of Illegally-practising Quacks.—We already have entirely too many quacks within the

profession whom we must tolerate; why, then, should we encourage by indifference the degreeless quacks, and those who are criminals in the eyes of the law? In one raid the New York police lately arrested sixteen abortionists. When the medical societies of a city employ no agent to ferret out such scoundrels, when all goes on silently and smoothly—there, assuredly, the vile work of the criminal quack and abortionist is active and unchecked. Not only this, but when hunted out of one city, or intimidated by prosecution, like their brother criminals of every stripe, they flock to neighboring cities where they can "work" without interference. To every physician there constantly comes the knowledge that these wretches are among us, the results of their crimes continually being left for him to repair as best he may, to keep silent about, and hence, really and indirectly to encourage.

The Refractionist is the name of a new "journal of practical ophthalmology," issued from Boston under the editorial care of Dr. Francis F. Whittier, in association with Drs. R. J. Phillips, W. F. Southard, M. F. Coomes, W. E. Baxter, J. W. Park, E. M. Marbourg. We are glad to see this new journal protesting in a practical way against the custom of opticians prescribing glasses. It announces that its advertising pages will not be open to such opticians. It is time the profession was aware of the injury to the public and to the profession by druggists, opticians, and instrument-makers entering into open competition with physicians in the treatment of disease. Sooner or later that sort of thing must end. Why not sooner?

SOCIETY PROCEEDINGS.

THE ELEVENTH INTERNATIONAL MEDICAL CONGRESS.

Held at Rome, from March 29 to April 5, 1894.

(Continued from p 442.)

Section of Surgery and Orthopedic Surgery.

Sir Spencer Wells, Sir W. Stokes, and Prof. Macewen were nominated as Presidents, and Mr. Noble Smith and Dr. David Newman were elected honorary secretaries.

Dr. Lucas Championnière demonstrated the good results obtained in the treatment of true epilepsy due to traumatic causes, as distinguished from those effected in the Jacksonian form of the disease. The report dealt with sixty-four cases in which operation had been performed. Of these, ten were cases of recent injury; the remainder were operated on for cerebral disease, either without injury to the skull or succeeding such injury. The method adopted consists in opening the skull with the crown of a trephine, and enlarging the opening in any desired direction by means of straight or curved pliers. Among the ten cases there were three deaths in cases operated on in a desperate condition. Among the fifty-four cases there were seven deaths; in two cases in which the period of survival was short the lesions were gross.

Prof. Macewen formulated the following conclusions: (1) All abscesses of the brain are formed subsequently to a primary focus of infective disease situated elsewhere; (2) the chief infective foci are formed in connection with middle-ear disease; (3) abscesses of the brain originating in middle-ear disease are generally in direct contact with the primary source of infection; (4) such abscesses are generally reached in the first place through the mastoid antrum; (5) the mastoid antrum is most easily opened through the supra-mental triangle, from which the whole tegmen antri and tegmen tympani may be exposed; (6) it is necessary to remove the whole infective tract; (7) after this has been done the skull is opened over the temporo-sphenoidal lobe of the brain.

Drs. Massa, La Vista, and d'Antona took part in the discussion.

Dr. d'Antona read a paper on "Resection of the Trigeminal Nerve," and described minutely the changes produced by impaired innervation upon the tissues previously supplied by the nerve.

Mr. Mayo Robson presented a table of all the operations, eighty in number, that he had performed on the gall-bladder and bile ducts. The operations included cholecystotomy, cholecystectomy, cholecysenterostomy, choledochotomy, cholelithotrity, and exploratory procedures. Of operations for gall-stones all of the cases had recovered but one, in which choledochotomy had been performed, and an accidental opening in the bowel, made on separating adhesions, escaped observation at the time of the operation. Sounding as an aid to diagnosis or aspiration of a distended gall-bladder as a means of treatment was not deemed advisable. For calculi impacted in the ducts, crushing the stone *in situ* was considered preferable when they were soft enough, and choledochotomy when cholelithotrity could not be accomplished.

Dr. E. Loumeau read a paper on "The Surgery of the Urinary Passages." In the treatment of painful cystitis in the male he advocated hypogastric drainage of the bladder. Seven cases were reported successfully treated in this manner. When the bladder is intolerant to the presence of a catheter a short and rigid canula might be employed. A belt with a urinal attached was shown, which enabled a patient to walk about with a catheter permanently inserted in the bladder.

Mr. Reginald Harrison read a paper on "The Treatment of Some Forms of Stone in the Bladder by Perineal Lithotrity." The report dealt with four hundred operations for stone in the male bladder, including fifty-six in children in which lateral lithotomy had been performed. The operation proposed consisted in making an opening in the membranous urethra at the apex of the prostate gland, on a grooved staff passed along the urethra, sufficient to admit the introduction of a Wheelhouse, small, tapering gorget, and subsequently the index finger into the bladder, and the use of a crushing forceps with a cutting rib within the blades, the more powerful instruments being fitted with a movable screw on the handle. The fragments may be subsequently withdrawn by means of aspirator-catheters passed through the wound, or even with the aid of forceps. The perineal wound should correspond in size with the evacuating catheters, which should be about the size of an index finger.

Mr. Noble Smith read a paper on "Spasmodic Torticollis and its Cure by Operation," formulating the following conclusions: (1) When the spasm is confined to the sterno-mastoid, removal of a piece of the spinal accessory nerve before it enters the muscle may be relied

upon as an absolutely certain curative remedy; (2) should there also be spasm of the splenius capitis or other muscles, operation upon the nerves supplying those muscles will also certainly be necessary, with the expectation of absolute cure; (3) as the nerve-supply to these posterior muscles is less definite than that to the sternomastoid it is probable that some slight spasmodic action may remain for a few weeks after operation; (4) ablation of pieces of the external branches of the posterior divisions of the second, third, and fourth cervical nerves is effectual in cutting off the nerve-supply of the splenius capitis; (5) no noteworthy disability remains after operation upon the spinal accessory nerve and the cervical nerves of one side, and even if the accessory nerve of one side and the cervical nerves of both sides are divided only a trivial amount of weakness remains.

Dr. Thomas H. Manley read a paper on the "Symptomatology and Diagnosis in Spinal Traumatism." He pointed out the infrequency of fracture of the spine except as the result of the application of great and concentrated physical force. In the majority of cases it is confined to the spinal apophyses, though occasionally it may extend into and involve the vertebral bodies.

Traumatic disorganization of the vertebral bodies, when of limited extent, is wanting in those ordinary serial signs so conspicuously present in fracture elsewhere. It may be said that fracture of the spine has no definite symptomatology, and it is only when there is very marked deformity, with mobility of the fragments, that one is warranted in assuming its presence. The presence of paraplegia in itself is no proof of vertebral fracture, for it may occur without bone-disorganization, and *vice versa*. In experimentation on dogs it was proved that in seven cases in which the vertebral column in different segments was forcibly fractured, no paralysis of any kind occurred, except in those in which the fragments were displaced inward on the spinal marrow. Of all the osseous structures in the body, the vertebræ after fracture manifest the least tendency to displacement. This is because of their powerful and numerous ligamentous supports, their peculiar conformation and imbricated arrangement. It is only when the fragments become displaced and are driven in on the spinal cord, that spinal fracture becomes a serious accident. There is every reason to assume then that vertebral fracture is more common than is generally supposed, or that it is seldom a cause of serious constitutional disturbance, except when internal complications are present.

Of late years, free exploratory incisions have been recommended as an aid to diagnosis in this type of fracture; it being maintained that aseptic division of the healthy tissues, for purposes not only of searching out the lesion, but also, if necessary, of reaching and operating on the bone if found shattered and displaced. It had been alleged that if we could safely open the cranium and expose the brain with readiness and general safety, we might do the same with the spinal cord; but for obvious anatomic reasons this assumption is not reasonable. In all cases incisions along the lateral grooves over the vertebral arches are attended with an unmanageable hemorrhage of alarming degree. Even now, if there be fracture with no displacement, it may escape detection; at all events, when the body is involved, it is quite impossible to detect a fracture through it by way of the spinal canal, posteriorly, with the cord and nerve-roots lying over it. In all grave fractures with marked displacement, the cord is quite totally destroyed at the point of compression at the moment of injury, and in this class serious coincident internal injuries are commonly present. This is the only class in which for a moment the question of laminectomy is to be considered; but if, by an exploratory incision, we are made cognizant of the actual vertebra involved, and the precise extent of medullary compression present, what will that avail us, for the conducting properties of the medulla spinalis are permanently interrupted?

Not only is spinal fracture difficult, and as a rule quite impossible, of detection when deformity is absent in the living; but even on the dead subject it may be entirely overlooked, unless special pains are taken and the autopsy is conducted in a manner appropriate for this class of lesions.

A post-mortem examination of the spine is always a tedious task, requiring special skill for its proper performance. An examination of this description by the inexperienced is of little value, for the reason that the parts are so mutilated that it may be difficult to determine how much was damaged by the injury, or how much by the misdirected, violent manipulation of the inexperienced operator. Many times these autopsies must be conducted hurriedly, without ample light. As a common practice nothing but the posterior plane of the spine is opened, and hence, only this area can be inspected; but, in order that the examination be thorough and exact, the whole spinal column must be scrutinized, stripped nude of all its investing soft parts anteriorly and posteriorly. In order to accomplish this, the whole column should be removed *en bloc* from the occiput to the sacrum; brought into a clear, strong light, and then, segment by segment, be cautiously manipulated and inspected; after which it may be returned into the breach from which it was removed, and fixed in position. Only by this method is it possible to make an autopsy on the spine which possesses accurate scientific value.

Section of Obstetrics and Gynecology.

Dr. Robert Barnes presented a memoir in Italian on "General Physiology and Pathology, Illustrated by the Study of Obstetrics."

Dr. Schmeltz presented a communication upon "The Use of Catgut Threads as a Means of Draining the Uterus and its Appendages." He enumerated the following conditions in which such a procedure was indicated: 1. Puerperal, catarrhal, or gonorrheal metritis; 2. Chronic catarrhal or purulent salpingitis; 3. Uterine displacements; 4. Amenorrhea and dysmenorrhea; 5. Atresia of the cervix uteri.

Dr. Granville Bantock read a paper entitled "A New Method of Operation in Certain Cases of Supravaginal Hysterectomy." After the application of a temporary elastic ligature around the uterus the peritoneum is divided for a short distance in advance of the ligature. The uterus is then separated from its loose connections in front, leaving a thin layer of uterine tissue attached to the peritoneum. When the body of the uterus is thus isolated as low as the level of the elastic ligature, about that of the internal os, the *serre-nœud* is at once applied and the uterus cut away. After the removal of

the ligature, the parietal and visceral layers of the peritoneum are sutured, and to prevent retraction double sutures are additionally used, one at the lower end of the wound next the pubes, and the other two on each side, passing through the whole thickness of the parietes, and tied over a small roll of gauze to prevent cutting through the skin. At the angle of the parietal wound above the stump the peritoneal edges are secured to that part of the envelop which covers the back of the uterus by means of two interrupted sutures, the first of which catches up the parietal peritoneum a quarter of an inch from the edges, the second involving the edges only, thus forming a sort of collar around what, for convenience' sake, may be called a stump. The remainder of the wound is closed in the ordinary way. Thus the whole of the raw surface is outside of the peritoneal cavity and the sac formed is packed with iodoform-gauze. The ovaries may be removed at any convenient stage of the operation.

Dr. Sinclair read a paper on "The Relation of Pregnancy to the Operation of Ventro-fixation." The conclusion was promulgated that, after making full allowance for the element of risk and the incidental drawbacks, the operation of ventro-fixation is not only justifiable, but is indicated in a certain limited class of cases of retroflexion of the uterus with complications.

Section of Internal Medicine.

Sir Dyce Duckworth read a paper on "The Rheumatic Nature of Chorea," in which he took the position that chorea is a cerebral form of rheumatism affecting the cortex. He pointed out that lesions may be found in the heart that during life and after death are indistinguishable from those found in rheumatism. While shock, mental overwork, or psychic emotion are viewed as the causes ordinarily producing chorea, these give rise to the disease only in children that have inherited a rheumatic taint. The symptoms of chorea point to the action of certain systemic poisons having a close affinity to those that give rise to the symptoms of rheumatism.

Dr. Saundby discussed the question of "Diet in the Treatment of Diabetes." He proposed that diabetics should be permitted to eat as much carbohydrates as they could assimilate without increasing their sugar-elimination. He has found that the majority of diabetics can take a moderate amount of carbohydrates without injury.

Dr. J. Schreiber read a paper on "The Different Forms of Sciatica and their Treatment." Basing his opinion upon observations in five hundred cases, he stated that in a large majority of cases the sensory troubles and the affections of locomotion were due to a rheumatic condition of muscle, tendon, fascia, ligament, or joint, rather than to any inherent neuroses. In female subjects the existence of puerperal peritonitis might complicate the symptomatology.

Dr. Reger read a paper upon the way in which infective diseases are spread, in which he stated that in his opinion the microörganism of a disease produces effects only when it is mature, and that the breaking out of the malady and the migration of germs to other people take place at the same time, the periods of incubation and of desquamation not being contagious.

Prof. Queirolo showed several *post-mortem* specimens from animals in which he had removed the liver from the circulation by uniting the portal vein with the vena cava inferior. He described his method of operating, and gave a brief review of the results he had obtained.

Drs. Rummo and Albertoni criticised Professor Queirolo's methods and results, and Professor Baümler considered that the toxins, not being eliminated by the liver, would be sure to produce diarrhea.

Dr. G. Zagari stated that as the result of his experiments he had come to the conclusion that the liver had important functions in the destruction and elimination of toxins and of bacteria.

Dr. de Backer communicated the result of an extensive series of observations upon the injection of sterilized cultures of yeast in the treatment of certain infectious diseases, especially tuberculous affections, and stated that this method of treatment had in his hands been most successful.

Dr. Mendizabal read a paper on "Influenza," in which he discussed the most important clinical varieties.

Dr. Szillai read a paper in which he stated that he had obtained good results from the treatment of croup with hydrochlorate of pilocarpin.

Dr. Revilliod read a paper, in which he drew attention to the great frequency of tuberculosis in man, and of the large number of cases in which an apparently complete cure occurs.

Dr. S. Bernheim read a paper in which he stated that immunized serum had a specific vaccinal action against tuberculosis.

Dr. S. Laache strongly advocated the early resection of a rib in empyema; and Prof Baümler advocated early aspiration of the chest, and, if necessary, resection of a rib in empyema in tuberculous patients.

Dr. O. Schrön read three papers, in the first of which he described and pointed out the diagnostic import of certain crystals which he had found in the sputa of tuberculous patients; in the second, he suggeated a new method of discovering tubercle-bacilli in sputum; and in the third, he recorded finding coccidia containing tubercle-bacilli in symbiosis in the lung in a case of rapid tuberculosis.

Dr. E. Grande stated that in his opinion corrosive sublimate and methylene-blue may be used with advantage in the treatment of pulmonary tuberculosis.

Dr. Crisafulli read a paper in which he stated that, in his opinion, traumatic and rheumatic tetanus are identical.

Dr. C. Forlanini gave reasons for considering that the production of pneumothorax artificially was only of value in pulmonary tuberculosis if done in the early stages.

Dr. E. Pittarelli described a new form of combined aspiration and injection syringe.

Dr. F. Rivolta discussed the etiology of pulmonary edema in croupous pneumonia, and Dr. F. Chaborg read a paper upon the influence of nasal affections upon various diseases of the pulmonary organs.

Amongst the many other papers read the following were of special interest: Dr. Carmon y Valle suggested that the muscular incoördination in locomotor ataxy is due to unequal relaxation of the muscular fibers. Prof. Stokvis described a method for the ready detec-

tion of hematoporphyrin in the urine, and stated that he considered its discovery to be of some diagnostic value. Dr. Fraser discussed the treatment of myxedema by thyroid gland, and also described a case of pernicious anemia which had received benefit from bone-marrow. Dr. E. Guerra described a case of solitary tubercle in the neighborhood of the right fissure of Rolando. Dr. Gouvea recorded an interesting case of apparent pulmonary tuberculosis which was shown to be pulmonary distomiasis by the discovery of a distoma hepaticum in the expectoration. Dr. Calabresi stated that the presence of either sugar or uric acid in the blood lessened its bactericidal power, and that quinin increased it. Dr. Da Rocha discussed the pathogenesis of those cases of diabetes characterized by dilatation of the stomach and diminished peristalsis of the intestine. Dr. De Renzi stated that he had produced diabetes by excision of the duodenum and of the salivary glands, and that in his opinion the diet in diabetes should, at any rate at first, be purely vegetable. In some cases such a treatment had in his hands resulted in the complete disappearance of sugar from the urine. Dr. A. Giovanni spoke of the necessity of treating the individual rather than the disease, each individual being characterized by a predisposition to a special class of disease. In his opinion, human beings can be divided into three groups, the first consisting of those who were especially liable to diseases of the respiratory organs, the second of those who had a predisposition to diseases of the circulatory organs, and the third of those in whom the digestive organs were especially liable to be attacked. Dr. A. Jolles described a method for approximately determining the quantity of biliary pigment in the urine. Dr. Tison stated that he had found aconitin nitrate of some value in the treatment of erysipelas, neuralgia, and laryngitis. Prof. Bouchard detailed clinical cases which had led him to conclude that the early appearance of pruritus in icterus suggested the presence of a neoplasm. Dr. Baccelli read a paper upon a special method that he had devised for making heart-measurements. He stated that the total action of the heart can be reduced to a parallelogram of forces, and if the movements of the heart are to be understood, they must be considered as a whole, and not as consisting of distinct systolic and diastolic phases. So far, experiments upon animals have not in his opinion resulted in solving the problems presented by the apex-beat, and if they are ever to be solved, he considered that it must be by looking at the movement as a systolic-diastolic one, and as being due not to the action of any one part of the heart, but to the movements of the heart as a whole, including those of the large vessels.

Section of Pathology.

Prof. Guarnieri stated that for some years he had been working on the question of the etiology of vaccinia and variola. He referred to the researches previously made in order to discover the active agent of both diseases, and showed that all attempts at isolating it had proved fruitless. Most of the previous investigators had thought that bacteria were the causative agents of this disease, but, from his own observations, he concluded that the active agents of vaccinia and variola were, in all probability, protozoa. He had found in the epithelium of the pustule of vaccina and variola a parasite which resembled some well-known protozoa. It was a small, round body, easily stainable with hematoxylin, lying in a clear vacuole in the protoplasm of the epithelial cells. It was constantly present in both diseases, and when vaccinia or variola was inoculated on the cornea of the rabbit, the cells of the epithelium of the cornea were found to contain these parasites in large numbers. He had been able to see the movements of the parasite, and he considered that it multiplied by simple division into two or more young protozoa. He thought that, although he could not bring absolute proof that this was the cause of vaccinia or variola, yet, in all probability, considering its constant presence in all cases, it would ultimately be proved to be so.

Prof. Monti stated that, from his own researches, he had come to the same conclusion as Prof. Guarnieri.

Dr. M. Armand Ruffer said that, in conjunction with his friend Dr. Plimmer, he had examined a large number of vaccinia-pustules in the cow, in the monkey, in man, etc., as well as three cases of severe variola, and that in all these he had found the cell-inclosures described by Prof. Guarnieri. He had seen that the epithelium in the neighborhood of these structures penetrated deeply into the tissues around, and that in this way appearances much resembling the early stages of carcinoma were produced. These bodies, he considered, were most probably parasites, though he was unable to assign to them their proper place in the animal kingdom. They differed essentially in their staining-reaction and in their appearance from those previously described by Pfeiffer, Van der Loeff, and others, and also from the carcinoma-parasites, as described by Prof. Foà himself, and others. He had, with Dr. Plimmer, studied minutely their occurrence in the various stages of the formation of the vaccine-pustule, and had been able to obtain a characteristic staining-reaction, founded on the combined use of carmin and Lichtgrün.

Prof. Hansemann gave an account of the morbid changes found in the pancreas of diabetic patients after death. He said that numerous experiments on dogs had shown that the total extirpation of the pancreas was followed by diabetes. He asked himself whether the facts of human pathology showed that there was a connection between disease of the pancreas and diabetes or not. In his opinion, diabetes might exist without disease of the pancreas, but in 50 per cent. of all cases diabetes was associated with disease of the pancreas; the most frequent lesion was simple atrophy, which might be easily distinguished from the cachectic atrophy. Moreover he found sclerosis due to an excess of fibrous tissue; atrophy, after blocking up of the duct, through tumors, etc. This last disease only led accidentally to diabetes—that is, when the atrophy had gone far enough; but the real primary atrophy of the pancreas was the disease which produced diabetes, even in the early stages of the disease. Diabetes occurred seldom only in cases of necrosis of the pancreas, owing to the rapid course of this disease, as it took time for the glycosuria to be established; however, as it often disappeared just before death in cases of total extirpation of the pancreas, there was not sufficient time left for the appearance of the glycosuria. Carcinoma, as a rule, did not produce diabetes, because the

carcinoma-cells, being descended from pancreas-cells, no longer secreted, but were able to fulfil their function—that is, the internal secretion.

Dr. John Lindsay Steven read a paper on "Necrosis of the Pancreas and its Association with Fat-necrosis." A short summary of the literature was given, and the work of Zenker, Balser, Chiari, Fitz, and Langerhans was more particularly referred to. Two cases of pancreatic disease associated with multiple fat-necrosis were then related in detail. The first occurred in 1889, and was that of a very stout man, a heavy drinker, aged thirty, who died after an illness of four days, during which the symptoms were mainly those of acute intestinal obstruction with collapse and fulness in the epigastrium. At the post-mortem examination there was found multiple fat-necrosis of the abdominal fat, with hemorrhage, enlargement, and infarction of the pancreas. The second case was that of a woman, aged thirty-four, who had been suffering from gastric pain for five months, since the birth of her last child. An obscure tumor was detected during life in the upper part of the abdomen, but it was impossible definitely to make out its precise nature. After death entire sequestration of the pancreas was discovered, the necrosed organ being contained in a large peripancreatic peritoneal cyst containing inky-black fluid. Here also there was a multiple fat-necrosis, and the body was very obese. In neither case was there anything remarkable in the other organs of the body. A short statement of the microscopic appearances was then given, after which the author formulated his conclusions thus: (1) In fat-necrosis and necrosis of the pancreas we have two distinct and independent lesions—that is, the one may exist without the other. It is possible, also, that fat-necrosis occurring in very fat subjects may be analogous to coagulation or caseous necrosis occurring in the central parts of a large neoplasm. (2) If fat-necrosis be very extensive it may lead by confluence of neighboring areas either to localized or complete necrosis of the pancreas; and the two cases recorded may be looked upon as illustrating different stages of the same process. It is necessary, however, to place pancreatic necrosis arising from this cause in a category by itself.

Dr. O. Israel spoke on the "Comparative Pathology of Necrosis." He said that practically the necrosis of the cells of the vegetable and animal kingdoms was one and the same process, and he gave an account of the various appearances seen during the process of dying and after death.

Prof. Roger spoke of "The Functions of the Liver in Infectious Disease." He said that most infectious diseases might determine anatomic lesions and functional disturbances in the liver. The lesions varied not only in different diseases, but even in one and the same disease, following its course in animals of different or the same species. In tuberculosis, for instance, one saw that the disease produced vitreous degeneration of the liver-cells of the fowl, amyloid degeneration of the same cells in pheasants, true tuberculosis or sclerosis of the liver in guinea-pigs, and in rabbits tuberculosis of a special cachexia. With a microbe which he called the bacillus septicus putidus, he had produced in the liver thrombosis, hyaline degeneration, embryonic tissue, and systematic periportal thrombosis. All these lesions he had also produced with the soluble substances contained in the cultures of this bacillus, and they were, in fact, all caused by the same toxic process. It was not enough to know the anatomic lesions of the liver without studying the state of its functions. It was well known that the liver arrested and transformed a large quantity of poisons brought to it by the portal vein, and more especially the microbic poisons, this function being, as he had shown, connected with the presence of glycogen. He was led to inquire what became of the glycogen during infectious diseases. He studied, in rabbits, anthrax and the disease produced by streptococci, and he saw that the quantity of glycogen contained in the cells remained normal during the first stages of this disease, in spite of the rise of temperature, which might exceed 103°. The quantity of sugar in the blood did not vary. Later on, when the serious symptoms appeared and the temperature became lower the glycogen gradually disappeared, the sugar in the blood increased, and in cases of anthrax might contain 2 or 3 per 1000 of sugar; but on the contrary the sugar diminished or disappeared in the disease due to streptococci. One might conclude from these facts that, in spite of the fever, the liver might continue to destroy the toxins which were formed during acute diseases. These results had many clinical applications. They enabled one to understand the seriousness of infectious diseases in patients in whom the liver has been previously the seat of disease. It would appear, according to some observations of Professor Roger, that the lesions of the liver were a predisposing cause in producing delirium tremens; but infectious disease occurring in the course of an hepatic disease was very often mortal, owing to the diseased state of the liver-cells.

Interesting papers were also read by Profs. Marchiafava, Bignami, and others, on the minute structure of the malarial parasites.

Section of Diseases of Children.

Prof. Baginsky described the Kaiser und Kaiserin Friedrich Children's Hospital in Berlin, and explained its construction and administration. His remarks were illustrated by plans and diagrams. The most striking feature in the administrative work of the hospital appeared to be the care taken to exclude all sources of infection, not only infections from scarlet fever and other exanthematous disorders, but also infection through air, water, and milk, which are, there can be little doubt, responsible for much of the diarrhea and bronchitis which now decimate so many children's hospitals in summer and winter respectively.

Dr. J. Bauzen read a paper on "Icterus Neonatorum," in the course of which he said that he had found that 57 per cent. of all children were at birth affected to some extent with a benign form of icterus. His observations were made in private practice, and compared with those made in hospitals—80 per cent.—showed a smaller proportion. As a rule, the icterus was not accompanied by any symptoms. It was due merely to the effusion into the cutaneous structures of coloring-matter derived from a degeneration of the blood-cells. Too early ligature of the cord was apparently a determining cause, the predisposing cause being some condition of general debility. He divided the more serious cases, in which the icterus generally came on later, into three main cate-

gories: (1) due to venous blood-changes; (2) due to abnormal destruction of biliary pigments; (3) due to hepatic derangements, and indicated numerous subclasses.

Dr. A. Titomanlio read a careful paper in which he sought to prove that congenital syphilis was a much more common cause of hydrocephalus than was generally supposed. As a rule the cases were chronic, but occasionally subacute or acute. Generally the acute cases were those which came on at an early age, the chronic those which developed later. The old belief in the value of mercury in hydrocephalus was probably founded on the existence of these syphilitic cases, and Dr. Titomanlio recommended inunctions of calomel, combined with the administration of iodid of sodium or potassium.

A paper by Dr. Celli on "Vaccination in Whooping-cough" led to a prolonged but desultory discussion, in which the author's view that vaccination had any influence over the disorder did not meet with much acceptance.

Section of Dermatology and Syphilography.

An interesting discussion on the nature of eczema was opened by Dr. Schwimmer.

Dr. Breda considered the microörganisms found in eczema as secondary and not the cause of the disease.

Dr. Kaposi considered that such forms of eczema as impetigo and eczema marginatum are probably caused by microörganisms, which grow on a skin predisposed to their invasion. He insisted, with Hebra, that typical eczema can be provoked in normal individuals by extraneous causes, such as heat, chemic action, etc., and that a lowering of the general nutrition will so affect the skin that it will be unable to resist the effect of such external irritations. Eczema, indeed, should be regarded as an inflammation of the skin which may be complicated by many concomitant conditions.

Several other members spoke on the subject, including Dr. Neisser, who believes that eczema is caused by microörganisms, and that impetigo contagiosa is a separate disease.

Dr. Kaposi related a case of peculiar growths on the scalp, of the nature of molluscum fibrosum, but malignant, and exhibited a beautifully-executed model.

Dr. Radcliffe Crocker stated that a case of similar character had been shown in London by Mr. Morrant Baker, and that it was proved to be a sarcoma, but a curious point was that some of the growths became absorbed.

A paper on "Syphilis d'Emblée" was read by Dr. Verchère, who believed that syphilis could be contracted without the usual initial lesion. He reported three cases which had been under close daily observation from the beginning, and alluded to experimental inoculation from them in which no chancres were produced.

Dr. Reale showed a large number of cultivations of the fungi microsporon furfur and M. minutissimum.

Dr. Giovannini detailed the histologic appearances observed by him after electrolytic epilation.

Section of Laryngology.

A discussion on the scope and limits of the surgical treatment of laryngeal tuberculosis was opened by Dr. Gouguenheim. He expressed himself a strong partisan of energetic surgical interference even in the most advanced cases, recommending the use of a punch-forceps for the removal of the diseased arytenoid cartilages—arytenoidectomy.

Dr. Heryng related instances of recovery as far as the larynx was concerned from surgical treatment, and showed a form of forceps with various attachments adapted for cutting in every direction. He stated certain indications and contra-indications, but admitted that they were not absolute. Tolerance, patience, and faith on the part of the patient were among the most necessary conditions.

Prof. Massei spoke very highly of the application to the larynx of a solution of pure phenol in sulphoricinate of soda, especially after the appropriate surgical treatment by means of curets or cutting-forceps, as introduced and recommended at the same meeting by Dr. Ruault, of Paris.

The tone of the discussion which followed indicated a strong feeling in favor of very great moderation in surgical activity in cases of laryngeal tuberculosis.

Dr. Bronner read a paper on "The Intra-tracheal Injection of Medicated Fluids."

Dr. Dundas Grant exhibited a safety endolaryngeal forceps.

Section of Otology.

Dr. Ludewig contributed a paper recommending the more extended practice of the operation of removal of the ossicles in chronic otorrhea.

Prof. Ferreri, while approving of it in the main, referred to the possibility of infecting the site of operation, and dwelt on the necessity for the thorough employment of the caustic treatment.

Dr. Dundas Grant exhibited and described a magnifying aural speculum adapted for operations, and a recurved bistoury for aural furuncles.

Section of Hygiene.

Dr. Pagliani presided.

A discussion on quarantine was introduced by Dr. L. Csatáry de Castar, who proposed that the Section should adopt a resolution to the effect that quarantine, especially land quarantine, was useless.

A short discussion took place, in the course of which Prof. Ruata observed that it was important that, under the pretence of "isolation," quarantine should not be reëstablished.

No speaker opposed the resolution, which was unanimously adopted.

The subject of the prevention of cholera was raised by Dr. Bocci, who stated that by the adoption of isolation and disinfection, cholera, which had appeared in the province last year, had been held in check, so that only some 100 cases had occurred, and the disease had never become epidemic.

Dr. Paolo Merlo described the precautions taken at the seaports, which had been most successful; in no case had the disease spread from them. Infected ships were sent to the Island of Asinara, an island off the coast of Sardinia, where they underwent disinfection.

Prof. Pagliani spoke of the general precautions taken in Italy, and presented an elaborate report.

Dr. Terni showed that in 1884 cholera reached the

head-waters of the Brembo, the infecting agent being a man who had arrived from Marseilles suffering from the disease. Subsequently all the villages and towns on this river suffered from epidemic cholera, but only these villages; others in the neighborhood drawing their water-supplies from other sources escaped.

A discussion on vaccination was opened by DR. LEONI, who described certain experimental researches which had enabled him to make improvements in the method of preparing the vaccine. He described the sources from which the lymph might become contaminated by pyogenic organisms, and detailed the precautions taken to obtain a lymph which was pure but specifically powerful. He spoke strongly as to the value of vaccination as a prophylactic.

The subject of alcoholism was introduced by DR. FAZIO, who presented a large series of statistics, which showed that excessive consumption of alcohol was nowhere prevalent in Italy to anything like the extent which prevailed in the northern countries of Europe. Curiously, also, it appeared that alcoholism was more common within the bounds of Italy in the northern provinces, Lombardy and Venice, than in the southern provinces of Umbria, Tuscany, and Rome, and least of all in the province of Naples and in Sicily.

The question of the necessity for some effective test of the competency of plumbers was brought before the Section by MR. COLES and DR. W. R. SMITH. The importance of good plumbing-work as a link in the chain of sanitary security was generally recognized. After some discussion a resolution was adopted, recommending the Director of Public Health to inquire into the matter, with the view of establishing a system of registration of qualified plumbers in Rome and other Italian cities.

At the conclusion of its work the Section of Hygiene visited the works on the Tiber, which are on a very large scale. The river for the whole extent of its course through the city is being enclosed in embankments of great height and massive construction. The work, which has involved an enormous expenditure not only in the actual construction of the embankments, which are of masonry, but also in the reconstruction of bridges and the rearrangement of sewers and drains, will, it is hoped, have a very considerable effect in increasing the healthiness of the city by preventing the occurrence of floods. There will also be a considerable advantage in the substitution of broad, open boulevards along the riverside for all sorts of irregular buildings which formerly backed on to the river, and by their sewerage contributed to its befoulment.

SECTION OF MILITARY MEDICINE AND SURGERY.

The work of this Section was carried on with much spirit, and was largely attended, especially by officers of the Italian military medical department. Several interesting discussions took place, among which mention may be made of that on the arrangements of the sanitary service on shipboard in future naval engagements, having regard to the peculiarities of construction of warships of the present types and the novel conditions of modern warfare. To this discussion Inspector-General Macdonald contributed an opening paper, in which he discussed the ambulance appliances suited for the naval service both ashore and afloat. The discussion was continued mainly by Italian officers. Questions connected with the influence on military surgery of the introduction of the new small-bore rifles occupied much of the time of the Section, many papers dealing more or less directly with this subject being read, and two formal discussions thereon were arranged. One afternoon was devoted to an inspection of the great military hospital of Rome. During this visit Dr. Jacoby demonstrated two new patterns of stretchers in use in Germany, and Dr. Strauss explained the construction of the special stretchers employed in the French Army. The Section also inspected a hospital train, and made a journey in it to Tivoli.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting March 5, 1894.

THE PRESIDENT, DR. WILLIAM HUNT, IN THE CHAIR.

(Continued from page 448)

DR. CHARLES B. PENROSE related "A Case of Abdominal Hysterectomy in which the Ureter was Resected and Implanted into the Bladder:"

I report this case because the immediate implantation into the bladder of a ureter, which has been divided during a celiotomy, is a rare proceeding.

The patient was a white woman, forty years old, who had a scirrhous carcinoma of the cervix uteri. The growth extended as high as the internal os, and infiltrated the left broad ligament, in a dense hard mass, to a distance of about one inch from the cervix. There was no involvement of the vagina. There were no symptoms of obstruction of the ureter.

Celiotomy was performed at the Gynecean Hospital in July, 1893. It was found that the left ureter passed directly through the hard mass in the left broad ligament; and in order to remove completely all diseased tissue it was necessary to excise about one inch of the ureter—the portion involved in the broad ligament.

After the uterus had been cut away at the vaginal junction, the distal end of the ureter was ligated with silk; the vagina was closed; the peritoneum was sutured over the seat of operation as much as possible; and the proximal portion of the ureter was then implanted into the body of the bladder. The operation was similar to, and was derived from, that used by Dr. Van Hook for uniting a ureter after complete transverse division, by lateral implantation of the proximal into the distal portion.[1] An incision was made antero-posteriorly in the body of the bladder, somewhat less than one-half inch in length. A needle armed with fine silk was passed through the bladder-wall from without in, at a point about one-third inch from the edge of the incision on the right, and brought out through the incision. It was then passed through the right wall of the ureter close to the extremity, carried back through the incision in the bladder and passed through the bladder-wall from within out, close to its point of entrance. A similar suture was passed on the left side of the incision in the bladder and through the left side of the wall of the divided ureter. Traction on these sutures dragged the

[1] Journ. Amer. Med. Assoc., March 4, 1893.

ureter into the bladder, and, when tied, they held it in this position.

The loose peritoneum, which formed a partial investment of the ureter, was drawn down and sutured to the peritoneum of the bladder by a continuous silk suture around the line of union of the ureter with bladder. The abdomen was closed without drainage. A soft rubber catheter was introduced through the urethra and was retained for three days. The patient made an unusually easy recovery.

There were no symptoms of vesical or renal disturbance. The quantity of urine passed was as follows: 10 ounces in the first twenty-four hours; 26 ounces in the second twenty-four hours; 22 ounces in the third twenty-four hours; and 38 ounces in the fourth twenty-four hours.

The woman left the hospital twenty days after the operation. Her physician wrote me in December that she was perfectly well and doing her own housework. He wrote again in February—over six months after the operation—that she was suffering with pain in the right iliac region—perhaps a recurrence of the disease.

She has at no time presented any symptoms whatever of disease of the urinary organs.

Our text-books on surgery advise that, in case the ureter be torn or cut across during the removal of an abdominal tumor, the renal end must be brought out through an opening made for this purpose in the loin. And in some instances nephrectomy had been performed for the relief of such an accident.

The clinical and experimental researches of Dr. Van Hook, of Chicago (paper read at the Forty-fourth Annual Meeting of the American Medical Association, June, 1893), a recently-reported case of Dr. H. A. Kelly, in which a divided ureter was immediately united by lateral implantation of the proximal into the distal portion, and the case just reported, go to show that the advice of our surgical text-books should be modified; and that, if the patient is able to endure a slightly prolonged operation, and the anatomic conditions are suitable, it is better immediately to implant the proximal portion of the ureter into the distal portion, or into the bladder.

Dr. Thomas S. K. Morton read a paper entitled "Conditions Justifying Removal of the Testicle in Radical Operations for Inguinal Hernia; with a Report of Three Successful Cases."

I am not here to advocate the indiscriminate sacrifice of an organ usually so highly prized as the testicle, but simply to point out certain of the conditions which would appear to me to jutify the procedure and to relate three cases in which I have considered it best to resort to it. These cases represent the total number in which I have deemed it prudent to add ablation of the gland to formal procedures for the radical cure of inguinal hernia, for instances are rare in which this course may be considered justifiable, and must become constantly more and more so as radical procedures become perfected.

With the operations proposed by Bassini, Postempski, and Halsted, together with their modifications, when the cord is displaced entirely from the inguinal canal, and, in the last, even removed from the internal ring to an entirely new opening made for the purpose in the muscular structures of the abdominal wall, the presence of the cord has almost ceased to be a hindrance to seemingly ideal radical cure. Hence any temptation to sacrifice the testicle vanishes, and the conditions necessitating or permitting such removal become correspondingly more circumscribed.

Removal of the testicle in operations for inguinal hernia would, therefore, in my estimation, be practically limited to the following conditions:

1. Certain cases of undescended testicle.

Here, if the testicle had entered the canal and was degenerated or otherwise diseased, or could not be separated from the sac without endangering its vitality, or if it was manifestly functionless, it might be removed without reluctance. But if it were normal, or almost normal in all respects save position, it would be best, if possible, to displace the cord from the canal by one of the modern methods and attempt to bring the organ into the scrotum and there fix it by sutures; or it might be pushed within the abdominal cavity through the internal ring, and there permitted to remain after close suture of the ring.

2. In some rare cases of congenital hernia.

Removal here must be very exceptionally called for with so many modern operative resources at hand.

3. In certain cases of chronic or acute disease of the testicle or cord complicating hernia and demanding removal of the organ upon its own account.

4. In rare cases in which severe traumatism has occurred to testicle or cord during or before operation.

Accidental division of some or all of the vessels of the cord would not necessarily demand excision of the testicle unless other severe complications were present. Wounding or section of the vas deferens likewise might be consistent with retention of the organ. But when the gland has been stripped entirely from all other connections, such injury to its vascular supply would produce so much danger of necrosis that ablation would become imperative.

5. In certain cases in which sloughing of the sac or interrupted circulation of the cord or testicle has involved these latter structures in a suppurative or sloughing process.

6. Perhaps occasionally in the very aged, to simplify or shorten operation, or for some of the before-mentioned conditions of less degree than would justify the procedure in a younger individual.

There are no conditions, of course, except senility, that would excuse the removal of a testicle under circumstances in which it was the sole reproductive gland possessed by the individual; even more rare would be the conditions justifying removal of both testicles in bilateral hernia.

Surgeons must be exceedingly cautious not to interfere with so highly valued a part without either a very clear understanding with the patient before witnesses (and preferably in writing) preliminary to the operation, or else be certain that the conditions for which the organ is removed will be convincing to others of the necessity for such removal. It is obviously important also for the operator to carefully preserve the specimens for his protection in case of dispute.

One word more of caution. It is not the easiest matter to tie off the testicular cord in such a manner as to leave it absolutely secure against recurring or secondary hem-

orrhage after its return to the abdominal cavity; and bleeding from it originates a peculiarly dangerous form of shock quite independent of the amount of blood lost, and which often is speedily fatal. Moreover, the bleeding will not be likely to cease spontaneously in the warm and moist peritoneal cavity to which the ligated stump has been returned, and an operation to secure it more firmly (if the diagnosis is made in time) would be a very formidable complication. Hence, excessive care must be exercised in its primary ligation. It should be transfixed and tied off in at least two portions. Silk is the only fit material for this purpose. A good button of tissue should be left above the ligatures, and, to be doubly sure, any apparent vessel-ends should be separately ligated upon the end of the stump before it is returned to the cavity. Searing the stump with a cautery below the main ligature would be equally, perhaps more, efficient than separate ligatures to the vessel-ends. If the cord were very large or edematous it should be ligated in even smaller portions.

CASE I. *Huge strangulated inguinal hernia; radical operation with removal of the testicle; recovery.*—Mr. M. C. B., a strong, healthy man of nearly fifty-seven years, strained himself fourteen years ago whilst pulling a heavy satchel across the floor. The satchel caught on a splinter, and, as a result of straining to dislodge it while in a stooping position, he felt something give way in the left groin, and became exceedingly faint. Shortly after this a small, reducible but constantly reappearing tumor came into the scrotum, and, as time went by, became gradually larger and larger.

Several years after the first appearance of the tumor, and when it had attained quite a large size, he became subject to occasional attacks of strangulation, which always required anesthesia for reduction. Then, after one of these attacks, a large portion of the tumor became irreducible, and so remained. After this when the seizures came on, strangulation could always be overcome by the reduction of a portion of the hernial contents, but the entire tumor could never be reduced. Several more attacks of strangulation occurred at varying times after this, when more intestine would become prolapsed, but relief was invariably obtained upon reduction of the newly prolapsed and strangulated portion. While strangulation lasted his chief symptom was always an agonizing dragging pain at the epigastrium. By wearing a truss over the site of the external abdominal ring, that portion of gut which prolapsed and became strangulated was more or less effectually kept up.

About 8 o'clock P.M., April 10, 1889, he felt the hernia slip out, and became a little faint and sick; but after lying down for a short time continued at his desk until midnight. At 1 o'clock A.M. he reached his home in West Philadelphia by street-car and foot from the city. His sensations were then different from anything that he experienced before, and he was certain that he was about to die—on similar occasions he had always been most confident and hopeful. At 3 o'clock A.M. he was seen by the late Dr. Michael Lampen, who always hitherto had been able to reduce the strangulation by taxis, and who, therefore, promptly placed the patient under anesthesia, but was unable to reduce the tumor after an hour's application of taxis. He, however, could not let up the ether on account of the man's terrific sufferings. Ether-narcosis, with an occasional application of taxis, had been kept up continuously from 3 A.M. to 8 A.M., when I saw the case in consultation. The patient's condition at the latter time was fairly good, but he was much depressed by the prolonged anesthesia. No fecal vomiting had occurred.

Upon examination an enormous left-sided inguinoscrotal hernia was discovered. It was fully as large as a man's head; the skin covering it was exceeding tense, shiny, and almost black from impeded circulation. Fluctuation was marked over the upper and outer portions of the tumor, whilst at the portion near the man's knees was present a large, semi-globular, boggy mass just beneath the skin.

Consent to operation having been obtained of the wife, taxis of a moment's duration was unsuccessfully employed, and operation at once proceeded with. Full aseptic measures prevailed throughout. A six-inch incision was made in the line of the tumor and inguinal canal, and carried down to the sac, which was punctured and torn to an equal extent. About a pint of brownish-tinged, odorless serum escaped from the opening, and the small intestine at once came into view. This was highly distended with flatus, almost black, and in places ecchymotic. The constriction was then sought for and found to be at the external ring. This was incised upward, and the prolapsed small intestine for a distance of three feet was—after it had begun to assume a pinkish color—with some difficulty returned to the abdominal cavity, a healthy portion having first been pulled down at each extremity, to make sure that no constriction existed at a higher or a lower point. Attention was now turned to the remaining prolapsed mass. This had the appearance of being an enormously hypertrophied omentum, and was not in the slightest degree congested or strangulated. Upon careful examination, however, this proved to be practically the entire colon (excepting possibly the cecum, which could not be recognized in the confused mass), as well as the omentum attached. This discovery was made by finding deep, between two layers of fat, a band of fibrous material through which muscular fibers coursed, and, later, by feeling a small fecal mass in the lumen. The bowel was absolutely collapsed, practically free from feces, and deeply buried in hyperplastic deposits. The mesocolon also participated in these changes, and was likewise rendered almost indistinguishable by a deposit of fat. Only a longitudinal half-inch strip of bowel could anywhere be brought to sight. The epiploic appendages were enormous. (An illustration that it should be an invariable rule to cut or ligate nothing about a hernia until absolutely sure of its nature.) The mass was separated from its many adhesions to the sac, but, from its great size, could not after separation be reduced through the abdominal rings, although these were much dilated. Hence the incision was enlarged upward along the inguinal canal, and the internal ring very freely divided upward upon the abdomen for a distance of several inches. The colon and omentum were then easily reduced, and attention was turned to the sac. This was found universally adherent and particularly to the peri-testicular tissues. Its dissection was finally accomplished up to and within the internal ring, where it was cut off and the ends sutured together. I did not employ the method of dealing with the sac in

this case that is advised by Macewen, because of the very large mass of perhaps devitalized tissue which would by that method have been returned to the abdomen. When the sac is not very large, however, that procedure is quite a favorite with me.

The left testicle was elongated, hypertrophied, and so enveloped by the sac as to give it much resemblance to a prolapsed kidney, but examination quickly demonstrated its identity. After the sac had been dissected up it was found that the testicle was left without any vascular attachment excepting through the cord. Then arose the question whether it should be allowed to remain. This, again with the consent of the wife, was decided in the negative for the following reasons: the organ was much hypertrophied and edematous, and likely would require more blood than could be conveyed to it by the perhaps bruised and occluded cord; the patient was fifty-six years of age; the opposite testicle was apparently quite healthy and normal; and, finally, a much more certainly radical operation could be done by having the cord out of the wound. Again, had the organ been allowed to remain, its life was by no means certain, and its necrosis might have made a very dangerous complication during convalescence. Hence the cord was ligated just below the internal ring and the testicle cut away. After being very certain that every vessel of the cord was firmly occluded by the ligatures, the pedicle was dropped within the abdomen. A glass drain-tube was placed in the extreme upper portion of the abdominal wound. Then a layer of deep sutures of chromic catgut was run along the muscular structure of the wound down to the internal ring, through that structure and down along the canal to and embracing the external ring, thus giving a secure and accurate apposition of all the parts concerned in the hernial opening unimpeded by the presence of the cord. Were I doing this same operation to-day I would probably not introduce the tube at all, but, if it were called for, would insert it through a separate median opening just above the pubis. However, in this case no harm resulted from leaving the upper portion of the wound weakened by a drain-tube orifice. The entire skin-wound was next approximated by interrupted silk sutures and a double-spica bandage applied over a copious dressing.

As soon as consciousness returned the man was put upon powders of calomel one-tenth grain, and podophyllin one-sixth grain, every hour. These he took for twelve hours, and then was placed upon one-dram doses of Epsom salts hourly. No food was permitted for twelve hours. With the assistance of an enema the bowels moved very freely the next morning. From the time of coming out of the ether until the following day the man was violently restless, pitching and tossing about the bed in an altogether uncontrollable manner. Somehow in the night he had, without the knowledge of those about him, managed to withdraw the drain-tube. This I found lying loose in the bed when I saw him early the the next day. The bowels having by that time moved freely, and the belly being entirely flat, I determined not to replace the tube unless compelled to do so. Jactitation was controlled by fifteen-grain doses of chloral.

On April 15th the belly was slightly distended. The man was still somewhat restless. The bowels again moved very freely. The temperature was not above normal. Violent bronchitis was present as a result of the prolonged anesthesia.

On the 16th the abdomen was much swollen, and there was nausea and non-fecal vomiting; there was much complaint of pain, and a racking hiccough was present; the bowels did not move on this day. I decided to reinsert the tube. I removed a stitch at the extreme upper portion of the wound and put a glass drain-tube down to the hollow of the sacrum, and through it drew off two ounces of the turbid, bloody, non-odorous serum. The wound was in excellent condition. I again put the man on fractional doses of calomel and podophyllin. The bronchitis was improving, but much purulent expectoration continued.

On the 17th the bowels were freely open. A small amount of serous, straw-colored fluid passed from the tube. Hiccough and vomiting continued obstinately. For these symptoms I ordered cocain one-tenth grain, cerium oxalate two grains, and sodium bicarbonate two grains every two hours.

On the 18th, vomiting and hiccough were entirely under control. The bowels moved of their own accord, and the abdomen was flat and painless. All discharge had ceased, and the tube was removed, as well as all of the skin-sutures. The patient was eating and sleeping well. The bronchitis had almost gone.

On May 4th the man sat up and began to get about; in two weeks more he was at his business again.

When seen about a year after the operation there was present a firm cicatrix, and no sign of return of the hernia. Up to the last time I heard from him, several years afterward, he continued entirely free from return of the hernia. (*Transactions of the Philadelphia County Medical Society*, 1889, p. 206.)

(To be concluded.)

CORRESPONDENCE.

A CASE OF TETANUS.

To the Editor of THE MEDICAL NEWS,

SIR: On June 14, 1893, L. M., fifty years of age, a teamster, came to me with a swollen thumb which, he said, he had struck the day before with a hammer, drawing blood, while driving a nail in his cow-stable. He suffered a good deal of pain, and I ordered hot fomentations with water previously boiled and linseed wool. The following day I met him on his wagon hauling stone. He said his thumb was now all right; the pain had stopped, the swelling having gone down after several hours of poulticing, as directed. The next day I met him again accidentally; he had his thumb clumsily tied up. On questioning him about this he said he had applied cow-manure, as a gathering had formed on the back of the thumb which had broken and discharged a little pus. I called his attention to the filthiness and danger of using cow-manure, urging him to remove it at once and to cleanse his hand thoroughly with warm water and soap. The following evening, June 17th, he came to my office complaining of pain in his chest and difficulty of breathing, which he attributed to some indiscretion in diet and "catching cold." I gave him a hypodermatic injection of a sixth of a grain of morphin sulphate and sent him home. At twelve o'clock the

same night I was called to see him again. He had received no benefit from the injection; well-marked symptoms of tetanus—tonic spasms of the muscles of the trunk, trismus, and opisthotonos—were beginning to develop. The temperature was normal, the pulse 80. The next morning his temperature and pulse-rate were the same. The pains and spasms increased, and he said he thought he was "foundered." I called in Dr. Whyte, of this place, and we saw in our patient a classic picture of tetanus, hourly growing worse in spite of the usual antispasmodic treatment. On the morning of June 18th his pulse was 90, the temperature 101.5° F. A few hours later, the last time I saw him alive, his temperature had risen to 105°, and he died at about one o'clock in the afternoon from hyperpyrexia. The temperature of his body was 110° F. a half-hour after death. His mind remained clear to the last. The period of incubation in tetanus varying from a few hours to two weeks, the question now presents itself: Did infection with the bacillus tetani take place when the thumb was struck with the hammer, or was it due to the application of cow-manure? Punctured wounds of the foot from stepping upon rusty nails are often treated by the ignorant with that home remedy of great repute—cow-dung.

Carl R. Feld.
Watertown, Wisconsin.

NEWS ITEMS.

The National Association of Railway Surgeons will hold its seventh annual convention at Galveston, Texas, May 8, 9, 10, and 11, 1894. An interesting program has been arranged. The following papers will be read: "Conservatism in the Treatment of Compound Comminuted Fractures of the Leg," by Dr. George R. Dean, of Spartanburg, S. C.; "Compound Fractures," by Dr. Milton Jay, of Chicago; "Plaster-of-Paris Splints for Fractures Simple and Compound," by Dr. J. G. Buchanan, of Pittsburg; "Anesthesia (Local and General) and its Proper Production," by Dr. E. A. McGannon, of Brockville, Ont., Can.; "Fracture and Dislocation of the Spine," by Dr. Thomas H. Manley, of New York; "Diagnosis of Injuries of the Cord and its Envelops, with and without Fractures of the Spine," by Dr. C. H. Hughes, of St. Louis: "Treatment of Injuries of the Cord and its Envelops, with and without Fracture of the Spine," by Dr. W. B. Outten, of St. Louis; "Some of the Uses of Hot Water in Recent Injuries in Railway Surgery," by Dr. N. A. Drake, of Kansas City; "Minor Surgery," by Dr. J. D. Myers, of Huntington, W. Va.; "Color-blindness," by Dr. D. Emmett Welsh, of Grand Rapids, Mich.; "Exhibition of New Tests for Simulated Blindness in one Eye," by Dr. James L. Minor, of Memphis, Tenn.; "Evisceration *vs.* Enucleation, following Injuries of the Eye," by Dr. A. E. Prince, of Springfield, Ill.; "Rectal and Anal Surgery and its Relation to Railway Injuries," by Dr. S. G. Gant, of Kansas City, Mo.; "Should the National Association of Railway Surgeons become a Delegatory Body?" by Dr. R. Harvey Reed, of Columbus, Ohio; "Quarantine and its Relation to the Railway Surgeon and Railway Surgeons' Relation to Quarantine," by Dr. Van B. Thornton, of Hempstead, Texas; "Litigation-psychosis," by Dr. Matthew D. Field, of New York; "A Case that ought to have been one of Railway Spine, and its Treatment," by Dr. C. M. Woodward, of Tecumseh, Mich.; "A Novel Case of Cerebral Traumatism," by Dr. J. R. Barnett, of Neenah, Wis.; "A Case of Fracture of the Spine—Operation followed by Improvement," by Dr. John E. Sylvester, of McArthur, Ohio; "The Evolution of Railway Surgery," by Dr. E. R. Lewis, of Kansas City; "Dressing of the Stump in Amputation," by Dr. A. B. Brumbaugh, of Huntingdon, Pa.; "Railways and Railway Surgery," by Clark Bell, Esq., of New York; "Improved Railway Stretcher," by Dr. R. Ortega, of Ciudad Porfirio Diaz, Mex.; "Thiersch's Grafts in Extensive Destruction of Soft Parts about Large Joints," by Dr. Henry W. Coe, of Portland, Ore.; "A Digest of Four Hundred Consecutive Railway Cases," by Dr. Howard J. Williams, of Macon, Ga.; "Management of Burns and Scalds, with Cases," by Dr. C. K. Cole, of Helena, Mont.; "A Case of Spinal Injury with Rupture of the Intestine—Operation, Recovery," by Dr. I. N. Warren, of Sioux City, Iowa; "Concussion," by Dr. George W. Cox, of Brownsville, Ore.; "Shock—its Phenomenal Results," by Dr. Willis M. Wilson, of Curtis, Neb.; "Clinical Cases—Shock, Hemorrhage, Tendon Suture," by Dr. John Van Duyn, of Syracuse, N. Y.; "Treatment of Shock," by Dr. James H. Letcher, of Henderson, Ky.

The American Gynecological Society will hold its nineteenth annual meeting at Washington, D. C., on May 29, 30, and 31, 1894. The following is the program arranged: Discussion—"Extirpation of the Uterus in Disease of the Adnexa." Opened in the affirmative by Dr. J. M. Baldy, followed by Drs. Florian Krug and H. T. Hanks; in the negative by Dr. T. A. Reamy, followed by Dr. W. G. Wylie. Discussion—"The Management of Face-presentation." Opened by Dr. Edward R. Reynolds, followed by Drs. Charles Jewett, B. C. Hirst, C. P. Noble, and E. P. Davis. "The Abuse of Trachelorrhaphy," by Dr. William R. Pryor, of New York; "Fatal Nausea and Vomiting of Pregnancy," by Dr. Edward P. Davis, of Philadelphia; "Myomectomy as a Substitute for Hystero-myomectomy," by Dr. E. C. Dudley, of Chicago. President's Address—"The Proper Position of Recent Surgical Methods in the Treatment of Uterine Fibroids." General discussion invited. Discussion—"Rupture of the Uterus; Palliative *vs.* Surgical Treatment." Opened by Dr. Charles M. Green, followed by Drs. Malcolm McLean and H. C. Coe. "The Alexander Operation," by Dr. Clement Cleveland, of New York; "The Ultimate Results of the Treatment of Retro-displacement by Pessaries," by Dr. Francis H. Davenport, of Boston; "The Influence of Laceration of the Perineum on the Uterus, and the Operation for its Repair," by Dr. W. Gill Wylie, of New York; "Retroperitoneal and Intra-ligamentous Tumors of the Uterus and Adnexa," by Dr. William H. Wathen, of Louisville; "Inflammation of the Ureters from a Medical Standpoint," by Dr. Matthew D. The American Dermatological Association will hold its eighteenth annual meeting at Washington, D. C., on May 29, 30, 31, and June 1, 1894. The following scientific program has been arranged:

Address by the President, Dr. R. B. Morison. "Thyroid Feeding in Diseases of the Skin," by Dr. G. T. Jackson. "The Rare Forms of Alopecia," by Dr. G. H. Fox. "A Case of Favus of the Head and Body," by Drs. J. A. Cantrell and E. J. Stout. Report of Committee on Statistics. "The Pathological Anatomy of Pearly Epithelioma of the Face," by Dr. J. A. Fordyce. "The Question of Contagiousness of Molluscum Contagiosum," by Dr. H. W. Stelwagon. "The Therapeutic Value of Urea in the Treatment of Skin-diseases," by Dr. C. W. Cutler. "Ichthyosis Congenita (so-called Harlequin Fetus); History of a Case still Living," by Dr. S. Sherwell. "The Distribution and Control of Leprosy in North America": First paper, "Distribution," by Dr. J. N. Hyde; discussion by Dr. J. E. Graham; second paper, "Diagnostic Features and Treatment," by Dr. P. A. Morrow; discussion by Dr. A. Van Harlingen; third paper, "Contagiousness, Prophylaxis, and Control," by Dr. J. C. White, discussion by Drs. G. H. Fox, J. D. Bryant, and Gen. W. C. Wyman, U. S. M. H. "Angioma Serpiginosum and some other rare Dermatoses," by Dr. J. C. White. "The Protozoa-like Bodies of Herpes Zoster; a Contribution to the Study of Psorospermosis," by Dr. M. B. Hartzell. "Cold as an Etiological Factor in Diseases of the Skin, with Report of Cases," by Dr. W. T. Corlett. "Acquired Idiosyncrasy for Quinin, showing Peculiar Cutaneous Manifestations," by Dr. C. W. Allen. Open discussion upon Dermatitis Exfoliativa: (*a*) Its clinical forms; (*b*) Its etiology; (*c*) Its treatment. Title to be announced, by Dr. E. B. Bronson. "The Relation of Impetigo Herpetiformis to Pemphigus Vegetans," by Dr. J. Zeisler. "Notes on Drug-eruptions," by Dr. J. A. Fordyce.

Obituary: Dr. Joseph Workman.—By the death of Dr. Workman, of Toronto, the profession of the neighboring Dominion has lost not only a prominent representative, but a striking and unusual character. He was born in Ireland in 1805, and after serving as a young man on the Ordnance Survey, emigrated to Montreal, where he studied medicine, graduating from McGill College in 1835. In 1836 he moved to Toronto, engaged in practice, and subsequently became Professor of Obstetrics in the Toronto School of Medicine. In 1853 he was appointed Superintendent of the Provincial Lunatic Asylum, a position which he held for twenty-six years. His chief contributions have been on the subject of insanity, and he was for many years a warm supporter of the *Utica Journal*. He was a familiar figure at the meetings of the Association of Asylum Superintendents in this country. Of late years he lived in retirement in Toronto, enjoying in an unusual degree the respect and esteem of his colleagues and citizens. His name has been familiar in the medical journals through translations from various European languages, and he did much to make the work of our Italian brethren, particularly in the department of nervous diseases, known in this country. One of the most accomplished linguists in our ranks, he was exceptionally well versed in the chief modern languages, and not alone in medical but in the general literature, particularly of Italy, Spain, and Scandinavia.

Until about a year ago, when he had a slight hemiplegic attack, he retained his mental and bodily energies in an exceptional degree, and took a deep interest in all matters relating to the welfare of the profession. His death took place on the 15th ult., after a brief illness.

The American Pediatric Society will hold its sixth annual meeting at Washington, D. C., May 29, 30, 31, and June 1, 1894. The following program has been arranged:

May 29th: Address by the First Vice-President, "A Eulogy on Drs. John M. Keating and Charles Warrington Earle," by F. Forchheimer, Cincinnati. "Eulogy on Dr. T. F. Sherman," by T. M. Rotch, Boston. "The Influence of the Blood-supply on the Irritability of the Spinal Motor Centers," by B. K. Rachford, Newport, Ky. "The Early Diagnosis of Pott's Disease of the Spine in Children," by Dillon Brown, New York City. "A Case," by William P. Northrup, New York City. "Tonsillotomy, followed by Diphtheria and 'Croup,'" by Augustus Caillé, New York City.

May 30th: Discussion on the Etiology and Prevention of Rickets: *a.* "Influence of Race (especially in Italians)," by Irving M. Snow, Buffalo. *b.* "Influence of Race (in Negroes)," by George N. Acker, Washington, D. C. "A Case of Congenital Rickets," by C. W. Townsend, Boston. "Infantile Scurvy, especially its Differential Diagnosis," by J. Henry Fruitnight, New York City. "An Aid to the Sterilization of Milk in Artificial Infant Feeding," by A. Seibert, New York City.

May 31st: "Report of the Committee on the Nomenclature of Diseases of the Gastro-enteric Tract," by T. M. Rotch, Chairman, Boston. "Report of the Committee on the Nomenclature of Diseases of the Mouth.

June 1st: "Acute Pyelitis in Infancy," by L. Emmett Holt, New York City. "Infantile Myxedema," by William P. Northrup, New York City. "The Hemorrhagic Diseases of the Newborn," by C. W. Townsend, Boston.

Dr. Wm. V. Keating died suddenly on April 18th in this city at the age of seventy-one years. He was graduated from the University of Pennsylvania in 1844, and in 1861 was elected Professor of Obstetrics in Jefferson Medical College, holding the latter position for but a short time. From 1862 to 1865 he was Medical Director of the United States Army Hospital at Broad and Cherry Streets. He was the Medical Director of St. Agnes', St. Mary's, and St. Joseph's Hospitals, and a member of numerous medical and scientific societies. He was the American editor of Ramsbotham's *Midwifery* and Churchhill's *Diseases of Women*.

The Wistar Institute of Anatomy of the University of Pennsylvania will be opened with appropriate ceremonies on May 22d, when an address will be delivered

by Dr. Wm. Osler, formerly Professor of Clinical Medicine in the University and now Chief of the Medical Department of Johns Hopkins University. Dr. Harrison Allen has been made Director of the Institute, and Dr. Milton J. Greenman, Assistant Director.

The Cleveland Medical Society will hold its second quarterly meeting on the evening of June 22d, on which occasion Dr. William Pepper will deliver an address. On the following morning Dr. Pepper will hold a clinic in one of the hospitals. Members of the medical profession generally are invited to be present.

The Nebraska State Medical Society will hold its twenty-sixth annual meeting at Lincoln, Neb., on May 1, 2, 3, 1894. An elaborate and attractive program has been arranged. Members of the medical profession are cordially invited to attend.

Medical College Consolidation.—The Cincinnati College of Medicine and Surgery has been affiliated with the University of Cincinnati, under the title of the Medical Department of the University of Cincinnati.

Medical Practitioners in Paris.—A recent enumeration shows that there are 2208 medical practitioners in the city of Paris, a proportion of 1 to about every 1000 inhabitants.

Pasteurism in Turkey.—It is announced that antirabic stations are to be established in various parts of Turkey. There is already such a station at Constantinople.

Prof. Rubner has been selected to succeed the late Prof. August Hirsch in the chair of the History of Medicine in the University of Berlin.

Raymond has been elected Professor Agrégé in the Paris Faculty of Medicine, and Physician to the Salpêtrière in succession to Charcot.

Dr. W. D. Miller has been elected Professor Extraordinary of Dentistry in the Medical Faculty of the University of Berlin.

ORIGINAL ARTICLES.

A SERIOUS FALLACY ATTENDING THE EMPLOYMENT OF CERTAIN DELICATE TESTS FOR THE DETECTION OF SERUM-ALBUMIN IN THE URINE, ESPECIALLY THE TRICHLORACETIC ACID TEST.[1]

BY D. D. STEWART, M.D.,
CLINICAL LECTURER ON MEDICINE AT JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

THERE is no point in medicine about which there is more universal disagreement and misapprehension than that relating to the absolute and relative value of recently introduced delicate tests for albumin in the urine. Certain it is that in the hands of any save those fully conscious of the many fallacies attending the use of these tests, and with disbelief in the existence of a normal albumina minima, it is far better to depend upon the less misleading, if also less delicate, and more practical time-honored methods—those by boiling[2] and by the use of nitric acid. Although certain complications attend the use of these, they are more easily overcome and are less likely to mislead than those surrounding such tests as trichloracetic acid, the reagents of Tanret, Sebelein, and Millard, glacial phosphoric and picric acids. Sources of error are so numerous with most of the latter tests that our best urinologists strongly question their practical clinical utility. Saundby, for instance, remarks[3] that "there are albuminoid bodies in the urine that have no known clinical significance, and these can only embarrass the practitioner who finds them when he is looking for a sign to which he attributes a significance based upon purely empirical foundation." Saundby discards all tests save that by boiling with a drop or two of dilute acetic acid. Many others, among whom is our own distinguished Tyson, hold very similar opinions, and view with small favor the substitution for the heat and the nitric-acid tests the more recent aspirants for favor. The many fallacies attending a reaction from these delicate tests are sufficiently dwelt upon in systematic treatises on urine-testing: for example, the presence in the urine of albumoses, peptone, drugs previously ingested, such as an alkaloid or a coal-tar derivative, an excess of urates and the like—all may at times confuse.

One source of error but little noticed, to which I wish now to direct especial attention, is that relating to the presence in normal urine of an albuminous body or bodies allied to serum-albumin, the so-called nucleo-albumin, the precise chemic nature of which is unfortunately little understood. Much that has been written in the past regarding the presence normally of traces of serum-albumin in the urine, as ascertained by the employment of most refined tests for its detection, is valueless, because of disregard of the fact of the existence of this substance in most urines in amount sufficient to respond to most of the delicate tests used for serum-albumin, and from which the reactions could not be distinguished. Such observers were either unaware of or disregarded the fact that nucleo-albumin[1] derived from the extra-renal urinary passages might readily have caused the response to the tests employed for the detection of traces of serum-albumin.[2] This substance is normally present in the urine of all in varying amount. The quantity, which is usually infinitesimal, though generally sufficient to react without concentration of urine to certain tests used for the detection of serum-albumin—notably such as the trichloracetic acid, the reagents of Tanret, and also Sebelein—may increase in conditions of irritation of the urinary passages induced by muscular exercise, or by the presence of a urine too acid and irritating (concentrated) to an amount to cause even doubt as to its differentiation by Heller's nitric-acid-contact method, a test regarded as a very certain one for the detection of serum-albumin.[3]

[1] Read as part of a discussion before the Society for Clinical Research, March 27, 1894.

[2] Applied to the upper stratum of clear acid urine in a test-tube, to be viewed with a light from above and a dark background for comparison with the unboiled stratum.

[3] Bright's Disease, p. 125. Bristol, 1889.

[1] There seems doubt whether or not urinary nucleo-albumin is a single body and identical with mucin. At all events it possesses a remarkable similarity to the nucleo-albumin of the bile, the basis of biliary mucin. Neubauer and Vogel fully discuss these points in their splendid work on the urine.

[2] Posner's researches as to a physiologic albuminuria are faulty in this particular, as are those of Capitan, Chateaubourg, and several others.

[3] Reissner, by estimation, found urinary mucin present to an amount varying from 0.05 to 0.1 per cent., and v. Noorden noted as much as 0.6 grm. to a liter of normal urine. (See Neubauer and Vogel, Wiesbaden, 1890.) Kirk, in a most admirable paper on "Urine-testing for Mucin" (*Lancet*, April 26 and May 3, 1890), gives instructive data as to the differentiation of mucin from serum-albumin. Kirk regards urinary mucin as a substance occupying an intermediate place between other forms of mucin and albumin. The first-mentioned authorities, than which there

In the thoroughly healthy, with urine normal as regards nitrogenous ingredients and free from ordinary indications of catarrhal conditions of the urinary passages, it is not unusual to obtain a trace of response from contact for from a few moments to a half-hour with a cold picric-acid solution, and I have found it common to obtain an almost instantaneous fine white ring by the other tests mentioned, the trichloracetic acid and that of Sebelein especially, but also by that of Tanret, and, less often, by that of Millard. Glacial phosphoric acid also reacts after from three to five minutes' contact. The presence of mucin in these same urines, if they be not too rich in salts,[1] may often be readily shown by the use of acetic acid as a precipitant. My own urine almost habitually responds to several of these very delicate tests, such as trichloracetic acid, to the reagents of Tanret and of Sebelein, and often to picric acid and to Millard's reagent, though it is absolutely normal as regards urea and freedom from casts. This response is probably due to the presence of mucin, perhaps derived from the bladder, which has a tendency toward irritability. I have often treated specimens with acetic acid after the manner detailed in the papers on "Non-albuminuric Nephritis," and have then always failed to obtain response with the treated specimen on subsequent testing with picric-acid. The test of Tanret, and the trichloracetic acid test, then, also, occasionally tried for experiment, would still not unfrequently give a response, but not to any extent the sharp reaction previously obtained.

I have in the past so repeatedly obtained a reaction to these tests in urines which I had with good reason regarded as normal that I long ago ceased to place any confidence in a positive response unless first, among other sources of error, the presence of this urinary mucin could be excluded. Unfortunately, this is impossible as regards several, and especially that of trichloracetic acid, that now most in vogue as a delicate test for albumin.[2] This acid, from its possessing properties similar to acetic acid, of which it is a substitution-derivative, I have become convinced is an absolutely uncertain and even dangerous reagent in this particular, so likely is it to mislead. As is well known to those accustomed to urinary analysis, it is an impossibility to separate traces of a mucinous substance from the urine even by the use of acetic acid with prolonged contact, though the latter be added in sufficient amount to overcome the neutralizing effects of the urinary salts;[1] and even should all be precipitated by long contact, which is doubtful, if it be present in any amount, as is so common with specimens of the diurnal urine, its complete separation on the filter is impossible. Insoluble substances, such as chalk, magnesia, barium sulphate, added to assist its precipitation, will also carry down traces of serum-albumin if naturally present or artificially added. I have, however, found again and again that with urines which I was convinced contained no serum-albumin, but which responded to picric acid and more markedly to the trichloracetic-acid contact-test, sufficient mucin could be removed with acetic acid to prevent further trace of response to the former, but not to the latter.

It is for these reasons that, though I have for the past eight years employed the unacidulated picric-acid test as a routine method, first overlaying the suspected urine with it before proceeding to the application of the heat or of other tests, I have placed far more confidence in a negative than in a positive result obtained by it. A reaction not occurring within a few moments, the employment of other tests was, naturally, regarded as unnecessary. A slight response appearing within this time, and not attributable to the other sources of error before mentioned, I had, until recently, attributed to traces of serum-albumin, and was inclined to believe in the existence of a normal slight albuminuria. More lately, however, experiments have convinced me that this response is due to the presence in the urine of a mucinous body.

To ascertain the frequency of reaction to the more delicate tests for albumin, of urines from normal individuals, those so far as was known that were without indications of renal disease, I recently examined specimens from 105 young men, all of whom save one regarded themselves in good health at the time, and but three of whom were known to be taking drugs of any sort. It was certain that none was a gonorrheal subject. The

are no more exact, do not look upon this body as true mucin, but call it nucleo-albumin, or *mucinähnliche Substanz*, as do, indeed, also Hammersten (Physiological Chemistry) and others of our best authorities.

[1] The urinary salts maintain mucin in solution. Concentrated urines, *i. e.*, those rich in salts, will not yield mucin to a small amount of acid, save by special treatment. In diluted or in dialyzed urines, or in those naturally poor in saline ingredients, the presence of mucin may be usually detected by the addition of a small amount of dilute acetic acid, and allowing to stand, care being taken not to add too much after dialysis. Some urines, from presumably normal individuals, cloud markedly almost instantly on the addition of an excess of the acid.

[2] Other of the delicate tests, such as those of Tanret, Sebelein, etc., containing free acetic acid, and also a mercurial salt, or tannin, are also unreliable, from their readiness to respond to traces of mucin, not at all in the dusty contact-haze that many advocating the use of these tests teach, but often as a sharply-defined ring, the appearance of which cannot be distinguished from serum-albumin. The best of the refined tests are the plain saturated solution of picric acid and Millard's solution. Although acetic acid enters into the composition of the latter, it is partly as an acetate, the action of which, as a precipitant of mucin, is slight. Yet this solution, too, reacts with mucin, as its originator acknowledged.

[1] One-tenth bulk of glacial, or its proportion of 25 per cent. acid.

specimens were collected for me by my friend Dr. Wolff, in the course of laboratory instruction, and in a manner that admitted of no deception being practised by the donors. The urethra was first flushed with urine which was discarded, so that mucus from this situation might be excluded.

The specimens were divided into two sets, one of 52, the other of 53. All of the 105 urines were those of the day. All save three of the first series were voided about three hours after breakfast, and as with the second series, which specimens were passed about four hours succeeding dinner, after the donors had been standing at laboratory work at least three-quarters of an hour. All of these specimens, therefore, represented the diurnal urine and food urine, in which the erect posture and evidences of muscular fatigue would aggravate an albuminuria if already present, and would likewise tend to induce an increase of mucinous substance in the urine such as would be similarly present in a mixed twenty-four-hour specimen from the same individuals.[1]

In the first series (52) three of the commonly-used delicate tests were employed—saturated solution of plain picric acid, trichloracetic acid, and glacial (meta)phosphoric acid.[2] In the second series (53), trichloracetic acid was the only one of the three tests employed.

For convenience, positive or negative response to the tests employed was noted at the end of three periods, and marked as occurring within these: ten seconds (which in the application of the contact-tests by picric acid and by trichloracetic acid was practically instantaneous), one minute, and five minutes.

In the first series the trichloracetic acid used was a specimen of Merck's C. P.,[3] which, originally crystalline, had liquefied after nearly two years' standing on the laboratory shelf, through the slow absorption of moisture from the air, the glass stopper of the bottle not having hermetically closed the neck. No water whatever had been added. The specimen, therefore, represented a highly-concentrated solution. I had previously found that the delicacy of reaction to the acid depended very greatly upon the degree of concentration of the solution. A solution which at one time I regarded as quite saturated, to which water had been added and no heat employed to insure solution, was noticed to react with no more delicacy than did Millard's solution or metaphosphoric acid. This fact is of importance, and probably explains the variation in result obtained by different experimenters with the acid.

In the second set of examinations, a freshly-obtained specimen[1] (labelled Kahlbaum, Berlin) of the crystalline acid was used, which was first liquefied in a water-bath and fluidity maintained by the addition of a small quantity of a concentrated, but not completely saturated, solution of the acid (Merck's C. P.). There was only sufficient of the first solution remaining for one comparative test with the last. By it the latter solution was found to not quite equal the former in delicacy of response, the reaction appearing somewhat later, and being less decided.

An unacidulated, saturated solution of picric acid was used. This and the trichloracetic acid were applied by the contact-method, viewed with a dark background by a light from above. The technique in examinations of this sort is of the greatest importance. It should be stated that as a background a piece of black cloth was always used. Most of the examinations were made at night, by aid of gaslight. When by day, illumination by sunlight was, of course, avoided. Inclination of the *upper part* of the tube toward one, with proper shading often demonstrated with the trichloracetic acid, a sharp, white, undoubted, though fine ring, that otherwise would have been overlooked in the contact-time mentioned. Tubes of three-eighths-inch diameter were used in applying the trichloracetic acid, the cost of the acid not permitting too large a quantity to be employed in each test. The urine was first added to the tube, and the acid subsequently deposited at the bottom with a pipet drawn out to a very capillary extremity.

In testing with picric acid the urine was overlaid. With the metaphosphoric acid, a small, thoroughly clean and clear portion of a cylinder was dropped into the urine, and the time of development of the slightest cloud about it noted within the time-limits stated. All the specimens tested were undecomposed. A small quantity of dilute acetic acid was added to all that were not decidedly acid. Any specimens that were at all cloudy were filtered.[2] With but three exceptions all of the 105

[1] This was not intentional. Morning specimens would have been preferred if obtainable without chance of deception. It is, however, of value, for the reasons stated.

[2] Picric acid was chosen as the test I most frequently employ; trichloracetic acid as one now coming much into vogue, and with which I had been disappointed in the past, as with Tanret's and Sebelein's reagents, from the too extreme delicacy misleading, as already stated. Millard's was not now employed, as I was satisfied from some comparative tests with it in the past that it corresponded very nearly in point of delicacy and exactness with picric acid. Tanret's solution was not used, as experiments had shown that it is a less delicate reagent for the detection of mucin or serum-albumin than trichloracetic acid. Metaphosphoric acid was used, as doubt existed as to its relative delicacy with the others employed.

[3] Given me by Dr. Leffmann. He had opened the bottle occasionally to remove a few crystals, using them and not a solution in his testing with it.

[1] From the Chemical Laboratory of the Jefferson Medical College, through Dr. Lawrence Wolff.

[2] Swedish filtering-paper was used. This is important, as the

specimens gave an undoubted response[1] to the trichloracetic-acid solutions, prepared as indicated, in the shape of a contact-ring within the five-minute limit. This reaction varied from a very narrow, always white, ring in the least marked to one of many lines in thickness in the most decided. Fifty-nine responded within ten seconds; of these, 22 reacted very markedly instantaneously;[2] 10 others by a sharp, though very thin white ring, becoming, as with nearly all, broader with longer contact. The remainder of the 59 reacted at first slightly, though undoubtedly the line became sharper with from one to five minutes' contact; 34 of the remaining responded within one minute, and of these, 13 only reacted slightly within the minute, becoming, however, except in two instances, more marked at the expiration of five minutes. Nine only of the 102 reacting showed no response at the end of a minute, the precipitate forming within the five-minute limit.

The three that gave no response save a trace of haze within the five minutes—the only ones of the 105 that did not unquestionably react—showed a pronounced contact-cloud of from three to four lines in depth within a few seconds after placing the tubes in hot water. The influence of heat, applied in all instances and most satisfactorily by placing the tube in a vessel containing water at the boiling-point, was found without exception to render the previously-obtained reaction more decided, developing in certain of them a contact-cloud instantly, which was almost a minute in appearing in a second tube not subjected to heat. So that trichloracetic acid seems a test the delicacy of which is even intensified by the application of heat.

With picric acid, 41 of the 52 tested responded within five minutes; 16 reacted within ten seconds; 7 of these 16 responded very markedly instantly (these were all albuminous). Four others of the 16 gave a sharp, but very narrow ring. The reaction in the remainder of the 16 (5) was a mere contact-haze, which in 3 deepened into a sharply-defined, though narrow ring, within one minute, the remaining 2 within five minutes. Thirteen of the 52 that did not respond in ten seconds reacted within the minute; of which 13, 2 showed a hazy contact-ring only, not increasing at the expiration of five minutes. Six others displayed a fine, sharply defined, though not broad ring, which had considerably increased at the expiration of five minutes. In the remainder of these the ring was better defined, though not broad. Of the 23 remaining of the 52 which gave no response at the end of one minute, 11 showed no trace of haze within five minutes, while the 12 reacted within this time. In 6 of these 12 the reaction amounted to a haze only; the remaining 6 gave a sharply-defined though narrow ring. Of the 11 giving no reaction to picric acid at the end of five minutes, all gave a precipitate, as has been stated, with trichloracetic acid—5 within one minute, 4 within five minutes, the remainder within ten seconds. In this same 11, metaphosphoric acid gave absolutely no reaction in 6; in the others, the response with the glacial acid was very slight or questionable (at five-minute contact).

With metaphosphoric acid, 10 of the 52 tested failed to show signs of cloud in five minutes, and 36 in one minute; 4 only responded at the end of a few seconds, and these were of those showing albumin by nitric acid. Twelve reacted within one minute that did not within ten seconds; of these, 7 responded very slightly and 5 markedly. Of the 5, 2 gave the HNO_3 contact-reaction. Ten of the 36 that failed to show a haze within one minute also gave no response within the five minutes. Of the remaining 26, 23 had reacted slightly at the end of five minutes; the other 3 had responded markedly.

The influence of heat on the reaction obtained with trichloracetic acid and with picric acid, applied in all cases after the occurrence of the response noted, showed that the precipitate was not due to urates or to a proteose or peptone. In several of these urines, other than those responding to coarser tests, there was a decided mucous precipitate, though the urines filtered perfectly clear. The action of acetic acid was tried on only one of these—this specimen was voided about four hours after dinner by a man with whom I am thrown much in contact and whom I know to be in the best of physical condition. This urine gave a slight ten-second response to trichloracetic acid: at the end of one minute the faint, white ring had become decided. A haze was shown in ten seconds' contact with picric acid. This, at the end of a minute, had also become a sharp ring. With metaphosphoric acid the reaction was but slight at the end of five minutes. With the nitric acid contact-test, at a distance of about four lines above the meeting-line of acid and urine, there occurred a cloud three or four

French gray paper contains, and will yield to the filtrate, sufficient vegetable albumin to cause response to the finer tests, as Millard pointed out.

[1] As regards comparative time of response, it is interesting that with the first series (of 52) the reaction appeared within ten seconds in 41, of which 6 were markedly serum-albuminous; while in the second set tested (53), with a different solution of trichloracetic acid, as already detailed, but 18 reacted within the ten seconds, of which 14 were also markedly albuminous. Of the first series, 2 only of the 52 failed to respond within the one-minute limit. These 2, however, reacted within the five minutes. Of course, this wide dissimilarity in time of reaction may be due to differences in the character of the urines, instead of in the degree of concentration of the two test-solutions.

[2] In 20 of these the reaction was so instantaneous and very decided as to leave no doubt as to the presence of serum-albumin in some amount, afterward confirmed by other tests.

lines in depth, unaffected by heat.[1] At the junction of the two fluids a marked chromogen ring was so decided as to obscure any slight reaction which might then be produced by traces of albumin; 5 c.c. of 25 per cent. glacial acetic acid added to 15 c.c. of this cold urine filtered, which was perfectly free from a trace of cloud, gave after standing a few moments a very marked smoky haze, unaffected by gentle heat, indicating a decidedly mucinous condition of the urine. It was impossible to separate by repeated filtration this precipitate, so that no further tests were proceeded with.

Though this interrogation was not undertaken for the purpose of ascertaining the frequency of occurrence of so-called "physiologic" albuminuria, it is of interest here to note that of 105 urines from adolescents and young men, all save one of whom regarded themselves as in very good health, 20 (19 per cent.) gave an undoubted serum-albumin reaction to nitric acid by the contact-method. The percentage of albumin in these urines, subsequently estimated by Esbach's method in nearly all, lay from one-fourth to one and one-fifth grams to the liter. I have carefully examined, physically,[2] all save one of the 20. No one of the 19 show evidences of renal disease. In nearly all the albuminuria is intermittent, and is probably the result of circulatory disturbances, due to the erect posture and a weak heart. In these albumin is absent from the urine on rising, but present in that after exercise during the day; and pulse-tension, ascertained by the sphygmograph as well as by the finger, is low, in several markedly so.

Excluding these cases of undoubted albuminuria, the results obtained indicate with little question either that, normally, urine contains traces of serum-albumin, or, more probably, that the response to trichloracetic acid and that occurring less frequently to picric and metaphosphoric acid was due to the presence of a body of nucleo-albuminous (or mucinous) character of extra-renal origin. The results obtained with these 83 urines reacting to trichloracetic acid and not to the coarse tests[3] were so constant and agree so perfectly with those I had obtained in prior examinations of urine from those with presumably healthy kidneys that I have no doubt as to the validity of this inference.

To my mind these results show conclusively that as a practicable *delicate* test[1] for albumin, the much vaunted trichloracetic acid is of little value. Responding as it does so universally, its utility is much less than that of metaphosphoric and especially that of picric acid, the last of which not only furnishes useful negative information, but also, from its less refined delicacy, positive results of value, excluding reactions to a few drugs when present in the urine,[2] a precipitate from urates, the proteoses or peptone,[3] and mucin or allied bodies, all readily differentiated, except the latter if in excess.[4]

With trichloracetic acid, unless the response be frank and outspoken—*i. e.*, unquestionable to tests less delicate but reliable, such as ebullition with the addition of a few drops of dilute acetic acid, than which there is none less likely to err; those tests, in other words, that do not so readily react to urinary mucin—the nature of the result must remain in doubt and cannot be utilized to account for the symptoms if nephritis be suspected, as it is, perhaps, more than likely not due to serum-albumin.

From the results here obtained and from those I have before published, with those of many other observers, notably Kirk, and those who preceded

[1] This reaction, so often met with in both albuminous and non-albuminous urines, has been shown by Kirk to be due to mucin (*Lancet*, May 3, 1890), as was first suggested by Roberts (*Medical Chronicle*, October, 1884, p. 1.)

[2] Time has not yet permitted microscopic examination of more than two of these urines. One of these men has a weak heart; he is an overtrained athlete. A second has a mitral systolic, and a third an aortic diastolic murmur. In neither of these two, however, are there other indications of back-working apparent. Compensation seems perfect.

[3] The contact nitric-acid test, supplemented by heat, was made with all urines responding in a suspiciously decided manner to trichloracetic acid.

[1] In a note concerning the test, by Reese of Johns Hopkins Hospital (*J. H. H. Bulletin*, February, 1890), it was regarded as one worthy of extended use in clinical work, because of its utility and delicacy. It was narrated that many cases had been encountered the urine of which responded to it (used in saturated solution), and not to control-tests, such as picric acid—that frequent source of error, urinary mucin, or an extra-renal albuminous body, not being regarded in question. In a number of these cases (eleven) granular, epithelial, and hyaline casts were found in the urine, and a subsequent necropsy showed distinct changes in the kidneys. This is of especial interest to me, indicating as it does the frequency of non-albuminuric nephritis; for in this category these cases must certainly be placed. The so-general response of the urine of the healthy to this test, and often to picric acid as I have shown, indicates beyond doubt in my mind that in the cases referred to by Dr. Reese, the trichloracetic-acid reaction was but a coincidence, obtainable markedly in as many consecutive healthy subjects.

[Since writing the foregoing I have learned that trichloracetic acid has ceased to be regarded with its former favor in this hospital, especially by Prof. Kelly, for the reason stated—its impracticable delicacy. Prof. Osler has recently written me that he is "rapidly coming to the conclusion that about one-half of the chronic degenerative changes in the kidneys are unaccompanied by albumin in the urine. The word comes over so constantly from the laboratory '*degenerative changes in the kidneys*' in patients whose urine showed no especial alterations." Prof. Osler has begun to think that "there are no normal kidneys in hospital patients above forty years of age."]

[2] Which, if in no other way, may be obviated by the withdrawal of medicines for the time.

[3] None of which is often obtained, but all of which may be recognized by placing the tube for a short time in hot water, the heat of which will immediately greatly diminish or dissipate the response.

[4] By removal with acetic acid in the manner I shall detail in a future communication.

him on similar lines, but who, unlike him, regarded the frequency of response in the healthy to refined tests as indicative of a normal, constant albumina minima, it may be finally concluded that the recognition by such reagents as trichloracetic acid of mere traces in the urine of what the most skeptical regard as albumin, even with symptoms suggestive of renal disturbance, can have little significance, because of the very general frequency of reaction of urines of normal individuals to the same test. If this reaction be due to serum-albumin, its significance is actually *nil*, as it would follow that a normal, slight albuminuria is common. It is, however, more probably, in the vast majority of instances, due to the presence of an albuminuous body of extra-renal origin, a nucleo-albumin, or so-called mucin. In certain other cases—pathologic subjects, with symptoms indicative of a type of chronic nephritis, in which serum-albumin, as ascertained by more reliable tests, is persistently absent from the urine—it may, and probably does, also arise from the epithelium of the tubules of the kidney,[1] due to a faulty metamorphosis of the same producing a renal mucinuria.[2] Its recognition in the latter, in which, for purposes of diagnosis, its differentiation from serum-albumin would be unnecessary, if further differentiation from the common extra-renal mucinuria could be arrived at, as by obtaining urine directly from ureter or kidney, would be of the highest value. But as the latter is a clinical impossibility, we must fall back upon our only actual reliable aids in the diagnosis of such renal suspects—the microscope and the ureometer—the examination of the measured twenty-four-hour urine for urea and its sediment for casts.

I am greatly indebted to Dr. L. Wolff, and his assistants Drs. Jacob and Strecker, for the trouble taken in obtaining the series of specimens of students' urine for examination; and to Professor H. Leffmann and Dr. G. P. Thomas, for great assistance in the examinations. In all the specimens examined, save some six, all reactions that appeared were carefully noted and timed by one of the latter of these, as well as by myself.

2620 NORTH FIFTH STREET.

The Medico-Legal Society of New York will hold its May meeting at the Academy of Medicine on the 9th of May, 1894, at 8 P. M. The following papers will be read: "Medical Witnesses," by H. W. Mitchell, M.D.; "Railways and Railway Surgeons," by Clark Bell, Esq. The meetings are open to all persons interested in the science.

[1] See remarks as to the presence of renal mucin in the urine in such cases, in the two papers on non-albuminuric nephritis, in the *Amer. Journ. Med. Sciences*, December, 1893, and THE MEDICAL NEWS, April 14, 1894.

[2] Associated usually with a cylindruria.

THE ELEMENT OF MALIGNANCY IN TUMORS.[1]

BY W. M. L. COPLIN, M.D.,
DEMONSTRATOR OF PATHOLOGY AND CURATOR OF THE MUSEUM OF THE JEFFERSON MEDICAL COLLEGE; SURGEON TO ST. MARY'S HOSPITAL; PATHOLOGIST TO THE PHILADELPHIA HOSPITAL.

THE cause or causes giving rise to the element recognized as "malignancy" in tumors has so far been only a bone of contention among pathologists and surgeons, without their ever having been able to present any distinct reason or theory which could seem to merit the general approval of able observers. Probably that view advanced by Cohnheim, namely, the factor of "reduced physiologic resistance" has met with a more hearty acceptance than have any of the so-called "blood-theories" that preceded it, and, so far as I am aware, it is the first so-called local explanation for malignancy that has been put forth.

The theories to be presented in this paper are partly a rearrangement of already existing views and partly the suggestion of some new ideas, so far as I am aware, now brought forward for the first time. Prior to the subject proper, there are some views to be considered that have been generally accepted as facts: 1. Tumors consisting of embryonic tissue afford in the highest degree the best example of malignancy. 2. The more purely cellular the tumor, the richer in bloodvessels and the less developed their coats, the more rapid its spread and the earlier and more certain its generalization. 3. The more nearly that a tumor represents adult histologic elements, the less the degree of malignancy, *e. g.*, the spindle-celled sarcomata are less malignant than the round-celled variety. 4. That there are marked blood-changes not in accordance with the local or general disturbance produced by the development of a neoplasm, cachexia and anemia occurring without ulceration or pain, and many times not at all in proportion to the mildness of these symptoms.

From the existing knowledge of embryonic tissue, it is to be presumed that it can be produced and its growth will be more rapid when the nutrition is lower than that required by adult tissues; it is also known that its growth is far more rapid in the embryo prior to that stage in embryonic life in which specialization of tissue occurs. There are many reasons for inferring that embryonic tissue does not require for its growth a nutritive value so high as do the adult tissues. It is a well-known fact that fractures in patients the subjects of cachexiæ producing alterations in the nutritive value of their blood are abundantly surrounded by a growth of embryonic tissue, while the organization of the new or inflammatory products does not take place,

[1] Read before the Philadelphia Pathological Society, January 15, 1894.

and hence the fractures do not unite with usual promptness. This condition occurs not only in subjects that are the bearers of malignant tumors, but in general blood-diseases, and more especially in those in whom the tendency is toward the lowering of the bodily nutrition. In long-standing suppuration, when the general body-nutrition is bad and adult tissue wasting, how often do we find the embryonic tissue growing exuberantly? So much is this tendency respected that surgeons often decline to operate when the cachexia is well marked. If then, we admit that embryonic tissue can and does reproduce itself when adult tissues cannot retain their vitality, then it remains to be supposed that the embryonic growth or neoplasm removes from the blood nutritive elements not yet elaborated for the adult tissues, and thus saps them of their nutrition prior to its full development. That such elements exist in the blood cannot be doubted if we believe that the bone-marrow, the lymphatic glands, and the spleen have anything to do with the elaboration of the blood.

The second fact with regard to the cellular elements of a tumor is partly defined in the preceding remarks upon the growth of embryonic tissue; but I do not think that sufficient attention has been given to the condition of the bloodvessels in new growths. In the malignant tumors, at least, these are almost devoid of walls, so much so that in some of the rapidly growing sarcomata they are no longer blood-vessels but are cavernous sluice-ways, irregular in their conformation and anastomosing at every point without the formality of contracting their caliber to anything like what might be called a capillary. These large blood-ways are not endowed with any contractility, and no vasomotor system is to be demonstrated either histologically or clinically; hence their caliber cannot be affected, and the quantity of blood which is supplied to a neoplasm of this class is always the same and not altered by the nervous modifications which are applied to the adult tissues. We should also remember that no part of the nutritive material utilized in the growth of neoplasms is for the production of force; neoplasms have no function, no conversion of food into energy is required, and hence the entire pabulum supplied is converted into cellular growth. In glands a certain amount of the food utilized is represented by secretion, but in glandular carcinomata there is no secretion.

With regard to the third point referred to, namely, that the more nearly a malignant growth represents an adult element, the less malignant it becomes, again bears out the blood-theory of its nutrition. It has now reached a point that its growth calls for the same degree of nutritive value that the adult tissue does, and when it can grow the adult tissue can survive; and often when such a tumor, a sarcoma of course, is found to suddenly spring into activity, upon removal it will be demonstrated that it has reverted from a large spindle-celled to a small spindle-celled, or even to a round-celled growth, and with this will be found the beginning emaciation already referred to. This sudden conversion of a spindle-celled tumor, growing slowly, into a round-celled tissue growing rapidly, I have seen demonstrated again and again, and at each change in cellular elements the general health showed the change after a very short interval. If a simple adult-tissue tumor becomes an embryonic-tissue neoplasm we have all noticed how rapidly cachexia follows, and we have also noticed how slowly cachexia comes on in the simple adult neoplasms, in which it is rare and occurs not from the growth itself, but as a rule from interference with other tissues and their function.

As to the last point in the consideration of this view of the malignancy of neoplasms, namely, the change in the blood itself, there are many elements that have not been duly considered. With the exception of a few Continental observers there have been few observations recorded upon the blood of patients suffering from malignant neoplasms. Freund, of Vienna, asserts that in carcinoma the blood contains sugar, and in sarcoma no sugar, but only peptone—a view confirmed by Andrews. Upon this I have not been able to make any observation, but after numerous observations upon cases of malignant neoplasms I can assert that the red and colorless blood-corpuscles are diminished and the coloring-matter reduced, in many cases lower even than in many of the marked cases of anemia. I recall one case occurring in the practice of Dr. Hearn, of this city, in which an enormous round-celled sarcoma of the breast, of rapid growth, not associated with any ulceration or pain, but only with the discomfort of its weight, had emaciated the woman to almost a skeleton. The tumor was removed at the request of the patient, and before she left the hospital she had gained considerably in weight, in the face of so severe an operative procedure. This gain continued until recurrence became well marked; then retrograde change evinced itself, and rapid emaciation again followed; a second operation was followed by a second improvement in the general nutrition, and once more a second recurrence was followed by as rapid a decline in the bodily nutrition. This fact of general improvement after operations in the most grave cases in which any operative interference seems debatable, may be well advanced for palliative operations, and the improvement seems to show that the removal of the growth at once modifies the general blood-condition, and the resulting improve-

ment of the bodily nutrition bears out the theory already advanced. Given a patient with a malignant tumor of even short duration, and tell twenty surgeons who have experience with tumors that it is a tumor, and they will from the face diagnosticate that it is malignant without seeing it, and many of them will venture its classification from the general appearances. I would again assert that these cachexiæ are often entirely out of proportion to the general symptoms and lesions which are found, and, contrary to much of the teaching are not, in many cases at least, associated with either pain, ulceration, or visceral metastasis. Besides, who has not seen a woman going about and looking well upon whose leg there was a chronic ulcer, probably attended with varicose veins, the suppurating surface two or three times as large as the area of ulceration of almost any carcinoma of the breast and productive of many times the degree of suffering. The cachexiæ of malignant tumors are not as a rule due to, although they may be intensified by, hemorrhage, pain, mechanical effects (*e. g.*, pressure, weight, etc.), and visceral metastasis, which but represents a new center of growth, and aids in sapping the system. Again, if the tumor required the same quality of pabulum as the adult tissue, why should it not waste when the adult tissues waste? Unless it be from some of the reasons already cited, the cause is yet to be sought.

THE ETIOLOGY, PATHOLOGY, AND TREATMENT OF OZENA.

By D. BRADEN KYLE, M.D.,
of Philadelphia;
Laryngologist, St. Agnes' Hospital; Bacteriologist, Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases; Instructor in Clinical Microscopy and Assistant Demonstrator of Pathology, Jefferson Medical College.

The term ozena is a most unfortunate one, for the condition is not a disease *per se*, but a symptom indicative of a number of pathologic tissue-changes with altered secretions. This condition, then, may occur in various inflammatory conditions of the nasal mucosa, as well as in ulcerative conditions, syphilis, malignant growths, retention of secretions from polypi, rhinoliths, and foreign bodies.

The atrophic change is the one to which this term is most commonly applied and upon which it really depends, and when considering the pathology and treatment we must, therefore, study the pathologic changes on which this condition depends.

The differences of opinion as to the cause of the disease furnish conclusive evidence that there is room for further investigation. In my opinion, it is subsequent to the so-called hypertrophic rhinitis. The mucous membrane consists of a basement-membrane upon which are arranged epithelial cells; underneath are bloodvessels, glands, and nerves, which are imbedded within the interstitial submucous tissue; its essential function is to secrete mucus.

Inflammatory conditions, with engorged vessels, causing intra-vascular pressure, are followed by exudation, which relieves the intra-vascular pressure, but which in turn brings about extra-vascular pressure or interstitial infiltration.

If this inflammatory material organize there will be interstitial thickening followed by contraction, but in either case nutrition will be interfered with, causing a certain amount of atrophy, with consequent degeneration and alterations dependent upon the extent of nutritive change. This alteration of tissue interferes with normal glandular secretion and elaboration, so that the material elaborated is more highly albuminous and slightly more fibrinous, rendering it highly coagulable; hence the tendency to the formation in the sinuosities of "crusts" or "slugs."

Herzfeld, of Berlin, has been able to demonstrate the presence of muscular fiber even in the Schneiderian membrane, and in this statement he has been confirmed by Kölliker and Zuckerkandl. Voltolini, however, failed to find such fiber.

If we grant that thickening and contraction do not take place, the atrophy can be explained in the same manner as red atrophy of the liver. When the mucosa is once passively congested it tends to remain so, and by continued intra-vascular pressure the interstitial tissue atrophies and degenerates. When the submucosa and cavernous tissue are cyanotic the epithelial lining dependent upon them for nutrition must necessarily undergo degenerative changes. The infiltrated cells, together with the proliferated, fixed cells, may from poor nutrition undergo granular change.[1] The transition from hypertrophy to atrophy does not necessarily imply the presence of ozena; in some cases with widespread atrophy, and in which the nasal capacity had greatly increased, no odor could be detected. According to Zuckerkandl, hypertrophy and atrophy are more pronounced in the respiratory region, yet by no means limited to that area, but not infrequently invade the olfactory area. This condition may exist in one or both nostrils. The condition of unusual size of the nostrils is more a result than a cause, dependent upon the amount of contraction and atrophy. In many cases there is narrowing of the rhino-pharynx; in some cases adenoid vegetations form an important element, and in such cases the rhino-pharynx should be carefully treated.

[1] The examination of sections made from tissue removed showed in three cases the thickened interstitial tissue, while in two cases the atrophy was due to pressure from engorged vessels. In each case the tissue was examined within twenty-four hours after removal.

Much has been written in regard to the effect of bacteria in catarrhal conditions. The normal nasal secretion may possess anti-microbic properties, but such is not the case with inflammatory exudates. That there is any etiologic connection between bacteria and the disease remains to be proved. In my own experience I have been able to isolate many germs from inoculations made from the diseased exudate in which marked odor existed. Some are pathogenic, others non-pathogenic, but against any one germ being an important factor is the fact that no one germ was always present. In most cases in which the odor was pronounced I found present a germ which by macroscopic and microscopic appearance, as well as by the test of *sense of smell*, was undoubtedly the bacillus fœtidus. It may be noted that Löwenberg, Christovitch, and Fraenkel believe in the microbian pathogenesis.

The history generally given by the patient is that the trouble began in a series of "colds in the head," followed by marked anterior and posterior nasal discharge. As the case progresses the character of this discharge alters from a thin, slightly colored discharge to a thick, purulent one, and continuing so for some months, with slight exacerbation, only to return with increased severity, the discharge becoming more albuminous, with a tendency of the secretions to dry, or "crust," and form "slugs" in the sinuosities of the fossæ, with some little odor noticeable. This condition goes on from bad to worse. The patient suffers from frontal headache, which is increased on stooping; sharp neuralgic pain over the malar prominence, or "face-ache;" itching and burning of the eyeballs; irritability and depression; constant itching and burning in the nares, due to the presence of altered secretions, and by constant blowing of the nostrils the condition is only aggravated. On swallowing, the patient experiences that peculiar sensation of fulness in the palate-region due to the accumulation and retention of secretions in the post nasal space. Usually the general health is impaired and the patient is anemic.

As to anemia, almost all cases exhibit it in which there is interference with nasal breathing. This has been clearly proved by a series of blood-examinations of cases in which there was nasal obstruction; counts being made before and after relief. Usually only two or three counts can be made after treatment, but in all cases the count shows a rapid increase in the number of corpuscles per cubic millimeter, and not only an increase in number, but the shape of the corpuscles, from being markedly irregular and crenated, becomes normal in appearance. My attention was first directed to this fact by Dr. Sajous, and through his suggestion I was led to make the investigations.

Zaufal observes that fetor of the breath is most marked in young subjects, and that after twenty it is less. In this I do not agree, as in some of the cases which came under my observation the patients were over thirty, and if the odor was then *less*, the preëxisting condition must have been pitiable. Surely those whose specialty necessitates their sitting in front of a patient afflicted with ozena will agree that it is one of the most offensive of conditions, and that its cure means to the patient what no one can realize except one thus afflicted.

During the hypertrophic stage of the disease small nodular masses are discharged, described by the patient as pieces of flesh. Microscopically, these masses are usually polypoid or adenoid; their presence is indicative of tissue-destruction.

The plan of treatment from which I have been able to obtain the best results is: (1) Thorough spraying of the membrane with some solvent of albuminous material; (2) washing away of this material by means of an alkaline antiseptic solution; (3) thorough drying of the membrane; (4) the application of the remedial agent, best in a solution, which will adhere to the membrane. After cleansing and drying the membrane the next step is to apply a stimulating, irritating substance which will establish an acute inflammation of the parts. This is simply applying to the mucous membrane the general surgical methods of treating chronic superficial inflammations by converting them into acute inflammations. In this way one will produce hyperemia of the parts, deplete the circulation by increased activity of the blood-current, and lessen the engorgement. This end is also furthered by transudation, which, being on a mucous surface, has free drainage.

When a copious watery discharge has existed for at least ten days then the cleansing and drying should be followed by a stimulating antiseptic solution. In cases in which the atrophic changes have been followed by degeneration the benefit derived from treatment is very slight except so far as relates to the lessening of the odor.

As a solvent for the albuminous material, hydrogen dioxid (15 vol.) is possibly the best. To wash away this material an alkaline solution of sodium biborate and bicarbonate with cinnamon-water and camphor-water, or any of the alkaline washes, is good. After carefully drying the membrane, the parts can be stimulated and irritated by applying oil of mustard in benzoinol or liquid albolin by means of an atomizer. As an irritant it should be used in some cases as strong as six or eight drops to the ounce.

If the condition is not too far advanced this plan of treatment has, in my hands, been most successful, the formation of slugs being entirely relieved, as well as the dryness and itching of the nares, the

fulness of the post-nasal space, the secretion becoming almost normal. The patient's general health must, of course, be improved by tonics, regular out-of-door exercise, and rest.

1632 Chestnut Street.

CLINICAL LECTURE.

PULMONARY TUBERCULOSIS.

A Clinical Lecture
delivered at the Philadelphia Hospital.

By SOLOMON SOLIS-COHEN, M.D.,
one of the physicians to the hospital; professor of clinical medicine and therapeutics in the philadelphia polyclinic, etc.

Gentlemen: I have brought this array of patients before you to-day in order to preach a sermon. I want to preach to you the gospel of hope in the treatment of tuberculosis.

We cannot say that patients in this hospital are subjected to the most favorable conditions for the treatment of pulmonary tuberculosis; we do the best for them that circumstances will permit; and we do much better for them than could be done by their relatives and friends at home. But we are not able to command all that we would like in the way of nutritive and other therapeutic measures. Notwithstanding this, we are still able to keep a large number of our patients comfortable, and to prolong their lives for considerable periods.

The patient to whom I first call your attention—Henry D.—is aged fifty years, and has been in this hospital about five years. When you read in the newspapers that somebody or other, perhaps a so-called physician, for many quacks have "regular" diplomas, and of all quackery the quackery of a physician fallen from grace is the worst—when you read that such a one has invented or discovered some wonderful remedy for consumption, and that he has given it to one or two or four thousand patients, and that in ten minutes or ten days they have all been cured, just remember that this patient has been here for five years and, though he is kept very comfortable and has frequently for many months together been without cough or night-sweats or febrile temperature, enough improvement, therefore, to build several newspaper "cures" upon, he is not well yet. Cases of pulmonary tuberculosis have, even when left to themselves, an average duration of life of some four years. Those, therefore, who talk about "curing" pulmonary tuberculosis by novel methods and who report cases of "cure" under anything less than five years, are either unfamiliar with the natural history of the disease or, for reasons sufficient to themselves, do not make use of their knowledge. In a few months, or even in one or two years, nothing can be said as to the ultimate issue of the case; and I want to impress this upon your minds, because I do not want you to be misled, either by quack things, like the "Amick Cure," or semi-quack things, as was the "Koch Cure" in its incipiency, into the belief that there is a "specific" against tuberculosis, or by the unfortunate example of Koch and his followers into premature announcement or premature adoption of any line of treatment. Six years at least must be allowed to elapse after the institution of any particular treatment in an ordinary case of pulmonary tuberculosis before one is entitled to say whether or not it has been curative. We may, of course, say in any reasonable time, in a few months if circumstances warrant, and more especially if the treatment has stood the test of years in other cases, that it has kept a patient comfortable, that it has increased his strength, that it has apparently augmented his chances of recovery; and this word—recovery—is the one that I would like you to use rather than *cure;* because *cure* implies that something brought in from the outside has conquered the disease, and *recovery* means that something within the patient has wrought a change in his condition which has brought the morbid processes to an end. We have to aim, in the treatment of this disease, at recovery, to be brought about not by "specifics," not by miracles, but by various measures, principally hygienic, which put the patient into such condition that the exciting causes of the disease are powerless to harm him. It is the *vis medicatrix naturæ* which limits and finally brings to an end the pathologic processes, and the physician's function is to stimulate that inherent tendency to recovery, to assist its action, to remove the obstacles that hinder its success.

The theory which I hold as to the causation of pulmonary tuberculosis, and tuberculosis in general, is somewhat different from that which is generally taught, and the treatment advised is, therefore, based upon a conception of the essential nature of the disease, differing in some respects from the generally accepted view. In order that you may understand the reasonableness of the treatment, it is necessary for me to say a few words concerning the etiology and clinical pathology of pulmonary tuberculosis. I assume a full knowledge upon your part of the morbid anatomy and histology so far as determined. Now do not understand me as claiming that the treatment to which these preliminaries are to lead up is novel or a special discovery of my own; there may be some points of detail founded upon personal experience, but the only personal element I wish to impress upon you is a point of view which will necessarily influence your estimate of the relative importance of the different therapeutic measures.

We all know, since Koch has shown us, that in tuberculous lesions there is usually found a certain microorganism which is called the *tubercle-bacillus;* and we all know that injections of the sputa of tuberculous subjects, or of cultures of the tubercle-bacillus, or of toxic materials containing either bacilli or their products, or products of the organism infected with bacilli, will set up a disease having lesions resembling those of human tuberculosis, in susceptible animals—in rabbits and guinea-pigs particularly. But we also know that injections of any of these substances will not ordinarily set up the disease in certain other animals—in horses or donkeys, for example, or in dogs, or in goats. Evidently, then, the poison administered to the one group of animals being the same as that administered to the other group, while the result is different, there must be some difference in the two sets of animals which causes this difference in result. The only possible conclusion, therefore, is that the tubercle-bacillus and its

products are not alone sufficient to cause the disease, but must act in conjunction with some peculiarity or defect in the constitution of the infected animals; because if the bacilli and their products were of themselves a sufficient cause of tuberculosis they would cause it in goats and dogs and horses just as readily as they cause it in guinea-pigs and rabbits and in certain kinds of cattle.

Extending our observations to man, we find upon clinical evidence that men can also be divided into two groups; that certain individuals cannot be infected with tuberculosis, and that other individuals can readily be so infected. Shall we then say that some persons are "susceptible" to the disease and others "insusceptible" or "resistant," and rest satisfied with that—imagining, perhaps, as is too often the case in medical problems, that by simply re-stating a fact in somewhat technical phraseology we have explained it.

Suppose that it had been determined, in this city, for example, that certain structures were more liable than others to be burned down—that if the torch were applied to certain houses they would quickly be in a blaze, but that certain other houses could not be set on fire, what would be the most rational method of preventing conflagrations? Would it not be to try to make all the houses alike "insusceptible" to fire, and before that was possible would it not be necessary to definitely find out in what the difference consisted that made the one house "resist" and the other "yield?" And the same principle must guide our steps in seeking the rational treatment of tuberculosis. We must not give time to the study of the bacillus alone—we must study it, of course, and find out all there is to find out about it—but we must study more particularly the human constitution and determine definitely why it is that some persons are resistant and others non-resistant to the tuberculizing process.

And this is the point wherein my teaching departs from the accepted doctrine. The existence and, at last, the importance, of "susceptibility" is acknowledged by all. A favorite comparison is that of "seed and soil." But I wish to go much farther than this. I hold that normally the human body is never a "favorable soil" for the "seed" of tuberculosis. To be such it must first become abnormal—that is, diseased. In other words, the condition that renders human beings liable to the invasion of tubercle-bacilli, and to the morbid processes thus set up, is the preëxistence of disease; and this disease is something definite, something to be sought, located, described, treated. It is the fundamental pathologic process concerned in the morbid complexus we call tuberculosis; the invasion of the bacillus and its results are epiphenomena. These epiphenomena involve dangers and require treatment on their own account—we must try to put out the fire if possible, but more important is the study and treatment of the condition of primary disease, without which the bacillus might come and go harmlessly. We must try to make our patients *fire-proof*, and they need not fear the incendiary.

But first let us take a step further toward the substitution of a definite conception for the vague term "susceptibility." In guinea-pigs and rabbits lesions histologically indistinguishable from those produced by living bacilli can be produced by dead bacilli, by powdered glass, and other non-living irritants. Similar lesions similarly caused have occasionally been seen in man. Cornil and Toupet report a case due to irritation by a fragment of oyster-shell. These lesions are called *pseudo*-tubercles nowadays, because they do not contain living bacilli—a remarkable illustration of the fallacy called in logical terminology *petitio principii*, "begging the question" or "arguing in a circle."

In pseudo-tuberculosis we have the histologic lesion, but not the toxemic symptoms of bacillary tuberculosis. But certain forms called "zoöglear tuberculosis" present both lesions and toxemia, although a different microbe from Koch's bacillus is found—probably several different microbes.

The evident conclusion is that long ago formulated by Formad: "a definite soil, an indefinite irritant," for the lesions, and for the toxemia different living organisms and chemic poisons resulting from their development and the reaction of the tissues.

In most cases, I grant, the irritant producing the lesions, and the organism producing some of the toxemia is Koch's bacillus; but even so, it is by no means certain as yet that some of the most destructive lesions and most of the toxemic phenomena are not due to the action of other associated organisms or of poisons produced by them.

Be that as it may, the lesions wherein we can best discover the nature of the "definite soil," in which alone tuberculous lesions can develop, are the pseudo-tubercles, because here the problem is purely histologic and uncomplicated by intoxication and its results. While the morphologic and chemic peculiarities that must exist have not yet been satisfactorily or completely elucidated, it seems to me that a certain broad generalization is fully warranted: that the production of the histologic tubercle is an evidence that *the tuberculized tissue lacks reparative force*. With dead bacilli and mechanical irritants the lesions are strictly localized to the points irritated. With living bacilli they are more or less diffused, because the irritant is reproduced within the body and carried to new areas. Yet in cases killed by "Koch's remedy" recent lesions without bacilli have been found, apparently indicating that under the peculiarly depressing effect of the tuberculous intoxication, tubercles may form even without local irritation.

In normal tissue partial breaking down or complete death of cells through exercise of function, through exhaustion of vitality, and probably through injury, is constantly taking place. As you have seen in non-infected wounds, repair takes place by the production of new tissue-elements or cells, which either produce a new tissue like the original or a fibrous scar-tissue.

In subjects who become tuberculous the vital energy resident in the cells or tissues is not sufficient to produce either new tissue like the original or durable scar-tissue; but when irritated, as by tubercle-bacilli or their toxin, or by powdered glass, etc., or broken down by function or by disease of various kinds, the tissues in an ineffectual attempt at repair produce degraded cells incapable of organization—in other words, tubercle-cells. Tubercle-cells perish from lack of nutriment or under bacterial attack, and ulceration or caseous degeneration takes place. In some subjects, to whom we will recur in a moment, the surrounding tissues react to form a scar, or

calcareous deposit takes place, and healing is thus brought about. The therapeutist's object is to put all his patients into such a condition that this may be the outcome. To learn how to do it a study of the different degrees of "susceptibility" is necessary.

First, in studying the group of susceptible persons, or as I prefer to call them, using a term introduced by Jaccoud, *hypotrophic* subjects (hy*po*, not hy*per*), we find them sharply divided into two classes—those in whom the condition is congenital, and those in whom it has been acquired after birth. Therapeutics can do most with the latter class, but much even with the former class. The congenitally hypotrophic may further be divided into those in whose families tuberculosis is hereditary, and those in whom other conditions than parental tuberculosis have given rise to hypotrophy in the offspring. For instance, carcinoma, syphilis, diabetes, alcoholism, and other conditions which lower the parents' vital energy make the children prone to tuberculosis. Among those who are not congenitally hypotrophic, the condition may be induced by privation, by excess, by depression. Thus it may be due to a life of poverty, or of debauchery, or of overwork; to the effects of influenza, of typhoid fever, of measles, of diabetes; to residence in damp places, especially if light and air are excluded; to severe exposure; to the exhaustion of prolonged lactation, or of too many or too frequent pregnancies. The rigorous practices and depressing doctrines of certain religious sects and orders notoriously render their members liable to consumption, as may mental or emotional shock or profound grief, as in disappointed love or defeated ambition; and one of the most potent causes is confinement, as in prison, or in certain occupations which must be carried on indoors, in crowded, ill-ventilated, and over-heated rooms.

Thus carnivorous animals, which in the wild state are probably not liable to tuberculosis, almost invariably die of this disease after a certain period of captivity; and, on the other hand, even animals so susceptible as rabbits may escape all evil consequences from inoculation with virulent cultures of tubercle-bacilli if, after infection, they are allowed liberty in the open air and sunlight.

Graves, one of the greatest of clinicians, said: "It is important to know how to make a man phthisical, as by pursuing an opposite course we may prevent it." The deduction from what I have said is so obvious that I need not take time now to elaborate it. One point only let me make in passing: If you want to keep healthy lungs you must give them facility for proper development in the open air; if you want to make tuberculous lungs healthy once more, you must exercise them in the open air; or, if they cannot properly exercise unaided, you must resort to artificial means, such as the inhalation of compressed air.

To resume our study of that particular group of persons who are susceptible to the action of the exciting causes of tuberculosis, we find certain differences in their susceptibility. In some the fire, once started, burns rapidly, and cannot be estopped until the structure is destroyed; in others it can be checked after it has burned half-way, or less, but remains smouldering indefinitely, ready to flame up again; in others, it can be quickly checked, and finally brought to an end.

We find, for example, a patient like Henry D., in whom there is a certain tendency to a limitation of the morbid processes, purely by the natural powers of reaction. Pathologic processes, like all others, can be limited in two relations—duration and extension, that is, in time and in space. We have extension in space and duration in time. In our tuberculous cases we must study the natural tendency of the human organism to limit the disease, and whether these natural powers limit the extension of the lesions in space, or the duration of the process in time, or both. Let us take, for example, the case of a normal or nearly normal man—one of the "insusceptible" group—who is performing the autopsy of a tuberculous subject, and is inoculated with the products of the disease. What happens? There may be no result, or there may be developed upon a wounded finger the "anatomist's tubercle." You have seen the growth—it resembles a wart. It is the result of a tuberculous process. But, although there are bacilli present, and histologically the characteristic cells of tuberculosis, the morbid product does not extend in space and the morbid process does not endure in time. Even if left to itself, the growth will in most cases disappear, and it always disappears very quickly if treated with lactic acid—a very simple therapeutic measure. This is an illustration of the highest tendency to limitation both in space and in time. Next in order, confining ourselves now to pulmonary lesions for the sake of simplicity, is the condition termed by Sir Andrew Clark "fibroid phthisis," or later, "fibroid tuberculosis." Histologically, tubercles consist of aggregations of degraded tissue-elements incapable of progressing to the formation of tissue like that from which they took origin, or even of durable scar-tissue. They are devoid of vascularity, and break down from want of nutriment, or under bacterial attack. Healing can take place only through the formation of scar-tissure, fibrosis, fibroid proliferation, by surrounding tissue. In fibroid phthisis cicatrization keeps pace with ulceration, the lesions are long confined in space, and the patient retains a fair degree of general health. Such cases are frequently mistaken for asthma. The process, however, is not limited in time, and may last for twenty or even forty years, the patient dying sometimes of intercurrent disease. In some instances the extension is at times, or toward the end, rapid, and the patient does not survive so long.

In Henry D., and in the man beside him, we have illustrations of a third degree of tendency to limitation in space, without much limitation in time. The process in these patients is confined to a limited area, principally at the apices of the lungs, and extends very slowly, but yet endures. It has endured, under our own observation, for five years in the one case, for three years in the other, notwithstanding the fact that the patients' resistance has been increased by treatment. In Henry's case there are two large cavities, one in each lung, in which from time to time we detect signs of activity, which, however, subside under treatment, and even without treatment. In another group of patients we will have an exactly opposite tendency. General reaction is good when aroused, but there is little local resistance. The lesions are but feebly limited in space, but there is a strong tendency to limitation of the morbid process in time; that

is to say, so long as it lasts it spreads more or less rapidly, and may involve a considerable extent of pulmonary tissue, yet it comes to an end in a comparatively short time. An illustration is shown by the patient G., in whom at present all active manifestations of the disease have ceased, but who has in a few months lost so much pulmonary tissue that a cavity in the middle of the right lung is easily demonstrated. The question, in a patient of this kind, is: Will the time-limitation come into play before the destruction of tissue has gone too far? Nature has been bountiful to us in the matter of lungs and other organs, and a total loss of half the normal amount of pulmonary structure is not incompatible with good health, as is shown by a remarkable case of Tillmann's, in which disease and surgery had practically removed the whole of one lung, the other lung remaining healthy.

And then we have, unfortunately, another group of patients, those in whom there is no tendency to limitation either in space or time, and they form the type of what is termed "galloping consumption." The morbid process extends rapidly, and is not limited, except by the death of the patient. I have never seen cases of that kind recover. Of the other classes, I have in many, many cases seen the recovery prolonged for a sufficient number of years to enable one to say positively—yes, this patient has recovered.

In some patients who exhibit a tendency to limitation of the process in time, or limitation of extent of the lesions in space, there happens a series of phenomena which it is very important for us to understand. The processes apparently come to an end; the patient is to all appearances well; upon physical examination we elicit not the signs of an active process, but merely the signs of the result of previous destruction. That state of affairs continues a number of months, or a number of years, and suddenly, without any well-recognized cause, or perhaps through the intervention of some exposure, or of something which reduces the vitality of the patient, such as mental anxiety or bad nutrition, everything starts up again. The patient gets into a very alarming condition, and the family expects his immediate dissolution. Then, just as the process stopped the first time, it stops again before very much damage has been done. We may thus have a case which goes on for almost an indefinite number of years with alternating periods of apparent good health and of acute disease. I have in mind now a case which has been under my observation for many years, in which there have been three such attacks, and yet the patient (from a letter which I received about two weeks ago) is now in such good condition that she weighs about 175 pounds; has no cough, no fever, and is, to all intents and purposes, well. That woman has been in an alarming condition, under my own observation, at least three times. Here is one illustration of what I mean by "preaching the gospel of hope." Never give up the ship in any case of pulmonary tuberculosis! You do not know until the final issue whether or not it is a case susceptible of limitation; and the harder you try, the greater will be the number of cases in which you will bring about the limitation in space, sufficient to save life for the time, even if the process remains latent, to break out again. Even if you strive hard in ten cases, and only one of them shows a good result, it is worth wasting your work on the other nine to save that one. But the proportion of successful results possible is much larger than one in ten. Under favorable circumstances—if we exclude galloping consumption and acute miliary tuberculosis—I should consider 50 per cent. of recoveries much under the mark. Further than this, even when recovery is impossible, life can be prolonged and suffering can be relieved.

The degree of success achieved will depend upon the hopefulness with which the treatment is undertaken and the persistence with which it is carried out, notwithstanding the supervention at times of alarming symptoms. Now, what is the proper line of treatment? I have already said that it is devoted almost entirely to increasing the resisting power of the patient. Let the bacillus alone and strengthen the patient, and if you strengthen the patient to the proper point, his own vital forces will be sufficient to take care of the bacillus. I think the French records show that in at least 50 per cent. of the cases submitted to autopsy in which there has been no other evidence of tuberculosis, clinically or pathologically, the bronchial glands are found to contain tubercle-bacilli. What does that mean? It means that all of us are practically attacked by tubercle-bacilli all the time, and that those of us who are in a normal condition possess the requisite amount of vital energy to enable the bronchial and other glands to closely imprison and finally destroy the invaders, and no harm is done. Therefore, let me once more repeat, for this is the lesson I want to teach, that the aim of treatment must be to make other people as strong as those who resist naturally. You remember what Oliver Wendell Holmes says in *The One-Horse Shay*, and it is good policy even in medicine:

> ". . . It's mighty plain
> The weakest place must stan' the strain;
> An' the way to fix it, ez I maintain,
> Is only jest to make that place as strong as the rest."

You remember that the one-horse shay ran for one hundred years without breaking down and then crumbled into powder. What the deacon did as a carriage-builder we must try to do as physicians—*make the weakest man as strong as the rest.* In the case of patients whom we know to be by heredity liable to tuberculosis, we must early institute preventive treatment. This has two branches: First, the avoidance of infection. Of this I will not now speak, except to emphasize the necessity for teaching your patients not to spit around indiscriminately, but to take such care of the sputa and other discharges that they may not become dried, ground into dust, and being wafted about by the air become a source of danger to others. Avoidance of infection is not always within our control, therefore the other branch of preventive treatment is even more important. This consists of invigoration, or in other words the reinforcement of vital energy.

The methods by which we may bring about this reinforcement of the vital energy of the patient are fortunately quite simple; the details are very many. To lecture upon the details would take several hours, but the principles are few, and if you once have a grasp of the principles you can make the detailed applications of them from your own common sense. The principles are the same, whether applied in prophylaxis (in the

endeavor to prevent disease) or in therapeusis (in treatment having for its object the facilitation of recovery). We must try to control the daily life of the patient—control it, so far as may be possible. First, in relation to his place of residence. That includes his exposure to light and air. The subject of climate cannot be treated in the few words now at my disposal. But this I will say: while proper climatic treatment can do much good, improper climatic treatment does much harm. One climate is not suitable for all cases, just as one coat will not fit everybody. As a rule patients with a robust tendency do better in cold and elevated regions, while those who are in need of soothing and protective measures, who easily take "cold" and have a tendency to fever or nervousness, are better off in warm, and if possible, comparatively dry places. Dryness is a great desideratum always, but it must not be excessive, as it may provoke hemorrhage. The open sea is beneficial in nearly all cases, but the seashore is to be avoided whenever active destruction of tissue is in progress. Many patients cannot avail themselves of change of climate. Such patients must be gradually encouraged to be much out of doors in all weather, proper means of fortifying them against violent changes being resorted to. Secondly, we must control the patient's clothing. We must see that he wears such clothing, light and porous, and not constricting the body at any point, as will best protect him from vicissitudes of weather. Woollen or silk underwear is preferable, as it keeps the skin, as regards moisture and the body-temperature, as nearly as possible in the same condition in different circumstances of weather. Women must be told to give up corsets, tight-waisted bodices, and the like, and all must avoid overheating scarfs, boas, and the like around the neck. Waterproof coats and overgarments are objectionable. Thirdly, we must control the patient's food; administering such aliment as will yield the greatest amount of energy with the least expenditure of vital force in its digestion and assimilation. Nitrogenous and fatty foods, predigested if necessary, and a moderate amount of greens, best fulfil the requirements. In most cases overfeeding, six meals a day, or feeding with the stomach-tube twice a day, will be useful. Fourthly, we must control the patient's activities. We must regulate his exercise and his rest. One authority will insist upon rest in the treatment of pulmonary tuberculosis, another with equal propriety urges the importance of proper exercise. They are both right, both wrong. Whoever urges rest without exercise looks only at one side of the shield; whoever urges exercise without rest looks only at the other side of the shield. You must regulate both—the patient's rest and the patient's exercise. When there is a continuous tendency to fever, the temperature reaching or exceeding 100° F., put the patient to bed and use ice to the chest, over the heart, until the fever is controlled. Under all other circumstances see that the patient spends as much time as possible out of doors, walking, riding, cycling, driving, but never to the point of fatigue. In other words, exercise graduated according to the patient's ability is what is needed. We must likewise take into consideration the patient's vocation and his avocations—that is, his ordinary pursuits, the work he does for his livelihood, and those pursuits which he takes up for recreation and amusement. These must be so arranged, if possible, as to be a part of the treatment. A business that keeps the patient out of doors is the one to be preferably followed; and a most important therapeutic factor in putting the patient into that condition where he can recover, is to afford him cheerful and innocent amusement. Fifthly, we must teach our patients to use their lungs properly, and we must dilate the unused or little used portions. This is accomplished by certain gymnastic measures and by the inhalation of air at modified pressures. Patients can be overfed while inhaling compressed air, who could not be overfed otherwise. Sixthly, we must insist upon the free use of water internally and externally. The proper, judicious use of cold water, by douching, sponging, bathing, and the like is one of the best measures we have for stimulation of nutrition and for education of the vessels to resist changes of weather. The drinking of hot water before meals keeps the digestive tract clean and facilitates secretion and excretion generally. This is especially necessary when large quantities of meat are eaten. Seventhly, we must pay careful attention to the patient's secretions and excretions, endeavoring by hygienic or medicinal means, as necessary, to keep them quantitatively and qualitatively normal. Finally, and least important—and yet of very great value—is the administration of drugs by the mouth, by inhalation, by the skin, or in any other way. I do not underrate drugs; I know we get much good from the use of drugs in the treatment of pulmonary tuberculosis, and I would not like to have to give up such agents as arsenic, strychnin, iodin in its various forms, alcohol, turpentine, hydrogen dioxid, and creosote. But if we should be compelled to choose between hygienic measures and drugs, I would unhesitatingly prefer the former. I believe that a greater proportion of cases would recover under the proper use of rest, exercise, air, sunlight, food, and water, than under the most approved medication with the neglect of the other means. And that is, I think, the reason why some physicians have taken too hopeless a view of the possibilities of therapeutics in the treatment of this disease; they have concentrated their attention upon drugs; they have looked for some specific which would work a miracle and change the constitution of a patient in an hour, or a day, or a year. It is an impossibility. But if, instead of simply writing a prescription for cod-liver oil or hypophosphites, which were the fads at one time, or for creosote, which is now the fad—all good fads in their way—if, instead of saying, "take this three times a day," the physician will talk with the patient for half an hour as to just how he is to live, just what he is to expect in the natural process of the disease, how he is to guard against different accidents which occur in the course of the disease; and then, not only that, if every time the patient comes we question him closely: "What are you eating, drinking, doing in the way of rest, exercise, amusement, and occupation?" and insist that our directions shall be carried out literally and exactly, we will accomplish results which cannot be accomplished in any other way. And therefore I desire you to make every case of pulmonary tuberculosis that comes under your care an individual study, giving such drugs as may be indicated, and concerning some of these we will have a talk hereafter, but above all regu-

lating the daily life of the patient in all the different relations of which I have spoken, in accordance with the different conditions which each particular case may exhibit.

CLINICAL MEMORANDUM.

PRACTICAL APPLICATIONS OF POTASSIUM PERMANGANATE AS AN ANTIDOTE TO LAUDANUM.

By EDWARD ROLLIN GREGG, M.D.,
AND
G. B. MORELAND, M.D.,
OF PITTSBURG, PA.

On the evening of March 13, 1894, the patrol-wagon brought to the Homeopathic Hospital of Pittsburg, at 10 o'clock, George D., in the third stage of opium-poisoning. He had taken two and a half ounces of laudanum at about 7.30 o'clock that evening. When discovered, in the stables of the Eureka Ice Co., his breathing was stertorous and he was entirely unconscious. A doctor was called, who treated the patient until nearly 10 o'clock, and then sent him to the hospital as a last resort.

Upon admittance the man was in the following condition: The face was livid, the lips blue, the respirations shallow and four per minute, the pupils smaller than a pin-head and inactive, the corneæ insensitive to touch, the pulse weak, the bladder distended. The patient was in a state of most profound coma. Pressure over the supra-orbital nerves failed to elicit any response.

Artificial respiration was at once practised and the patient was catheterized.

From the apparent hopelessness of the case it was decided to try the newly suggested and experimental antidote—potassium permanganate. A solution of this salt was hurriedly made (which was afterward computed to be one-half the strength of a saturated solution), and two drams injected hypodermatically into the left arm at ten minutes after 10 o'clock. Artificial respiration was continued, the stomach was washed out with water, then with coffee, and one pint of coffee was allowed to remain in the stomach.

The man's condition remaining unchanged, he was given $\frac{1}{100}$ of a grain of atropin hypodermatically at 10.45 P.M.; and $\frac{1}{120}$ of a grain of atropin in the same manner at about 11 o'clock, but with no effect, not even upon the pupils. Ice-water was thrown over him and he was slapped with towels, but all in vain.

At 11.45 P.M. the man was barely alive; he was then given another two drams of the same permanganate solution hypodermatically. This injection seemed to increase the depth of the respirations very slightly, but otherwise there was no change. At 12.15 A.M., March 14th, he was given still another hypodermatic injection of two drams of the permanganate. Almost immediately there was noticed a perceptible increase in the depth and number of respirations; the face became less livid, and the patient's condition seemed slightly changed for the better. At 12.30 A.M. a slight movement of the fingers was noticed, and the man was again given a hypodermatic injection of two drams of the same solution of permanganate. The effect of this was noticed almost at once. The patient put his hand to his mouth, his respirations became still deeper, his face and lips became brighter, and a sigh escaped him. At 12.45 A.M. he was given still another hypodermatic injection of permanganate of the same strength and amount. Immediately he put his hand to his mouth, moved his legs, opened his eyes for a moment when loudly spoken to, and in response to a question tried to answer, but could not articulate. At 1 A.M. another injection of the same strength and amount as before was given him. This increased the depth and number of the respirations still more and his corneæ became sensitive to touch for the first time.

At 1.15 A.M. the man's respirations were full and 10 to the minute. He opened his eyes and answered "What," when called by name, but relapsed into a lethargic state, from which he could be aroused by speaking loudly to him. The corneæ were now very sensitive to touch. He was again catheterized and twelve ounces of urine withdrawn.

At 1.30 A.M., after a brisk slapping he recognized his employer, who was present.

At 2.15 A.M., the respirations were 10 per minute and full, the pulse was 104, and the temperature 96°. The patient now answered questions, but wanted to sleep. He was now pronounced out of danger, was left in the care of a nurse, and Dr. Moreland and I retired.

At 4 A.M. I was called and found the patient rather stupid, but otherwise in good condition. He talked intelligently, although his pupils were still contracted and inactive. I now ordered him to be walked until I should see him again, which I did at about 8.30 A.M. on March 14th. I found him at this time perfectly sensible, though shaky and trembling. He informed me with a smile that he was "dead tired" and would like to go to bed. I allowed him to sit down, with someone to watch him, but he did not go to sleep.

About 10 A.M. he had nausea and vomited. At noon he was still shaky, his tongue dry, and he said that he had no appetite. However he drank a bowl of milk for his dinner. He complained all the afternoon of being tired, but he was not allowed to go to bed. At 5 P.M. his respirations were 18, the pulse 82, and the temperature 100°. For supper he ate some bread and drank some tea. In the evening I found him as sensible and talking as intelligently as could be desired. His left arm was now quite painful. He had been given hypodermatic injections in each arm, those in the left rather deeply. He was allowed to retire early, but the pain in his left arm kept him awake the greater part of the night.

The next morning (March 15th) his condition was improved, though his tongue was still dry. He was bright and clear-minded. Not until toward evening did his pupils return to their normal size and react to light. His arm was much swollen, very painful, and quite red; the redness extending from the shoulder to the elbow and increasing in intensity. At 5 P.M. his respirations were 24, pulse 112, and temperature 102.4°.

From this time until March 18th the man's condition remained about the same. An incision about two inches long was made in the left arm followed by a gush of about twelve ounces of pus, which was thin, brown, and malodorous. The night of March 18th the man was slightly delirious, but the temperature was only 100.4°. The night of March 19th there was a high delirium all

night, though unaccompanied by violence. At 4 A.M. of the 20th, the thermometer registered 99°, the respirations were 20, and the pulse 80, continuing the same during the day. The swelling and redness were disappearing rapidly from the arm. The delirium continued during the next two days unabated. On March 22d, fluctuation was detected in the right arm at the seat of the injections. Incision gave vent to about two ounces of odorless pus. The temperature now became about normal, and the arms better in appearance, with lessening of the delirium. From this time the man's condition steadily improved in all ways, and he was discharged cured on March 31st.

I cannot readily account for the delirium in this case. It did not appear until *after* the pus had been evacuated from the left arm, and continued for several days, while the temperature was not over 101°, and sometimes normal. After the pus in the right arm had been freed the delirium subsided, and yet I cannot think that it was due to this retained pus, for there was but two ounces, and the inflammation in that arm had been very mild, with very little pain or inconvenience. I have not been able to decide satisfactorily whether the delirium was due to the permanganate, to the after-effects of the opium, or to the previous drinking-habit of the patient. Certain it is, that in the following case of Dr. King's, there was no delirium following the administration of permanganate, although there was an inflamed arm, but no abscess.

In this case the permanganate received a crucial test (as the man could have been in no worse a condition and living), and it proved itself worthy.

On March 14th, the day following the admission of this patient, a patient suffering from laudanum-poisoning was taken to the Allegheny General Hospital, and permanganate of potassium was administered. The patient returned to consciousness soon after the administration of the permanganate. Unfortunately, the amount of laudanum given could not be ascertained, so that in this case the quick return to consciousness cannot positively be credited to the permanganate; that there was a marked improvement after the injection of the permanganate cannot be denied.

A few days later, Dr. W. D. King, of this city, was called to see a case of accidental poisoning in a woman who had taken one ounce of laudanum. When Dr. King arrived the woman was in a comatose condition. He immediately injected half a dram of a saturated solution of permanganate of potassium hypodermatically, and in one hour left the house pronouncing the patient out of danger. Dr. King does not claim that *only* the permanganate would have saved her life, but he does claim that it saved him the trouble and fatigue of walking his patient for several hours. These two cases I took the trouble to investigate, and give the facts as they were told to me.

These cases seem almost sufficient to prove that permanganate of potassium is the quickest-acting, if not the best, antidote to opium and its derivatives.

Dr. Juhel-Renoy, a promising Parisian physician, died recently, at the age of thirty-nine years, of typhoid fever. He made numerous valuable contributions to medical literature. His most recent work was, perhaps, his advocacy of the cold-bath treatment of typhoid fever.

HOSPITAL NOTE.

EXTRAVASATION OF URINE: EXTERNAL PERINEAL URETHROTOMY WITHOUT A GUIDE; DEATH FROM UREMIA.

Surgical Wards, Philadelphia Hospital.

SERVICE OF ERNEST LAPLACE, M.D.

[Reported by ALVAH M. DAVIS, M.D., *Resident Physician.*]

L. B., aged thirty-one, a bookbinder, and a native of Philadelphia, with a negative family history, had enjoyed perfect health until one year ago, when he contracted an acute gonorrhea, which lasted three weeks and left him with a slight discharge, which persisted up to the time of entering the hospital.

On admission, some dysuria with *ardor urinæ* and pain over the region of the bladder was complained of. The temperature was 99.4°, the pulse 68, the respirations 24. Physical examination showed the bladder to be somewhat distended and tender on pressure, and on squeezing the urethra a few drops of thin, gleety discharge exuded. The epididymis, testicles, and scrotum were apparently normal. Fully a quart of urine, very turbid and filled with flocculi, was withdrawn by catheterization. Examination showed the fluid to be of acid reaction, to have a sp. gr. of 1025, the nitric-acid contact-test showing a faint ring of urates; no albumin or sugar was present, but there was considerable mucus. Microscopically, bladder-cells, shreds of mucus, uric-acid crystals, and crystals of oxalate of lime were seen. On exploring the urethra, a stricture of large caliber was detected just anterior to the bulbo-membranous junction, admitting a No. 20 sound. After dilatation of the stricture the patient was able to void urine more freely, but complained of severe pains in the lumbar and suprapubic regions, with extreme prostration. The temperature became remittent or hectic in type, ranging from 102° to 103° evenings, to from 99° to 100° mornings. Stimulants and diuretics were given, and the bladder washed out daily with a quart of equal parts of distilled water and a hot, saturated solution of boric acid. Four days after admission the skin at the junction of the penis with the scrotum became inflamed, swollen, and tender to the touch, and on careful palpation an indurated area about the size of a peach-kernel could be detected, extending on either side of the median line. At this time considerable pain was experienced during the act of micturition, the patient being able to expel a few drops of urine only with violent straining efforts. On exploring the urethra it was found impossible to pass even a filiform bougie, enough urine, however, being voided to keep the bladder from becoming over-distended. Opium by the rectum, and hot compresses to the perineum were employed without affording much relief. The area of induration increased rapidly in extent, the skin of the prepuce and scrotal tissues becoming markedly edematous, and, forty-eight hours after the appearance of the extravasation, operation was considered advisable. The seat of the operation having been properly prepared and the patient anesthetized, an incision, about three inches in length, was made in the median line of the perineum, entering the urethra at its membranous portion.

About six ounces of acrid urine, mixed with pus,

escaped. A sound was then introduced into the bladder, and the incision continued upward in the urethra, cutting through the stricture. At this point some pus escaped, demonstrating the existence of a peri-urethral abscess. A staff being next inserted, the portion of the urethra containing the stricture and fistula was completely obliterated. During the operation considerable venous oozing occurred, but very little arterial hemorrhage. The wound, after being thoroughly irrigated, was packed with iodoform-gauze and the dressing held in place by means of a T-bandage. The temperature immediately after the operation was 102°, the pulse 112, the respirations 28. The heart-sounds were feeble, the muscular element of the first sound being especially weak. Urine trickled through the wound, and the edema of the prepuce and scrotum disappeared to some extent. Unfortunately, because of the constant escape of urine, the quantity secreted in twenty-four hours could not be measured, nor could it be examined subsequently for the presence of albumin. Internally, sulphate of strychnin, tincture of ferric chlorid, and whiskey were given, together with diuretics, but the patient's condition did not improve. A low form of delirium developed, accompanied by carphology and *subsultus tendinum*, the temperature (after the shock of the operation) remaining continuously high, with slight remissions. On the third day following the operation an attempt was made to repack the wound, when considerable venous hemorrhage occurred, being controlled with difficulty by constant digital pressure. The surrounding tissues looked flabby and indolent, showing no signs of granulation. Twenty-four hours later urine ceased to flow through the wound and another attempt was made to repack it, when venous hemorrhage again occurred and was again controlled with difficulty. On the fourth day after the operation the respiration became of the Cheyne-Stokes type, the delirium giving place to stupor and coma, the pupils became dilated, the pulse feeble and fluttering, the temperature subnormal, and death quickly followed.

The clinical diagnosis of the cause of death was uremia and extravasation of urine.

At the autopsy the following interesting conditions were noted: The weight of the left kidney was 5.5 ounces. The capsule was adherent in places, but otherwise stripped off readily and to an abnormal degree. The cortex was somewhat swollen and studded with minute, white, slightly elevated points, which extended downward into the pyramids. At one point in the cortex there existed a crater-like cicatrix, possibly gummatous. The left suprarenal capsule showed marked pigmentation; the right was normal. The pelvis of the right kidney was distended with a cloudy, serous fluid with a slightly ammoniacal odor. The cortex was striated and fatty, the same elevations being noted as were seen in the other kidney. The organ weighed 6 ounces. The tissues surrounding the wound were in a sloughing condition: namely, the scrotum and its contents, and the membranous and bulbous portions of the urethra. The heart weighed 12.5 ounces, and showed some hypertrophy of the left ventricular wall, but it was otherwise normal.

The other organs were in apparently good condition.

The pathologic diagnosis was: Large white kidney; acute hydronephrosis on one side; sloughing of the external genitals and perineal contents.

MEDICAL PROGRESS.

Esophagotomy and Gastrotomy for the Removal of a Denture from the Esophagus.—Wallace (*Lancet*, No. 3862, p. 734) has reported the case of a woman, twenty-eight years old, who during sleep accidentally swallowed a denture with five teeth attached, the presence of which in the esophagus was with considerable difficulty detected by means of a coin-catcher. Attempts at its removal without undue force, however, failed, and its position having been located at about midway between the manubrium sterni and the stomach, esophagotomy was performed as low down as possible. Even now the plate could not readily be removed, and, accordingly, gastrotomy was undertaken. After a little difficulty the esophageal opening into the stomach was found and the denture was then easily extricated with the aid of a pair of dressing-forceps. The mucous membrane of the stomach was brought together by a continuous suture and the serous coat by the Lembert suture. The wound in the abdominal wall was closed in the usual way. The esophageal wound was closed with fine catgut and the superficial parts with interrupted sutures, a small piece of iodoform-gauze being introduced to facilitate drainage. Dressings were then applied and the patient was put to bed. For forty-four hours after the operation nothing was given by the mouth, but nutrient enemata were given every four hours. For five days the enemata were retained and gave rise to no irritation. Morphin suppositories were introduced thrice daily. On the sixth day a slight diarrhea set in and continued for a week, although the enemata were withheld. Forty-four hours after the operation the strip of gauze was removed from the esophagotomy-wound, which was healthy in appearance and presented no evidence of saliva having escaped into it. A smaller, fresh piece of gauze was introduced, the wound having been powdered with iodoform. Two ounces of milk and barley-water were given by the mouth, but none escaped into the esophagotomy-wound. Thereafter, milk, cream, and barley-water were administered every four hours. On the fifth day, however, it was noticed that a little milk escaped into the esophagotomy-wound. It was, therefore, concluded to feed the patient through a tube passed through the mouth into the stomach. For a time the woman did badly, losing ground, for a brief period being actually maniacal, and her management was attended with a good deal of difficulty. By careful attention to the esophagotomy-wound cicatrization was brought about after the lapse of a month, and a few days later the woman was dismissed, cured. The report is concluded with the following propositions: 1. It is extremely dangerous to leave a foreign body in the esophagus, as disastrous results almost invariably ensue. 2. Such disastrous results may not occur for some time after impaction. 3. If attempts at removal of the foreign body with instruments fail, one should at once proceed to operative interference. 4. The operation of esophagotomy is not, *per se*, dangerous. 5. If the body be impacted low down, near the cardiac opening of the esophagus, gastrotomy is preferable to esophagotomy when the body is irregular. 6. By one or the other of these operations all parts of the esophagus are within reach. 7. The danger of opera-

tive procedure is mainly due to the difficulty of alimentation. 8. The superficial parts in the esophagotomy-wound should be left freely open, so as to heal by granulation.

Merycism.—From long and careful observation of a case of merycism in a male and from a study of the literature of the subject, LEMOINE and LINOSSIER (*Revue de Médecine*, 1894, No. 3, p. 200) conclude that this condition should be considered as presenting two varieties—a simple form and a pathologic form; while the latter includes three sub-varieties—a neuropathic form, with or without dyspepsia, a form of dyspeptic origin and directly related to the dyspepsia, and a form of dyspeptic origin but not disappearing with the relief of the dyspepsia. The condition must in its intimate nature be considered a gastric neurosis. The act of regurgitation is a reflex phenomenon whose point of departure resides in a congenital or acquired exaggerated sensibility of the mucous membrane of the stomach. The mechanism of the condition corresponds with that described in ruminants, and consists essentially in a spasm of the diaphragm and of the muscles of inspiration, diminishing the intra-thoracic pressure and tending to dilate the esophagus, while the abdominal muscles compress the stomach and cause the expulsion of its contents.

Appendicular Colic.—JESSOP (*British Medical Journal*, No. 1734, p. 627) contends that the vermiform appendix is liable to partial occlusion of its canal from various causes, some of which are permanent whilst others are transient. The symptoms by which such incomplete obstruction is to be recognized are those of appendicular colic. In cases of recurring appendicular colic, and especially if there be at the same time an increasing severity, the practice should be to recommend the removal of the appendix. The time is believed to be past when such misleading terms as typhlitis, perityphlitis, cecal and pericecal abscesses should longer be applied to diseases having their origin in the vermiform appendix, as appendicular colic, appendicitis, and appendicular abscess more accurately describe the conditions present.

THERAPEUTIC NOTES.

The Treatment of Typhoid Fever by the Ingestion of Large Quantities of Water.—MAILLART (*Revue de Médecine*, November 10, 1893, March 10, 1894) maintains that the treatment of typhoid fever by the ingestion of large quantities of water is worthy of recognition as a useful therapeutic measure. In order that the treatment shall be efficacious the patient should receive from five to six quarts of water daily during the febrile period. There is no contra-indication to this mode of treatment; weakness of the heart constitutes an indication rather than the reverse. The results obtained by this mode of treatment consist in a progressive subsidence of the febrile process, a disappearance of the dryness of the tongue, and a marked sedative influence upon the nervous, circulatory, and renal phenomena. These results are to be ascribed to the oxidation, the solution, and the elimination of the toxins produced in the progress of the disease and also of the dejecta. The oxidation is indicated by an increased production of urea, and its elimination by the skin and the kidneys in the profuse perspiration and abundant diuresis. The diuresis aids in the restoration of the integrity of the kidneys, as shown by the disappearance of the albuminuria. This mode of treatment has no noteworthy influence upon the course, the duration or the evolution of the disease. It is not attended with any unpleasant complications. It has the great merit of facility of application, and the coöperation of the patient is readily obtained.

Chloroform and Morphin in the Treatment of Chorea.—CHURTON (*British Medical Journal*, No. 1734, p. 633) has reported the case of a girl, seventeen years old, with a rheumatic history but no existing arthritis, who came under observation in an attack of moderately severe chorea. The movements increased rapidly in violence, unchecked by chloral given frequently in doses of 20 grains. Beginning with gr. ⅙ of morphin hypodermatically, immediately followed by the inhalation of chloroform for a few minutes, and gradually increasing the dose of morphin to gr. ¼, always in conjunction with inhalations of chloroform, the movements were kept under control with the greatest ease. The smaller doses produced sleep lasting from one to three hours, the patient waking no better; but after the dose of gr. ¼ she slept almost uninterruptedly for nine hours, and was then so greatly improved that she required no further medication except by the mouth—in fact became an ordinary, mild case, and left the hospital well at the end of about six weeks. It is pointed out that with moderate doses of morphin there is often a delay of many minutes before sleep occurs; the inhalation of chloroform for two or three minutes produces immediate sleep, which is continued by the action of morphin. If necessary the chloroform may precede the injection of morphin.

The Treatment of Fracture of the Patella by Arthrotomy and Metallic Suture.—After an experience of five years, covering fourteen successful cases, LENGER (*Journal des Practiciens*, 1894, No. 24, p. 283) recommends the performance of arthrotomy, with suture of the fragments, in the treatment of fracture of the patella. He details the steps of the operation as follows: The knee is made aseptic by means of washing with soap and carbolized water; and is then rubbed with ether. An incision is made in front of the patella, the articular cavity is irrigated with a 2.5 per cent. solution of carbolic acid, and drainage is provided for in the most dependent situation. At least two holes are bored in each fragment, and through these strong silver sutures are passed, and approximation effected by twisting. The periosteum and the fibrous tissues are sutured with silk thread, and the parts are again irrigated with a 2.5 per cent. solution of carbolic acid. The cutaneous wound is sutured with silver wire, and the dressing is completed with iodoform-gauze and absorbent cotton. The extremity is placed in a position of extension, and immobilized in a splint. The treatment occupies four weeks. The drainage-tube may be removed at the end of a week. The union is believed to be osseous. The only contra-indications to this method of treatment are furnished by nephritis, diabetes, obesity, and cachectic conditions.

CRANIOTOMY, CESAREAN SECTION, AND SYMPHYSIOTOMY, FAIRLY CONSIDERED AS OBSTETRIC EXPEDIENTS.

1. *Craniotomy* is a very ancient operation, so old that we can form no idea when it began. It appears to have suggested itself to Arabian and Japanese obstetricians many centuries ago, as a means of saving the life of the mother, at the expense of that of the child, an excuse for which lay in the fact that there was no other alternative method of delivery. So the head was opened and emptied, a hook or hooked forceps applied, and the fetus delivered if practicable, but if not, the mother died undelivered.

The first alternative method was that of the Cesarean operation, introduced in 1498, which enabled the obstetrician to deliver the fetus in cases in which the pelvis was too small to admit of its passage after craniotomy. To save the fetus alive at an additional risk to the mother was scarcely ever thought of, and a resort to the method was rarely decided upon until the woman had been long in labor. The operation was soon regarded as almost an equivalent to a doom of death, and the dread of it, begotten of delay, became a most potent factor in rendering its fatality certain. No one ever sewed up the uterus, and its atony, engendered by muscular fatigue, left an open wound for leakage into the abdominal cavity of a fluid that in nearly all cases produced peritonitis and death. This neglect of the uterine wound is to us unaccountable, and especially as we know that the first man who ventured to sew it up was bitterly censured, although the woman recovered.

The second alternative method was the *free* introduction of the use of the obstetric forceps, in 1733. This instrument is an alternative only to a limited degree in saving the fetus; but within this limit it has enabled the obstetrician to save many children that would otherwise have been sacrificed. It was a great improvement upon the Cesarean delivery of the period, as, the element of fear being absent, there was no incentive to delay in resorting to its application.

2. *The Cesarean operation* of to-day has nothing of the original section left in it, except that the two incisions are in the median line. The first vital improvement was the sewing up of the uterine wound; the second was operating early in labor; the third was the use of anesthetics; the fourth was the adoption of antiseptic treatment before and afterward; and the fifth was the multiple suturing of the uterus in two rows, deep and superficial. The end and aim in this operation for the last fifteen years has been to reduce its mortality, and this has been accomplished to a marvellous degree in certain Continental maternities, notably those of Leipzig, Dresden, and Vienna. The possibilities of the operation are best attained in hospital service, and under operators whose repeated sections under favorable circumstances make terminations in death very exceptional. It is not at all difficult to predict before an operation what will in all probability be its result. This has been done repeatedly, and every favorable prognosis was followed by recovery—a result that is largely due to the prior condition of the woman. Cesarean section, considered in itself, may be regarded as an operation having comparatively little danger. Few men believe this, and some think it an extravagant opinion; but operators like SÄNGER, ZWEIFEL, and LEOPOLD have reason, in their repeated successes, for holding the same view. As one observer in this city has seen eleven women recover in order, it is not to be wondered at that his faith resembles that which PROF. SÄNGER claimed to hold after his first eleven cases had recovered and he had saved all of the children but the first, which was some time dead before delivery.

The general work of a large country like our own has little in it to give encouragement. Private and hospital cases, village and city operations, grouped together cannot be expected to give from 6 to 10 per cent. of mortality. We do not do it, and probably never will. When the improved operation was introduced, men were sanguine of success in anticipation, but their ardor cooled many degrees when the first 8 women died and all of the children were dead but 2, and one of these died in thirty-two hours. The dead fetuses tell the reason of failure. Labors of "thiry-six hours," "three and a half days," "a week," "nine days," and "forty-two hours," give no encouragement to the performance of "*puerperal celio-hysterotomy*." We have had 100 of these operations in the United States since October 1, 1882, and have lost 38 women and 20 children. We know why each of these women died; and death came in but few instances as a natural sequence of the mode of delivery. Obstetricians have a great deal to learn and act up to before the general mortality of our country can be reduced even to 20 per cent. It will be below this in city maternities, but private cases in little towns will keep up the death rate.

In a recent discussion before the London Obstetrical Society an opinion was expressed that the mortality under the Cesarean operation in Great Britain had been reduced to 10 per cent. "in fair cases." Now it is true that Prof. Murdoch Cameron, of Glasgow, did save 27 women out of 30, thereby showing the possibility of the operation in his own country; but where is the statistical evidence that even London has come down as low as 20 per cent?[1] No one, not even the late Dr. Thomas Radford, of Manchester, ever made a thorough search for the unpublished Cesarean cases of Great Britain, such as has been done through correspondence and the distribution of return-blanks in the United States. Such a statistical research has been desired for London alone, but no one has been willing to undertake the labor. These conjectural calculations have no value and teach nothing. Few men know the value of statistics as they do who collect them properly and analyze their teaching after they are chronologically arranged. It is an error to presume that because cases have never been reported they are to be regarded as in all probability unsuccessful. We know well to the contrary, in respect to operations at home and abroad. Many an operator feels much more at home with his knife than with his pen; if asked for a report of a case, however creditable, he fails to respond; if sent a skeleton-blank to fill up, and he sees his report all mapped out and how little trouble it is to give him, he act promptly, and all the points required can be gotten. Statistics are not collected as curiosities; the cases teach how and when to operate for the saving of life, and their study has been the means, as in ovarian cystectomy, of making a highly dangerous operation one of comparatively little gravity.

3. *Symphysiotomy.* We have sometimes wished that this operation had no early history, and that it had been introduced at the time of its revival in 1866, because of the fact that this same early history lives in obstetric text-books as an obstacle to its being accepted as a legitimate and valuable alternative to the destructive operation of craniotomy in cases of moderate pelvic obstruction. It matters not that 55 Italian symphysiotomies (1886–1893) have saved 53 women and 48 children, for there stand Baudelocque and the old writers to show its fatality; its capabilities for maiming the subject; its unphilosophic character; and how little can be gained by it, in the true conjugate of the pelvis. Case after case is appealed to, to show how the forceps failed to deliver the head until after the symphysis was opened; when the same instrument availed to deliver a living fetus. Philosophic or unphilosophic, the proof stands unquestioned. Prof. Morisani, of Naples, thought that his experiments demonstrated that this operation had a philosophic basis, and he therefore reintroduced it. The Cesarean operation in Naples had cost the lives of 25 out of 27 women, although all of the children were delivered alive. Mark the difference: the first 27 pubic sections saved 20 women, and lost 5 children. Thus much for the operation prior to the change effected by antisepsis.

They tell us in London that this operation has a higher rate of mortality than the Cesarean section, which may be true or may not be, according to the way the comparison is made. It is not correct, if we compare Leipzig with Naples; but is so, if the Cesarean work of Leipzig is compared with the symphysiotomies of Paris. It is very far from true, if we make the comparison in the United States. The Cesarean record shows a mortality of 38 per

[1] We have just learned that London, from Nov. 1, 1886, to Nov. 1, 1893, lost 9 women and 5 children as the result of 22 operations.

cent. There have now been 44 symphysiotomies under asepsis, with the following results: deaths of women, 5; children dead before operation, 4; died under operation, 4; died after operation, 4=12; women lost after last 28 operations, only 2; lost after the last 37 improved Cesarean, 9, or nearly $3\frac{1}{2}$ times as many under the fairest possible comparison, *i. e.*, $7\frac{1}{7}$ per cent. of death against $24\frac{1}{3}$ per cent.

Symphysiotomy can only to a very limited extent be a substitute for the Cesarean operation, and properly comes between the domain of the forceps and Cesarean section, just covering the ground where craniotomy has been most abundantly resorted to, and can be employed with the least possible degree of risk. Certain German obstetricians use the forceps in such cases, and failing with this form of traction, perforate the head and reapply the instrument, claiming that their hospital records show no deaths of mothers in these cases. This is largely the practice in Great Britain now, and was at one time the universal expedient in American practice. But the introduction of symphysiotomy, and its diminishing mortality, has set the medical world to thinking upon the question of the right of the fetus *in utero* to be saved, even if in securing it the mother has to run a small additional risk. At one period the Cesarean section was the expedient to be avoided if possible, because of its death-rate, and men taxed their brains to contrive instruments that would extract a mutilated fetus through a conjugate, down to $1\frac{1}{2}$ inches. But the fact that operating in this way, under a measurement of "$2\frac{1}{4}$ inches or less," was shown to destroy the life of one woman in five, checked the use of the cranioclast, and it has now been largely retired, since the introduction of the improved Cesarean section from Leipzig and Dresden.

Symphysiotomy is now being performed in many Continental countries, and there were 84 operations with 10 deaths in all localities in 1892, in contrast with 12 in Naples in 1891, with no death. England has made two trials, Ireland one, and Canada three. The United States stands second to Italy in successful results, and there are about as many operations now performed in Philadelphia as in Naples. When we look back four decades we see that great changes have taken place, and are now in progress, in regard to the propriety of fetal destruction; and old obstetricians, who at one time would not have hesitated to perforate the skull of a living fetus, have come to think that craniotomy should be avoided, as there are alternatives for saving the child.

EDITORIAL COMMENTS.

Cardiac Asthenia or Heart exhaustion.—Death sometimes occurs without more obvious cause than heart-failure. Such an event may be brought about as the result of inflammatory or degenerative changes in the myocardium, or possibly through involvement of the cardiac nervous apparatus. Further, a heart may be intrinsically weak, the myocardium participating in the lack of tone that affects the muscular system generally. In an address recently delivered before the Medical Classes of the University of Pennsylvania, DR. J. M. DA COSTA[1] made an important contribution to this hitherto rather unelaborated subject. In this paper Dr. Da Costa deals with the feeble heart resulting from enervation or asthenia, on the one hand, and with that due to atonicity or intrinsic muscular weakness, on the other hand. In the first of these states, which usually develops in the sequence of nervous strain, the action of the heart is feeble and accelerated; the pulse is small and compressible; there is a sense of uneasiness in the precordium, but rarely actual pain; the extremities are often cold; the temperature is likely to be subnormal. The capillary circulation is poor and the skin pale, though occasionally injected or flushed. The cardiac impulse is feeble. The area of percussion-dulness is unaltered. The rhythm of the heart is rarely disturbed. The first sound is short, feeble, indistinct, lacking in volume, obscure; the second unchanged. The breathing is conspicuously unaltered, although there may be a sense of oppression. Insomnia may be complained of; depression of spirits is common. The patient is obliged to stay in bed; attempts to rise produce a sense of swooning and a vanishing pulse; or there may be actual syncope. The prognosis is favorable, though the affection pursues a protracted course. Therapeutically rest in bed is the primary indication. When the patient is able to sit up nothing does so much good as graduated shower-baths. Massage, too, may be employed, but it is more useful a little later. Swedish movements may then also be recommended, together with carefully regulated exercise, such as walking, gentle horseback-riding, or light gymnastics. The food should be most nutritious and taken as frequently and in as large quantities as the digestion will tolerate; stimulants must often be resorted to. Errors of secretion and excretion must obviously be corrected. Of drugs, strychnin, in doses of gr. $\frac{1}{30}$, three times a day, has proved the most useful; next in value is arsenic; of heart-tonics digitalis is the best; caffein and cocain are useful; iron is not indicated unless anemia be present; nitroglycerin is of no avail, unless there be cardiac pain, or unless used in conjunction with digitalis. Bromids, valerian, and opium are to be reserved to meet special indications. The second form of weak heart presents, in addition to the symptoms detailed, shortness of breath, especially on exertion, and edema of the ankles and insteps. The first sound of the heart is even more indistinct and ill-defined; duplication of either sound and functional dynamic apical murmurs are more common. The influences that lead up to this condition are not at all clear; the changes if any, that take place are not evident. The prognosis is less favorable than in cases of simple cardiac asthenia. The

[1] "Cardiac Asthenia or Heart-exhaustion," American Journal of the Medical Sciences, April, 1894, p. 361.

treatment for the two conditions is much the same. It is probable that in some cases the two forms of cardiac weakness here discussed are associated.

The Proper Sphere of Women's Work.—In a recent address Sir Dyce Duckworth claims that the experience arising from a long period of practice in the medical profession renders its owner peculiarly well-fitted to form an opinion on the proper sphere of women's work. Briefly, he takes up the position that the fixed sexual differences between women and men make it impossible for the former to expose themselves to the training and influences suitable to the latter, without materially and disastrously affecting the welfare and happiness of the human race. Speaking as a physician, he maintains that the physical strength and energy of all but exceptional married women find ample scope for their exercise in the household and family work, which can be efficiently performed by none other than themselves, and asks where are the "wonderful women" who, after properly discharging those duties, can yet find time and energy to compete with men in the pursuit of business or public work? To those who are without such duties or find them insufficient, he would advise the adoption of interesting and suitable outside work, but would avoid politics, public work of most descriptions, the professions, and above all that of medicine, as being unsuited to the very nature of the female sex.

This opinion of a well-qualified observer is, however, contradicted by the opinion of thousands of better-qualified American physicians. We say better-qualified, meaning thereby more experienced in the special matter. Thousands of women as well as men find "the welfare and happiness of the human race" affected for good by the work of women in medicine. Entirely too much has been made of the old bogey of the "fixed sexual differences between women and men." It is hardly good logic or good morals to put a person in a dark room for years and then blame the person for paleness and weakess. The position of women has outfitted them with some lack of "physical strength and energy," but they should hardly be blamed for it, and the girls even in England seem to be able to outdo the boys in the contests for university honors, and with us there are many excellent and successful women physicians.

Attenuated Quackery.—We have received from the —— Surgical Instrument Co., a letter, a pamphlet, and an instrument. The letter asks us to notice the instrument, which is "not advertised as a cure-all," but "comes nearer to being one than any of the thousand things that are so advertised." The pamphlet is a reprint of Dr. ——'s paper in *The Medical* ——, describing the instrument, together with price-list of instrument and medicine to be used with it.

The instrument ("patent applied for") appears to be a good device for applying well-known principles long in use and often written of by well-known physicians of Philadelphia and elsewhere. The method of its advertisers comes so near to quackery that it takes an expert casuist to draw the line.

We do not suppose that Dr. —— is responsible for the doings of the —— Surgical Instrument Co., but we would advise him in the interest of his good name and his deservedly high reputation to insist on a modification of the pamphlets, circulars, etc., furnished with his instruments.

If the code-revisers have their way, and patenting of medical and surgical instruments and remedies is allowed, it will be a sorry day for the medical profession. The narrow line between the doings of the —— Instrument Co. and quackery would soon be overstepped, and the result would be degrading to all concerned.

Protracted Anuria.—We have to add another case to those already recorded (see THE NEWS, November 18, 1893, p. 582) in which functions ordinarily viewed as vital have remained for many days in abeyance. KAEFER (*Berliner klinische Wochenschr.*, 1894, No. 13, p. 319) reports the case of a man, sixty-eight years old, and previously in excellent health, who came under observation after not having passed urine for six days. He suffered no discomfort and, but for the consciousness of the failure of the renal function, would have had no concern. It was only after having been struck by the fact that he had passed no urine for more than twenty-four hours that the man found, on attempting to do so, that he was unable to evacuate a drop. There was a little abdominal pain, but there had been no attack of colic. On the eighth day, however, such an attack did occur, after which for a time the secretion of urine was resumed; the fluid was found to contain pus-corpuscles and epithelial cells, but no urates. A short time later a second attack of anuria occurred, lasting for five days, when death took place amid the manifestations of pulmonary edema. The post-mortem examination disclosed the presence of obstruction of both ureters by calculi, with beginning hydronephrosis on the left side.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Meeting March 5, 1894.

THE PRESIDENT, DR. WILLIAM HUNT, IN THE CHAIR.

(Continued from page 473.)

CASE II. *Large strangulated inguinal hernia; sloughing intestine; radical operation, with removal of testicle; recovery.*—Jacob B., aged forty-three years, was brought to me by his physician, Dr. James Robinson, on March 6, 1893, and admitted to the Polyclinic Hospital. He stated that he had had a large tumor in the left scrotum from childhood, and could not remember when it had originated. By manipulation at times he thought that it had become somewhat smaller. It never had given him any annoyance.

On March 1st, while in apparently perfect health, he drank a quantity of ice-water, which induced vomiting, during which he felt a sensation of something in the left inguinal region "giving way." From this time he continued to vomit everything taken, and to experience extreme nausea. The bowels also ceased to move. The tumor became more and more painful and swollen. He continued in this condition five days, and then summoned Dr. Robinson, who applied taxis for thirty mitutes without making any impression on the mass. On the sixth day he walked a number of squares to the hospital.

Upon admission I found a tumor the size of a large cocoanut occupying the left scrotum and inguinal canal. The testicle was below the general mass, and could be outlined as distinct from it. The whole tumor was very tender and somewhat edematous. Deep fluctuation was marked. No percussion-resonance or succussion could be elicited. A very resisting mass occupied the inguinal canal. The bowels had not moved for six days. There was constant fecal vomiting. The general condition was fair.

A diagnosis of chronic hernia of the omentum, with acute entanglement of a portion of the intestine, together with hydrocele, of the hernial sac, was made, and immediate operation insisted upon.

After preliminary cleansing and anesthesia, without waiting to make prolonged taxis, which was clearly prohibited by the long duration of the strangulation (as the subsequent history clearly demonstrated), a five-inch incision was made in the line of the inguinal canal and scrotum. The cellular tissues were edematous and had some odor of decomposition. The sac was exceedingly thick and highly discolored, as if about to break down. It was freely incised, and half a pint of dark, turbid fluid of putrefactive odor escaped. The sac contained a large mass of hypertrophied omentum of the character so frequently found in omental hernias; it was adherent by firmly organized attachments to most of the sac-wall. It was purple in color, intensely congested, and very edematous. The whole was stripped from its adhesions and carefully spread out, whereupon a portion of small intestine came into view that had been entirely wrapped up in the folds of the omentum. This again illustrates the extreme care that is always so necessary in handling the contents of a hernia; for it would have been exceedingly easy to have ligated off the omentum and bowel together in this case, and to have returned the stump to the abdomen, thus insuring a fatal issue. A finger passed into the inguinal canal discovered a very tight constriction at the internal ring, which was freely divided upward. The omentum could now be pulled down with ease until entirely healthy portions appeared, when it was ligated off in two bundles by transfixion, and the stump returned to the cavity and fixed immediately behind the internal ring by bringing both of the ligature-ends through different portions of the muscular wall, and then tying them down, as suggested by Macewen for making a protecting pad of the sac in his radical operation. The prolapsed intestine could now be freely inspected.

Upon the free margin was a gangrenous spot, one-half inch in diameter, and which appeared to be in imminent danger of rupture. The remaining portions of intestine were almost black from venous stasis, but were not actually sloughing. The sloughing portion was buried under healthy peritoneum by means of Lembert sutures, buckled into the lumen of the bowel, as it were, just as if perforation had taken place. Fortunately, this procedure did not too much diminish the lumen of the bowel; and by the time that it was completed all excepting the sloughing portions of the intestine had, under hot irrigation, resumed the beautiful pink tint of returning circulation. The bowel was then returned to the abdominal cavity.

After a very difficult dissection the sac was freed of its attachments to the scrotal, testicular, and cordal tissues, and ligated off in two sections at the internal ring. The stump of omentum was next fixed behind the ring as described. Attention was now turned to the testicle and cord. These structures were edematous, had the general foul odor of all the surroundings, and, in spite of careful separation, had been considerably injured by the dissection and other manipulations. It was considered that leaving such structures in a wound already gravely threatened with suppuration, if not sloughing, was an unjustifiable risk to which to subject the patient, as the testicle, under these circumstances, was likely to break down and slough, with accompanying dissecting suppuration, and especially was it desirable to secure for this hard-working man a radical cure, if possible. Hence the cord was ligated at the internal ring most carefully by a transfixing double ligature of silk, and also returned to the abdomen. This permitted a careful and complete closure of the internal ring and the whole inguinal canal by buried silkworm-gut sutures placed about three-eighths of an inch apart. A small rubber drain was placed in the lower portion of the scrotal wound, but none in the upper portion, and the skin-margins were approximated by silk sutures.

Excepting a small amount of suppuration in the scrotum, the entire wound healed by primary intent. The drain was removed on the third day. The bowels moved within twenty-four hours spontaneously, and naturally each day thereafter. There were some small clots of blood in the first stool, but none subsequently. The man was given absolutely nothing by the mouth for thirty hours subsequently to the operation; but rectal enemata of warm water were frequently administered, and this prevented thirst. Then liquid diet was started and full diet gradually resumed. The man was kept in bed three weeks, and resumed his duties as an hotel-waiter in five weeks. He was instructed not to wear a truss.

I last saw this man on November 2, 1893. There was no sign of return of the hernia. The cicatrix was sound. He has been working hard at his occupation ever since the operation, has not worn a support, and expressed himself as stronger and better in every way than he had been for years.

Case III. *Strangulated congenital inguinal hernia; radical operation, with removal of undescended testicle; recovery.*—Irvin B., aged nineteen years, was admitted to the Polyclinic Hospital, May 9, 1893. He had enjoyed excellent health all his life, but had always had a "come-and-go" tumor in the right scrotum, and had never been able to distinguish a testicle upon that side. The opposite testicle was large and firm. The tumor could always be reduced with ease, and likewise disappeared whenever he laid down. It was painless. He had never worn a truss.

On the morning of May 8th, upon slight straining while at his work of tile-setting, he felt a painful and unusual sensation in the right side of the scrotum, and went home, nauseated and in great suffering. He then discovered that a tumor much larger than usual was present, and that it was tender and irreducible. The bowels moved a few hours subsequently.

On May 9th he applied to me for relief, and I insisted upon his entering a hospital. No movement of the

bowels had taken place except shortly after strangulation. There was much nausea and anorexia, but no actual vomiting had taken place. The belly was somewhat distended, but the general condition was good. In the right inguinal region was a tumor of considerable proportions and very sensitive. Fluctuation was very marked in the dependent portion of the scrotum. There was no succussion and no percussion-resonance. The inguinal canal was tense and occupied by a solid mass. The testicle could not be defined.

Upon admission the man was given a bath, and, consent to removal of the undescended testicle having been secured, immediately etherized. Taxis was then made for five minutes, and failed. Immediately upon failure of taxis a long incision was made over the inguinal canal and tumor and carried down through the tissues until a thin-walled sac was freely exposed. This was also incised, and four ounces of brownish serum escaped, disclosing a web of congested omentum and about four inches of small intestine. The omentum was inky-black, the intestine not quite so much injected. A very small and tight constriction was found at the internal ring. This was divided with a Cooper hernia-knife with considerable difficulty, owing to the high location of the ring and to the intense constriction—bowel as well as sac overlapping on all sides. A small rent in the serous covering of the bowel resulted, but was immediately repaired with half a dozen Lembert sutures. I have since learned to cut the ring from above in all difficult cases, and thus to avoid the risk of wounding the bowel or other structures passing through the ring. As a division of the ring and roof of the canal from above is now an established procedure when making radical cures for hernia in this situation, division of the ring from below may go entirely out of fashion, excepting in desperate cases or in the very aged or feeble, in whom radical operations must be ruled out, owing to the increased danger to life inseparable from prolonged operative manipulation.

As soon as the constriction was relieved the bowel and omentum at once resumed their normal color and circulation. The omentum was ligated off in portions and the stump returned to the abdominal cavity. More intestine was then pulled down, as usual, but no further constriction was found, and it was also returned to the cavity.

In the sac-wall at the position of the external abdominal ring was found an undeveloped, undescended testicle, about half an inch long and three-eighths of an inch wide. This was dissected out with a portion of the sac, the pedicle securely ligated, the testicle cut away, and the stump returned to the peritoneal cavity. It could have been reduced with the sac, but could not have been returned to the scrotum with a cord manufactured out of a portion of the sac-wall including the testicular vessels and vas deferens. When I considered the uselessness of the organ in its undeveloped condition, its well-known propensity to degenerations and other diseased conditions, and, moreover, as I had secured the man's consent to its removal, and could make so much better a radical operation with no structure traversing the rings or inguinal canal, it appeared more than justifiable to sacrifice the organ, especially as its fellow was in perfect condition. The sac (containing the pedicle of the cord) was next dissected free from its surroundings up to and a little within the internal ring. Here it was puckered up after the method of Macewen with a thread and needle and fixed just behind the internal ring, to act as a pad to protect that region from the possible return of a portion of gut. The internal ring and the inguinal canal were then completely obliterated by silk sutures and the skin likewise sutured by silkworm-gut. No drainage was employed. The bowels were moved by fractional doses of calomel and podophyllin within twenty-four hours, and in three days he was eating semi-solid diet. The wound healed throughout by primary union. He was kept upon his back for three weeks and resumed his occupation in five weeks. No truss was prescribed.

I have seen this patient recently—almost one year since the operation—and found the cicatrix sound, with no sign of return of hernia.

Dr. John H. Packard: I wish simply to refer to one practical point in the treatment of these cases, and that is the use of swimming drawers to hold the dressings in place. It is difficult to apply a bandage that will keep its place perfectly, and I have found this method to answer an exceedingly good purpose after various operations in the pelvic region.

Dr. John B. Deaver: In this connection I should like to state that Bassini reported one year ago 560 operations, with 15 relapses and no deaths.

There are only two points which I wish to mention One is the kangaroo tendon now used by most surgeons The second is enveloping in a plaster-of-Paris bandage. A great deal of the perfect asepsis is due to the latter.

Dr. Orville Horwitz exhibited an improved Wheelhouse staff.

CORRESPONDENCE.

LONDON LETTER.

Ventro-fixation of the Uterus—The Bruits of Chlorosis—A Method of Examining the Bladder in Patients with Enlarged Prostate—Raynaud's Disease—Sulphur as an Antiseptic.

Dr. Sinclair reports twelve cases of ventro-fixation of the uterus, or hysteropexy, as it is called in France, for the relief of retroflexion. They were all successful, and in two cases pregnancy afterward occurred without untoward result. Sinclair recommends that the fundus of the uterus should be seized exactly in the middle line by a small volsella, by which it can be drawn up and held in any position, which proceeding he thinks is much better than the use of a lever inside. The vesico-uterine fold is first obliterated by two rows of catgut sutures passed through the parietal peritoneum and the peritoneum of the uterus. Higher up, near the origin of the broad ligament, the uterus is fixed to the parietal peritoneum, the permanent sutures entering the uterine tissue but only passing through the peritoneum on the parietal side. Finally, two silk sutures are passed through the whole thickness of the parietes, through a portion of the uterine tissue on the anterior surface of the uterus and out again through the parietes. (These

are only temporary supports and are removed on the third day.) The abdominal wound is closed by silk sutures in the ordinary way. There were no deaths after the operation and no cause for anxiety. The most disagreeable results have been the occurrence of sinuses produced by the suturing material and of ventral hernia in some cases, especially those in which pregnancy took place. The operation seemed in every case to give great relief from the pain and discomfort for the removal of which it was performed, and Dr. Sinclair appears to think that (*a*) the danger of the operation is almost *une quantité négligeable*; (*b*) when efficiently performed it is a permanent cure for the troubles caused by chronic retroflexion with adhesions or inflammatory affections of the tubes and ovaries; (*c*) no unusual phenomena are observable during pregnancy or parturition occurring after the operation; (*d*) bladder-troubles are quite the exception; (*e*) ventral hernia occurs at the site of the cicatrix in a certain number of cases; (*f*) after making full allowance for the element of risk and the incidental drawbacks, the operation of ventro-fixation is not only justifiable, but is indicated in a certain limited class of cases of retroflexion of the uterus with complications.

Dr. Frederick Coley draws attention again to the venerable questions, which have been discussed so often and from so many points of view, as to the meaning of the vascular bruits heard in cases of chlorosis. What is of importance, however, is that he is able to assert that, contrary to what is so often taught, a bruit is not at all uncommonly discoverable in chlorosis not only at the apex of the heart but extending outward to the axilla and to the angle of the scapula. Among 400 consecutive cases of chlorosis he found 278 which presented a bruit at the apex and 123 having a bruit at the angle of the scapula also. It is well to remember that the bruits connected with chlorosis alter much with change of position, and that while one at the apex and in the axilla can often be discovered only when the patient is lying down, a bruit at the angle of the scapula is never so heard unless it is also audible in the upright position. No doubt these abnormal sounds are the result of dilatation of the left ventricle; and when questions arise as to whether a given bruit is due to organic disease or to the dilatation common in chlorosis, it is worth remembering that the two conditions may exist together and that under such circumstances it is most important not to overlook the chlorosis, for the intercurrence of this condition, itself sufficient to cause dilatation, is the thing of all others most likely to lead to failure of compensation in a case of organic heart-disease.

Mr. Hurry Fenwick has described to the Medical Society a method of examining the bladder which he finds useful in those very troublesome cases in which symptoms of stone exist along with a prostate so large as to prevent a proper investigation of the pouch behind it. Of course, in such cases, a stone may chance to be felt at once, but it is extremely difficult to assure oneself that no stone exists when it shows no sign. Mr. Hurry Fenwick fills the bladder, punctures with a trocar above the pubes, and then introducing a sound or an electric cystoscope through the canula is able to thoroughly investigate this pouch which has so often been a cause of embarrassment. If on examination anything should be found making it desirable to open the bladder more completely, it is easy to make the canula a guide for the incision, and Mr. Fenwick showed a calculus which he had in this way discovered and removed from its attachment to the posterior surface of the prostate; removing at the same time the projecting portion of the prostate itself.

After giving the clinical history of a case of Raynaud's disease, Dr. Hale White discusses its pathology. It is clear at once that the condition which we see is due to a constriction of the minute vessels of the affected part. The larger vessels are found beating quite near the disease, and after death are found free from embolism or disease. In discussing its origin, then, we may assume that the local syncope and the local asphyxia, which in some cases lead to local death, are the result of spasm of the minute vessels. That drives one at once to the nervous system as the cause, or, at any rate, the route by which the spasm is set up. And, as a fact, peripheral neuritis has in a certain number of cases been shown to exist. It seems, however, by no means certain that this neuritis was not set up by the changes induced by the vascular derangement, and that it was not in fact the result rather than the cause of the disease. Then we must remember that vasomotor changes can be produced by diseases of other portions of the nervous system; in fact, spasm is more suggestive of either central disease or reflex irritation than it is of peripheral neuritis, and there is the suggestive fact that many of the cases of Raynaud's disease occur in hysteric and insane subjects. We should then look upon it as a symptom indicative of disease affecting some portion of the nervous vasomotor system, shading off, quite imperceptibly, into the cold dead fingers to which we are all liable. This puts it into alliance with erythromelalgia, a vasomotor neurosis in which the vessels dilate instead of contracting, and also with cases of urticaria and local mottlings. This view warns us not to expect to find an organic cause for the disease. We can no more hope always to find an organic explanation for paroxysmal vasomotor attacks leading to blueness of the fingers, than always to find an organic explanation for paroxysmal epileptic fits.

Sulphur is no doubt in some surroundings a very harmless substance. It evidently, however, when in combination with oxygen or hydrogen, produces compounds which act strongly as bactericides, and Mr. Arbuthnot Lane has during recent months used it largely at Guy's Hospital as an antiseptic. Innocuous as it may seem, and as it actually is to skin and mucous membrane, it produces, in contact with recently incised tissues, compounds which are powerfully caustic in their action, and must, therefore, be used with caution. Perhaps the best plan is to make it into an emulsion with glycerin, by means of which its action is rendered less violent and more generally diffused. If sulphur is used in any quantity it must be removed in a day or two, and the wound irrigated. Cases of tuberculous disease in which there is doubt whether the whole of the infected tissue has been removed, and cases of injury in which dirt has been deeply imbedded, would seem to be the typical cases for its employment, in both of which, from its slow conversion into substances fatal to organisms, it acts as a continuously acting reservoir of bactericidal material. It may also be used as an application to lupus, carcinomatous or sarcomatous ulcerations, or in cases of ulcerative stomatitis.

The fact that during its presence in a wound H_2S is formed must be borne in mind, otherwise the smell might give rise to a false impression that septic decomposition was in progress.

ENUCLEATION OF THE UTERUS.

To the Editor of The Medical News,

Sir: In the issue of February 10, 1894, of your esteemed journal, which I saw only yesterday, I find an article by Dr. Robert Reyburn, on "Vaginal Hysterectomy for Carcinoma of the Uterus performed by Enucleation without Hemorrhage," which reminds me forcibly of a discussion on the possibility of this operation at a meeting of the New York Obstetrical Society held October 17, 1876 (*Amer. Journ. Obstet.*, vol. x, p. 106). Noeggerath reported a case of vaginal removal of a carcinomatous uterus with a fatal result, and during the discussion the following remarks were made: "Dr. Mundé referred to a case reported by Dr. Alexander Patterson, of Glasgow (*Glasgow Med. Journ.*, 1876), of the successful removal of the whole prolapsed uterus by an operation very similar to that performed by Dr. Noeggerath. Bearing on a case of his own, reported in the *American Journal of Obstetrics* for August, 1872, in which the whole uterus (at least what was left of it, fundus and body) sloughed out after the operation of curetting and applying chromic acid for cancer of the cervix, *Dr. Mundé asked whether, in case of relaxation of the connective tissue attachments between the uterus and the peritoneum it might not be possible to peel the uterus out of its peritoneal envelop without opening the peritoneal cavity.* [Italics new.] Dr. Noeggerath replied that, in certain abnormally relaxed cases it might be possible; in the normal or ordinary condition never. In this opinion Drs. Peaslee and Thomas concurred."

It will thus be seen that the *possibility* of the operation performed by Dr. Reyburn had occurred to me as long as eighteen years ago. But experimenting on the dead uterus showed me that such an enucleation of the body of the uterus from its peritoneal envelop was impossible, and I have placed myself on record elsewhere in regard to this subject. (See an article on "Obscure Pelvic Abscess in Women" in Seguin's *Archives of Medicine*, December, 1880, page 3 of the article.) There, speaking of the existence of cellular tissue between the pelvic organs, I said:

"Spiegelberg says in a clinical lecture that the whole cervical portion of the uterus—that is, the portion of the cervix situated between the reflection of the vagina and the internal os—on all sides except in front, is surrounded by abundant loose connective tissue, and that the retro-uterine peritoneum is not closely attached to the uterus. *Of this I have had occasion to satisfy myself while testing the possibility of enucleating a uterus from its peritoneal envelop through the vagina, as would be indicated in carcinoma of that organ. I found that the peritoneum could very easily be detached from the uterus up to the os internum, but that above it was impossible to separate it except by actual dissection with the knife. In front this detachment was by far less easy than behind and at the sides, owing to the small amount and density of the connective tissue, which, at a spot corresponding to the os internum, is interspersed with muscular fibers and assumes the character of a ligament, whereby the uterus and the bladder are so closely connected as to be almost inseparable.*" [Italics new.]

Unless Dr. Reyburn's case was an unusually favorable one for enucleation, owing to the senile, relaxed condition of the peritoneal envelop of the body and fundus of the uterus (as the Doctor himself admits), I can hardly think it possible to peel off the peritoneum as easily as he describes it to have been done. Indeed, I am inclined to look upon the operation more as a dissecting away of the uterine body from its peritoneal covering than as an enucleation or peeling out. In this respect the operation would not differ so much from the step-by-step excision of the carcinomatous uterus carried out years ago by J. Marion Sims, when often but a shell of the organ was left. I am sure that in a younger woman the division of the vessels leading to the uterus would not have been as bloodless as in Dr. Reyburn's case.

I shall look with interest for further reports of this operation, which, now that it comes from an authentic source, assumes a far more credible aspect than when it was reported from a doubtful and irregular quarter.

Since writing the foregoing my attention has been called to a second article by Dr. Reyburn in The Medical News for February 24th, in which he discusses the question of the priority of the idea and supposed execution of "enucleating" the uterus. It is not my intention to claim any such priority, although I was not aware that *any* operator had ever thus *actually enucleated* the uterus. My object, indeed, is to question the possibility of doing so, on account of the naturally too firm adhesion of the peritoneum to the body of the organ. Dr. Reyburn quotes Langenbeck's case (1813) as the first detailed one of enucleation. But a reference to Langenbeck's description, as quoted by Dr. Reyburn, shows that that operator left a slice of the fundus uteri attached to the peritoneum. Besides, the uterus was prolapsed, that being the reason for its removal, and probably the peritoneal attachment was much loosened. Such loosening does not occur with the uterus *in situ*. The uncertainty of Langenbeck's operation is shown by his thinking he had removed the ovaries when the post-mortem showed that he had not done so. Malgaigne's account of enucleation is apparently theoretic only, as is also that of Récamier. Sauter, of Constance, who in 1822 first removed the uterus *per vaginam*, did so in a manner similar to our present method of vaginal hysterectomy. While abroad in 1868 I accidentally came across an illustrated graduation-thesis by a Dr. von Siebold, a nephew of the celebrated obstetrician Prof. von Siebold, printed in Göttingen in 1827, describing in all its details Sauter's operation. I valued this thesis very highly, both for its historic interest and for the excellent engravings of the operation. But I unfortunately lent it some years ago to a friend whose identity I have forgotten, and it was never returned.

I will say in conclusion that I neither question nor criticise Dr. Reyburn's operation. I merely wish to call attention to the fact that eighteen years ago I had the same idea and found its execution impossible on the dead uterus.

Paul F. Mundé.

20 West Forty-fifth Street, New York,
April 7, 1894.

A CASE OF ARRESTED DEVELOPMENT.

To the Editor of THE MEDICAL NEWS,

SIR: I send you for publication the following statement descriptive of what I consider a very remarkable case of arrested development. The examination was made June 25, 1883. I have not seen the subject for six years, but learn that he is now living in an adjoining county. I was not able to learn at the time of taking the measurements whether or not the mother was subjected to any unusual mental strain during pregnancy.

L. F., of Balltown, Mo., aged fourteen years and six months; weight sixty-eight pounds, height three feet two inches; wore a No. 7 hat. The boy was bright and intelligent. His body was of usual size for his age, and was well developed. The humerus of each side was normal. On the right side, the ulna was three inches and the radius one inch in length. There was an appearance of intra-uterine amputation at the radio-carpal articulation. On the left side, the radius and ulna were three inches in length. The wrist contained four or five imperfectly developed carpal bones. There were two metacarpal bones, viz., those of the thumb and index finger. There were no phalanges for the thumb, but there was a well-developed nail on the end of the metacarpal bone. There was no osseous but only cartilaginous development of the first phalanx of the index finger, which was without a nail. The left femur was seven inches in length; the right femur five and a half inches in length, and was set at a right angle to the pelvis, the knee being on a level with the acetabulum. The tibia and fibula in both legs were well developed, except that on the right side they were about one and a half inches shorter than on the left. The left foot was well developed except the great toe, which was abnormally large. The tarsal bones of the right foot were imperfectly developed, with talipes varus.

The left testicle was down and well developed. The right tunica vaginalis seemed to be perfect, but the testicle was wanting. The child was the second in a family of nine children. The rest are all of average size and well developed.

Respectfully,

J. ROBERT BUCHANAN.

NEVADA, MO.

A PLEA FOR CHAIRS OF THE HISTORY OF MEDICINE IN MEDICAL COLLEGES.

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS for March 24, p. 336, under the heading "Medical Progress in Cleveland, Ohio," your correspondent says:

"Professor Kelly presented to the [Cleveland Medical] Society a rare old book—a copy of the work on *Anatomy*, published by Vesalius in 1514, and also one published by Tulf, in Amsterdam, in 1716, entitled *The Century of Observations*."

Vesalius, the Luther of anatomy, was born in the year 1514, at Brussels. His monumental work: *De humani corporis fabrica libri septem*, was published, not by himself but by Oporinus, of Basel, in 1543. Doubtless this is the work of which your correspondent speaks. This, however, was not the earliest of the books of Vesalius, for, in 1537, his *Paraphrasis in nonum librum Rhasae ad Almansorem*, was issued at Basel. His first anatomic book, an epitome of human anatomy, was published in the same city in 1542. It is upon the first work mentioned that the fame of this great man securely rests.

Now a word as to Tulp or Tulpius, *not Tulf*. Born at Amsterdam in 1593, Tulpius was a surgeon of great renown. His face is the most prominent figure in Rembrandt's celebrated painting, *The Lesson in Anatomy*, which hangs in the Hague Gallery. The only one of his books in my library is the *Observationes Medicæ*, published at Amsterdam, by Daniel Elzevir, in 1672. Tulpius died in 1674.

It is unnecessary to state that I have derived much pleasure, as well as some profit, from the works of Vesalius, being the fortunate possessor of two editions of his great *Anatomy*: Basel, 1543, and Leyden, 1725.

I may also be pardoned for expressing the opinion that it is time for the medical schools of America to establish chairs of the History of Medicine, as has been done by many leading schools of the Continent.

Very truly,

JAMES MOORES BALL,

Professor of Ophthalmology and Lecturer on the History of Medicine in Keokuk Medical College, Keokuk, Iowa.

A MONSTROSITY.

To the Editor of THE MEDICAL NEWS,

SIR: On March 19, 1894, I was called to attend Mrs. J. L., in her sixth confinement. Although insane for the last seven years, she has borne three children, two bright, intelligent ones and a third, the subject of this paper. Her physical health has been good; but about two and a half years ago she had to be confined in an asylum until about one year since, when she returned in her usual harmless, insane condition.

This last confinement had just terminated when I arrived at her home and was told by the neighbor in attendance that it had been a breech-delivery. On inspection, the child appeared to be at full term, but was dead, as existence was an impossibility with the anomalies that presented themselves.

The head, shoulders, and arms were perfectly developed. The chest was in shape a sharp ovoid, pointing antero-posteriorly. There was complete ectopia of the heart and all the abdominal and pelvic viscera, the cord, four inches in length, having the placenta attached throughout its entire length. Evidently all the uterine contents had been expelled *en masse*. No semblance of sexual organs could be discovered, there being an absence of the pubic arch. What should have been internal organs were well developed and distinguishable, but the rectum terminated in a blind pouch. From the point of the missing pubic arch the perineum was perfectly smooth, there being no vestige of an anus.

A spina bifida, including the two lower lumbar vertebræ and a portion of the sacrum, gave rise to a tumor as large as an ordinary orange. Complete double equinovarus of the feet existed, and the legs were crossed tailor-fashion and could scarcely be made to assume any other position. The big toe projected from the left foot at a right angle like the thumb of a hand. The entire weight was six pounds. WILLIAM W. PENNELL.

FREDERICKTOWN, OHIO.

A SYMPHYSIOTOMY.

To the Editor of THE MEDICAL NEWS,

SIR: The following case of symphysiotomy has so far not been reported:

I operated on Mrs. M., August 28, 1893, after the recognized method, and extracted a fetus, alive, weighing fifteen and one-half pounds. The child lived eight days, dying, not as a result of the operation, but from severe diarrhea, from which, indeed, all of the inmates of the house suffered at the same time.

The great distention of the parts beneath the symphysis caused a laceration, beginning at the left side of the meatus urinarius, extending backward along that side of the urethra, and involving the bladder. This laceration was subsequently repaired. The patient is now well.

SEATTLE, WASHINGTON.

NEWS ITEMS.

The International Sanitary Conference, recently held at Paris, after having been in session for nine weeks, formulated conclusions which were formally agreed to by all of the participants except the representatives of Turkey and the United States. The Conference divided its labors into three branches. The first had to do with the whole question of the Mecca pilgrimage both from the East and from the Mediterranean, and it was dealt with by a "Red Sea Committee." The idea was to carry out such regulations at ports of departure, during the voyage, and on arrival in the Hedjaz, as would prevent any cholera reaching the Holy Places either from India and the Dutch Indies on the one hand, or from the basin of the Mediterranean whenever that disease prevailed in the west. Great Britain and India have willingly consented to have all intending pilgrims subjected to medical examination before starting; to maintain them under medical supervision between Indian ports and Aden, and to report the result at the latter place, where any infected vessel would be adequately dealt with; to insist on having a properly qualified medical man on board every pilgrim vessel; to increase the space allotted to pilgrims on board; and to enforce very substantial fines for any breach of a large number of regulations affecting the voyage. In return for this they claimed a diminution of restrictions in the Red Sea, and they condemned in no very measured terms the cruel and evil results following the quarantine imposed on pilgrims in the island of Camaran before disembarking at Jeddah. The result has been a decision of the Conference calling upon the Turkish Government to discontinue putting healthy vessels into quarantine, and admitting for the future only a short detention of forty-eight hours in order to examine the pilgrims and disinfect their personal effects. The Turkish Government has also undertaken to erect decent buildings on the island for the reception of the pilgrims, and also to arrange for an improved water-supply and better sanitary arrangements. Much the same arrangements have been made as to pilgrims reaching the Red Sea from the north, and the Turkish delegates have also assured the Conference that measures are now being adopted to improve the sanitary conditions of Jeddah and Mecca.

The second branch of the work of the Conference was prepared by a committee called the "Persian Gulf Committee." It proposed to transfer from Bassorah on the Euphrates to Fao at the mouth of the Shat-el-Arab, the principal quarantine-station for the Gulf, and to carry out there a system of inspection and detention under observation much on the lines of the arrangements laid down in the Dresden Convention. It was also intended to establish at different points along the Gulf a series of sanitary stations. The British and Indian delegates all along declared that this was not a route by which cholera was so likely to travel as to justify a serious hindrance to commerce; and since the scheme involved in addition a number of territorial and other allied questions, the British delegation have refused to accept the decisions of the Conference on this subject.

The third branch of the work was undertaken by a committee of "ways and means." It has decided what the Turkish Government is bound to do in return for the almost endless taxes it imposes on the pilgrims; it has set out how the Council of Constantinople should spend some of its receipts; and, above all, it has come to an almost unanimous decision that a new body is to be formed within the Council of Constantinople to administer and carry out the terms of the Convention. No country is to be represented in this body unless it has accepted the terms of the Venice, Dresden, and Paris Conventions, and thus there will be elimination of those representatives who are delegated by quarantining countries. A period of one year will elapse before the final ratification of the agreement.—*Lancet*, April 7, 1894, p. 898.

Surgical Section of the College of Physicians.—At the next meeting of the Section, to be held on Friday, May 11th, at 8 P.M., in addition to other interesting material, Dr. J. William White will read an elaborate essay on "Appendicitis." Dr. Robert F. Weir, of New York, will open the surgical and Dr. William Pepper the medical discussion, which will be continued by Drs. William W. Keen, John H. Musser, Thomas G. Morton, S. Solis-Cohen, John B. Roberts, De Forest Willard, Harrison Allen, and others.

Cholera has again made its appearance in various parts of Europe. On April 25th there were reported at Lisbon 225 fresh cases of mild type; on April 26th, 87 cases; on April 28th, 128 cases; on April 29th, 45 cases; on April 30th, 26 cases. The disease prevails also in East Galicia, in parts of Russia, and in France. It is announced that the Russian Government has erected five sanitary sations on the Austrian frontier, owing to the prevalence of cholera.

The Medical Profession in Russia.—There are said to be 18,334 practising physicians throughout the Russian empire, among a population of 110,000,000, a bout 1:6000. In the cities and larger towns the proportion is about 1:2700, while in the smaller towns and villages it is about 1:30,000, and in some of the more remote provinces it is said to be not more than 1:120,000 inhabitants.

Dr. Ludwig Pfeiffer, of Munich, has been made Professor of Hygiene in the University of Rostock.

SOME PRACTICAL POINTS IN THE TREATMENT OF DIPHTHERIA BY CALOMEL-FUMIGATIONS.[1]

BY DILLON BROWN, M.D.,
ADJUNCT PROFESSOR OF DISEASES OF CHILDREN, NEW YORK POLYCLINIC.

WHEN the true cause of diphtheria was recognized, although the constitutional treatment remained an important adjunct in counteracting the poisoning from the absorption of the toxic products of the bacilli which are present in this disease, the local treatment immediately assumed the more prominent position, and this was especially true of laryngeal diphtheria, for in the majority of these cases the danger is not from sepsis, but from the mechanical obstruction due to the presence of membrane in the larynx or the bronchi. Therefore the indications for treatment are very clear: (*a*) Destroy the bacilli and other germs which are producing the disease. (*b*) Prevent the extension of the infection by protecting any lesions which may be present in the neighboring mucous membrane, and by putting the patient in such good condition with fresh air, sunlight, good, nourishing food, and alcohol that the soil will be unfavorable for the development of the germs.

There is no mode of treatment for laryngeal disease which fulfils these indications as well as the inhalation of the fumes of subliming calomel, for not only do the fumes reach the site of the disease and destroy the germs, but they prevent all accidental lesions from being infected by protecting them with a deposit of calomel. This method has the additional advantage of preventing the sick-room from becoming saturated with the contagion, and thus being a source of the spread of the disease and of reinfection of the patient.

It is undoubtedly the best and most practical method at our command, and the credit for its conception and application is due to Dr. Job Corbin, of Brooklyn, who read his first communication on this subject before the Medical Society of the County of Kings on the evening of Tuesday, July 19, 1881, and which was published in the *Proceedings* of this Society for 1881, vol. vi, p. 153, under the title "Mercurial Fumigations in Diphtheria." Four cases are reported, all of which recovered, one after a tracheotomy and three without operative interference. The first case was treated in November, 1874, and the black oxid of mercury was used in the form of fumigation, but in all the other cases calomel was used, a half-dram every two hours. The only other published papers on this subject are by Dr. Corbin, in the *New York Medical Journal* for March 10, 1888; by Dr. George McNaughton, in *Gaillard's Medical Journal* for 1889, vol. xlviii, p. 64; Dr. George E. Law, in the *Brooklyn Medical Journal* for 1890, vol. iv, p. 525; and Drs. McNaughton and Maddren, in the *Brooklyn Medical Journal* for 1893, vol. viii, p. 457.

Since its systematic use was begun in my own practice (November, 1890) the results have greatly improved, not only in the number of recoveries after operative interference, but in the number of recoveries without intubation or tracheotomy.

This is well shown by the following summary of my cases of laryngeal diphtheria to date (March 20, 1894):

PREVIOUS TO NOVEMBER, 1890.

CASES.	
358	Intubation; no fumigations. 101, or 28.2 per cent., recovered.
44	No intubation; no fumigations. All recovered.
16	Died before my arrival.
10	Refused operation and died.
8	Died of sepsis with only slight obstruction.

SINCE NOVEMBER, 1890.

75	Intubation; no fumigations. 20, or 27 per cent., recovered.
218	Intubation; fumigations. 87, or 39.9 per cent., recovered.
6	No intubation; no fumigations. All recovered.
32	No intubation; fumigations. All recovered.
16	Died before my arrival.
9	Refused operation and died.
7	Died of sepsis with only very slight obstruction.
799	Of which 290, or 36.3 per cent., recovered.

Excluding those cases that died before my arrival, those that refused operation, and those that died of sepsis, with only slight or no obstruction in the larynx, we have left 733 cases of laryngeal diphtheria with 290, or 39.5 per cent., recoveries; of which 483 were treated without calomel-fumigations, with 171, or 35.4 per cent., recoveries; and 250 were treated with fumigations, and 119, or 47.6 per cent., recovered.

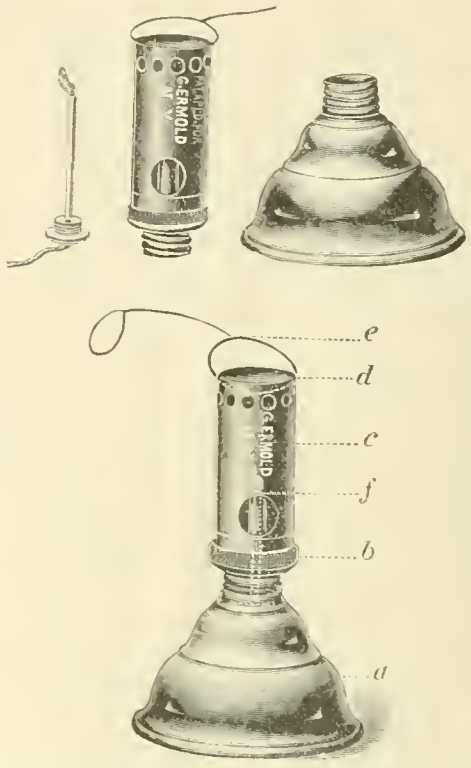
This does not by any means tell the whole story of the advantages of this mode of treatment. Under ordinary circumstances about from 8 to 10 per cent. of the cases of laryngeal diphtheria which are seen by the general practitioner make a good recovery

[1] Read before the Metropolitan Medical Society, April 25, 1894.

without operative interference, and this is such a small proportion, and after the case has developed any marked obstruction, the result is so uniformly bad, that nearly every case is seen by the consultant, if it is the custom of the attending physician to call in aid for his intubation or tracheotomy. However, since the introduction of the Corbin method the results without operative interference have improved so greatly, and the family doctor sees so many cases make a good recovery (in my own experience nearly 50 per cent.), that he is not so anxious as formerly, and besides needing aid in only half the cases, he does not send for it so early. The consultant is liable to see a larger proportion of those cases which do not yield readily to the fumigations, and a larger proportion of such cases in which the treatment is not carried out thoroughly and intelligently owing to their surroundings, or to the ignorance and carelessness of the attendants.

In this connection the statistics of McNaughton and Maddren are interesting. Reports were received from 242 physicians in different parts of the country. There were 2417 tracheotomies, showing 586 recoveries, or 24.2 per cent., and 5546 intubations, showing 1691 recoveries, or 30.5 per cent.; 505 cases of true croup were treated with the mercurial fumigations, and 275 recovered, or 54.5 per cent. Eighty-five of the 505 were operated upon after having been unsuccessfully treated by the sublimation-method. Of these, 29 recovered, thus leaving 48.7 per cent. of recoveries from the sublimation-method alone. It is worthy of note that in these statistics the percentage of recoveries in those cases first treated by the sublimation-method, and then either intubated or tracheotomized, is greater (34 1 per cent.) than that among those treated either by tracheotomy (24.2 per cent.) or by intubation (30.5 per cent.) without the sublimation-treatment. The best way to sublime the calomel is by means of the Ermold calomel-sublimer, made by George Ermold, 312 East Twenty-second street, New York. Its construction is very clearly shown by the accompanying sketches. It is very simple; it is economical, using one-third as much alcohol as an ordinary lamp, and each outfit contains three dozen ten-grain calomel tablets, which at the ordinary prescription prices would cost almost as much as the complete outfit; and it is absolutely safe, for the wick stands high above the air-holes, the heat from the chimney is cut off from the cup by a double asbestos washer, and the cup is filled with asbestos, which prevents the alcohol from escaping if the lamp is upset. The alcohol, which is vaporized, escapes along a double tube to the flame, where it is consumed.

Of course many other ways to sublime the calomel can be suggested, as putting it on a hot stove-lid or on some burning coals held on a shovel; but probably the most practical is to put the alcohol lamp in an ordinary *pot de chambre*, and over that a strip of tin or iron, on which the calomel is placed, so that the flame of the lamp comes directly below it.



The patient is put under a tent made of sheets, and the fumes of the subliming calomel are directed so as to fill the tent with a rather dense white smoke, which the child freely inhales. Ordinarily, these fumes do not cause any irritation; but if the child coughs and struggles much, the wick of the lamp may be turned down, so that the calomel will not be sublimed so rapidly. When there is much coughing and struggling, these are due either to the use of impure calomel or, more often, to fear, from lack of tact and judgment in handling the child. Most children, especially when very sick, will object to being enclosed in a tent, and they will object even more vigorously if to this is added the sight of a lot of smoke filling it, interfering with vision and causing some slight irritation when inhaled. It is often, therefore, wise to put up the tent gradually, letting first one side of the sheet down, until he gets accustomed to it, and gradually letting down the others until he is completely enclosed. Do not begin the fumigation until he is thoroughly accustomed to the presence of the tent, and often an hour wasted in the beginning of the treatment may save much trouble and inconvenience.

Be sure that the calomel is *pure* by having it freshly sublimated and washed free of the irritating impurities which are often present.

One of the best and most satisfactory tents is made by fastening to one corner of the crib or bed, or back of a chair, an open umbrella, and throwing the sheet over this; another is made by throwing the sheet over a framework made by fastening to each corner of the crib a cane or bed-slat; and still another by tacking one end of the sheet to the head of the bed and throwing the other end over a chair which is put at the foot. Many other ways readily suggest themselves, as throwing the sheet over a strong piece of string stretched across the room directly over the crib, or putting a sheet over the framework of an ordinary mosquito-bar.

In all cases of diphtheria it is well to sublime 20 grains of calomel three times daily as a prophylactic against laryngeal invasion. As soon as laryngeal symptoms present themselves 15 grains should be sublimed every one, two, or three hours, according to the progress of the disease. It ought to take from eight to ten minutes to sublime 15 grains. If the symptoms grow worse rapidly the frequency and size of the dose should be increased until at least 60 grains are used every hour. In spite of this a certain number of cases will require operative interference; but after the intubation or tracheotomy the fumigation should be continued, using for the first three days from 15 to 40 grains every hour and gradually decreasing the size and frequency of the dose, according to the indications. This must necessarily be, to a great extent, a matter of judgment and experience; but the average case that recovers will receive 20 grains by fumigation every hour for three days, and the interval will be increased one hour every day for the next three days, when it is stopped or used once or twice daily as a prophylactic, if membrane persists in the nose or pharynx. If in doubt as to what amount to use, the larger dose should always be used. I have seen many cases in which over 2000 grains have been used during the course of the disease, and the patient has recovered with few or no bad symptoms. The only cases of unmistakable bronchial diphtheria which have gotten well, in my experience, were three in which this treatment was used; in one case from 30 to 40 grains were used every hour for six days (making a total of nearly 5000 grains). The child was not affected, except by a very slight stomatitis and some weakness and anemia.

It is to be remembered that the dose is determined, not by the amount of calomel which is sublimed, but by the amount which is inhaled; therefore, even more important than the number of grains of calomel used and the rapidity of the sublimation is the size of the tent and the density of the fumes which fill the tent.

The effect on the children of such large amounts of calomel is to cause more or less prostration and anemia, occasionally a diarrhea with some abdominal pain, very rarely a stomatitis, almost never salivation, and in only one case have I seen a conjunctivitis. It is remarkable how well these children stand the fumes, while the attendants must take the greatest precautions to avoid them, or they will be quickly salivated, and they may suffer from pain and a constricted feeling in the chest.

Practically, as far as the patient is concerned, the only objection to this treatment resides in the prostration and anemia which it causes, and the occasional salivation. However, the percentage of deaths from exhaustion has not increased in my practice since its use was begun, and the percentage of recoveries has greatly increased. I believe that in a certain proportion of cases convalescence has been more or less protracted by the effects of this treatment, and I always try to counteract this as much as possible by giving a mixture containing iron, and before or after each sublimation a small dose of whiskey, brandy, or other stimulant.

The following precautions should be observed:

1. The nurses and attendants should be warned against inhaling the fumes.

2. The child's skin should be covered, so that the full effect of the fumes may be confined as much as possible to the local deposit on the mucous membrane.

3. Before each sublimation the child should be given a small dose of whiskey.

4. After each sublimation the mouth, gums, and teeth should be cleaned with a weak solution of potassium chlorate, and if the gums become sensitive they should be sponged three times a day with a mixture of equal parts of tinct. myrrh., tinct. nuc. gall., and tinct. ratanhiæ. All the re-deposited calomel should be wiped up from the furniture, etc., and the room well ventilated.

5. If the prostration and anemia seem to be greater than the local manifestations would account for, the amount and frequency of the calomel should be diminished and the stimulants increased.

6. If the nasal passages are not infected, it may be wise, especially in older children who are taking very large doses, to cut off the fumes from the nose with a loose plug of cotton or ramie in each nostril.

7. It is very important to use pure calomel that has been washed free from all irritating impurities.

SIX CASES OF APPENDICITIS.[1]

BY W. T. DODGE, M.D.,
OF BIG RAPIDS, MICHIGAN;
PHYSICIAN AND SURGEON TO MERCY HOSPITAL.

THE cases reported in this paper that were treated in Mercy Hospital were under the joint care of Dr. J. L. Burkart and myself, and we are equally entitled to credit or discredit for the results obtained.

In THE MEDICAL NEWS of January, 1891, I published a report of the cases of appendicitis that had been under my care up to that time. Since then I have seen six cases either as attendant or consultant, five of whom submitted to operation and recovered, while one died without operation:

CASE I. *Appendicitis; ulceration; abscess of three months' duration; rupture; general peritonitis; death.*—This case is interesting as illustrating the wonderful endurance of some men and the comparatively mild symptoms sometimes produced by a collection of pus in the abdomen.

T. McK. was admitted to the Mercy Hospital, March 29, 1892. He had travelled forty miles on the cars, and rode from the depot to the hospital in a hack. He complained of some abdominal pain, more particularly in the right side. There was much localized iliac tenderness and a general rigidity of the abdominal muscles. He said he had suffered from rheumatism in the right hip and leg all winter, but had been working in the woods right along until three days before, when he had a sudden, severe attack of pain in the right side, and not feeling better after two days' rest he had come to the hospital. His pulse was 76, full and strong, and his temperature was 100°. We made a probable diagnosis of appendicitis, and appointed an operation for the following day. The next morning, upon arriving at the hospital, we found the patient dead. He had not attracted particular attention until some time during the night, when he was found to be failing, and in spite of the free administration of stimulants he died at about 6 o'clock. An immediate autopsy was held, and the peritoneal cavity was discovered to be full of foul-smelling pus. Much lymph covered the intestines, showing that general peritonitis had been going on for several days at least. On the right side, behind the cecum and ascending colon, was a large abscess-cavity, extending from the cecum to the liver. The walls of this cavity were half an inch thick, and near the upper border, below the liver, a small opening connected with the general peritoneum. The sloughing remnant of the appendix, after considerable search, was found hanging from the cecum, thus indicating the origin of the trouble. The remarkable fact was thus demonstrated that this man had actually for months worked in the lumber woods with a large collection of pus in his abdomen, and had attributed the pain it produced to rheumatism. He had finally given up work, and come for treatment, when the rupture took place into the peritoneum, and even then, after a long journey, not presenting critical symptoms.

This case corroborates the contention of Dr. J. B. Murphy* (*Journal of the American Medical Association*, March 3, 10, 17, 24, 1894), that shock does not follow immediately upon the rupture of an abscess into the peritoneum, but that septic peritonitis is first developed without the occurrence of the so-called classic symptoms, and that finally, perhaps several days after the rupture, the system is overwhelmed by absorption of the products of inflammation, collapse supervenes, and death soon follows.

CASE II. *Appendicitis; ulceration of the tip; amputation of appendix; recovery.*—C. L., thirteen years of age, was a patient of Dr. Burkart, and was attended by him for several weeks before admission to the hospital. He had the usual history of pain in the right iliac region, constipation, and fever. A well-defined swelling made its appearance early, and when I first saw him, two weeks before the operation, it was about the size of a hen's egg. This proved to be a slow case in its development, the swelling at times subsiding temporarily, and the parents would not consent to an operation for several weeks. Their consent being finally obtained, the boy was removed to the hospital, and an operation performed on October 19, 1892. The appendix was easily discovered. It was much thickened and inflamed; its tip was ulcerated and firmly adherent to the adjacent intestine. There was no pus, but the tissues appeared decidedly necrotic. The appendix was ligated and removed, the parts irrigated, and a packing of iodoform-gauze introduced. Considerable suppuration followed, and the wound did not become firmly closed for several weeks. The boy has since remained well.

CASE III. *Recurrent appendicitis; numerous attacks during a period of four years; operation; separation of adhesions; appendix not removed; recovery, with no return of symptoms up to the present time.*—A. C. was admitted to the hospital November 28, 1892. He had a swelling in the right inguinal region, somewhat tender on manipulation, which he said had appeared at intervals of a few weeks for four years. Some of the attacks had been very severe, confining him to the house several weeks at a time. His bowels generally moved every day, and on admission he had no elevation of temperature, the present attack having been a mild one. Operation was advised, and consent being given it was immediately performed. The cecum and loops of the small intestine were found to be firmly bound together by adhesions. These were separated as much as possible, and some hard fecal masses in the cecum were broken up. It was impossible to separate all of the adhesions or to find the appendix, although nearly three hours was devoted to the task. At one point the cecum was very firmly adherent, the peritoneal coat giving way before we abandoned our attempt to liberate the intestine, and it is probable that the appendix was there involved. We introduced a gauze drain, and closed the abdomen, not

[1] Read before the Michigan State Medical Society, May 3, 1894.

expecting that our patient would be much benefited by our manipulations. A considerable discharge of pus occurred when the gauze was removed a few days later, and the suppuration continued several weeks, when the abdominal wound was firmly united. The lad called upon me in March, 1894, when a careful examination failed to discover the presence of any thickening in the right side, and he stated that he had no symptom of his former trouble since leaving the hospital.

Case IV. *Ulcerative appendicitis; removal of appendix; suppuration; fecal fistula; recovery.*—In August, 1892, a young man entered my office, walking with much difficulty, his body being strongly inclined to the right. He said that he had been taken sick about a week previously in Wisconsin, with intense pain in the right inguinal region; that he had been confined to his bed a few days, had then come to Big Rapids by boat and railroad, and then walked a distance of three miles to his home. There he had remained two days without treatment, and then rode to town and climbed the stairs to my office. I found a well-defined, ovoid swelling in the right inguinal region, not very sensitive to manipulation, but the seat of constant dull pain. I diagnosticated appendicitis, and recommended an operation. He was not disposed to consent to that, and I sent him home and ordered him to remain in bed, where I saw him a few times, renewing the advice for operative interference. After the third visit I received word not to come again, and a few days subsequently was invited by Dr. L. S. Griswold to see the case with him. The doctor had been called, and his advice being also for operation, the patient gave his consent, and on August 30, 1892, Dr. Griswold performed the operation, assisted by Dr. Burkart and myself. The appendix was found to be firmly adherent to the bowel, and when separated disclosed a large hole, from which an ordinary white bean protruded. Suppuration had not occurred, but would certainly have done so soon, as the tissues were in a necrotic condition. The appendix was ligated and removed, gauze drainage introduced, and the abdominal wound closed. Suppuration followed, and a few days later a large discharge of feces occurred from the wound. The fecal fistula closed spontaneously in a short time, and the patient made a good recovery.

Case V. *Suppurative appendicitis; operation; recovery.*—In January, 1893, I was called in consultation with Dr. J. T. Clark, of Stanwood, to see a young lady who had been sick for four weeks. She had at first been under the care of Dr. Brown, of Morley, and early in her sickness had been seen by Dr. Griswold. Appendicitis had been diagnosticated at that time, and operation recommended, but refused. She had been very sick, with high temperature, much pain, and obstinate constipation. Dr. Clark had given several large enemata a week before I saw the patient, with the result of removing large quantities of fecal matter and allaying many of the acute symptoms. At the date of my visit the patient was cheerful, free from pain, and believed that she was recovering rapidly. There was a large ovoid-shaped tumor in the right inguinal region, slightly sensitive to touch. I did not suspect the presence of pus, but recommended removal of the appendix. Consent was readily granted, and I performed the operation on the following day—January 11th—with the assistance of Drs. Clark, Burkart, and Bradley. On opening the peritoneum a quantity of pus immediately appeared. The cavity was washed out thoroughly, and adhesions carefully separated, and two other and larger pus-cavities were discovered. The sloughing appendix was found in one of the pus-cavities, and was ligated and removed. It contained a small, hard, fecal concretion. Thorough irrigation of the abdomen was practised, a drainage-tube introduced, and the wound closed. The patient made a rapid recovery, the after-treatment being under the care of Dr. Clark. On the seventh day the ligature that had been applied to the appendix came away, and with it a small quantity of feces. No further fecal discharges occurred, and the abdominal wound rapidly closed.

Case VI. *Suppurative appendicitis; operation; recovery.*—I saw Mrs. B., a widow, on September 21, 1893, in consultation with Dr. Darr, of Morley. She had for two or three weeks experienced uneasy sensations in her right side, had been constipated, and had noticed a swelling in the right inguinal region, but these symptoms had not been severe enough to prevent her from following her vocation or to induce her to consult a physician until the evening of September 15th, when she was in Grand Rapids, in attendance upon the Maccabee meeting in that city. She had been on her feet a good deal for several days, and on that evening had a sudden, severe attack of pain in the swelling she had previously discovered in the right side. A physician was called, who pronounced the trouble "falling of the womb," gave her an opiate, and endeavored to persuade her to remain in the city and allow him to treat the so-called womb-displacement. This she refused to do, and went to her home in Morley on Saturday morning. Almost immediately upon her arrival home the pain returned, and Dr. Darr was consulted. Symptoms of peritonitis rapidly developed; she had severe abdominal pain, tympanites, and vomiting, with high temperature. When I saw her on the following Thursday evening she had a temperature of 104°, a rapid pulse, tympanites, a highly sensitive abdomen, drawn up limbs, and an anxious expression of countenance. She was profoundly under the influence of morphin, and was said to be in great agony when not controlled by that drug. There was dulness in the right inguinal region, but no well-defined tumor could be made out on account of the general abdominal distention. Through the vagina a well-defined thickening could be distinguished on the right side. I recommended immediate celiotomy, and consent being readily granted, I performed the operation the following morning, with the assistance of Drs. Darr and Brown. A lateral incision was made, and when the peritoneum was opened we were greeted with a gush of pus, quickly followed by a loop of inflamed intestine. My finger passed at once into the peritoneal cavity. The pus was not large in amount, and was only found around the cecum, which was not walled in by

adhesions, and the general peritoneum throughout the abdomen was red and inflamed. The appendix was easily recognized and removed. It was enormously enlarged, thickened, and perforated. It will be seen by an examination of the specimen that it is as large as and much resembles in appearance a typical pus-tube. Between the mucous and peritoneal coats was found a fragment of beef-bone, which was undoubtedly the cause of the trouble. It had ulcerated through the mucous coat, and was traveling back under the peritoneum toward the bowel. It was apparent that there should have been no time spared in operating on this patient. A few more days delay and she would have been in her grave. The entire abdomen was repeatedly flushed with hot water, iodoform-gauze drainage was established, and the abdomen was closed. Convalescence was somewhat protracted, and the woman was annoyed for some time with tympanites and constipation, but recovery was ultimately complete. The after-treatment was in charge of Dr. Darr.

My experience has made me a firm advocate of early operation in all cases of appendicitis. Undoubtedly some cases recover without operation, and by operating early an occasional abdomen may be opened in which the appendix is unaffected. But this will not often occur, and need not be a serious matter when it does. It is better occasionally to open an abdomen unnecessarily than to permit a case to run the great dangers of suppuration and peritonitis. If the operation is done early, before much necrosis of tissue or suppuration has occurred, it is a comparatively harmless procedure, and the victim will be spared many long hours of suffering that the expectant plan of treatment will subject him to. I think the majority of surgeons advocate the plan of leaving the appendix *in situ* when pus is discovered, satisfying themselves with washing out the pus-cavity and packing with gauze, or introducing a tubular drain. Doubtless this procedure is sufficient in many cases, but it is not so in all. The first case I operated on—in 1882—terminated fatally, because there was more than one pus-cavity, and I did not break up the adhesions and liberate all of the pus. I cannot see how any operator can be sure that he has only one circumscribed pus-cavity to deal with, or that the appendix may not be in the condition of the specimen exhibited, unless he separates all of the adhesions and removes the offending organ. If the procedure is done with care, irrigation practised freely, and subsequent drainage established, I do not think there is great danger of general peritonitis developing. Certainly the danger is not so great if all adhesions are broken up and all pus removed, as it is if a large pus-cavity is left behind or a large suppurating appendix like this specimen is left undisturbed. To sum up, then, I am in favor of operating early in all cases of appendicitis, or suspected appendicitis, before pus forms, if possible. If, however, pus has formed, I favor careful separation of adhesions, thorough irrigation, and removal of the appendix.

CLINICAL MEMORANDA.

FRACTURE OF THE SKULL; TREPHINING; RETRO-ANTEROGRADE AMNESIA; RECOVERY; DEATH ONE MONTH SUBSEQUENTLY FROM OTHER CAUSES; AUTOPSY.

J. T. ESKRIDGE, M.D.,
OF DENVER, COL.;
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS.

SURGICAL REPORT, BY DR. ROGERS.

WILLIAM D., a passenger on a Rio Grande train coming into Denver on the night of June 7, 1893, while intoxicated, walked off the train, which was running at full speed, and was soon after missed. Upon search being made, he was found lying beside the track unconscious, with a very severe wound in the head. He was picked up and placed in the bunk of a freight caboose, where the torn scalp and exposed skull were in contact with the fittings, brought seventy-five miles into Denver, and, after he had examined the wound on the head, transferred by the police surgeon to St. Luke's Hospital. I saw him there immediately. He appeared to be perfectly conscious and stated that he had been hurt in a coal mine by an accident which had happened the day before; that his head had been slightly injured, but that he knew the injury was not severe. On being questioned more closely he stated that he had come to Denver for treatment of his own free will; that he had knowingly passed Pueblo, where the company's hospital is situated, because he did not care to be treated there. He answered every question about the journey and about the accident rationally and was quite positive that the statements he made were correct; still he was not dogmatic. His story seemed so rational and so well connected that I telephoned again to the railroad company for assurances as to how the accident had happened.

On examining the head I found that the scalp on the left side had been caught toward the front side by a backward blow, and an extended flap, triangular in shape, had torn backward. Just inside the apex of the flap was a very extensive compound fracture, also angular in shape, corresponding to the line of tear of the scalp. The depression was quite marked at the apex of this triangle, which was situated one inch in front of the sagittal suture and about three inches below the median line. Externally the two sides of the fracture diverged at an angle of about thirty-five degrees backward, and were each about two inches long. As there were no urgent symptoms I cleansed the wound

thoroughly, put on a temporary dressing, and left the patient till the following afternoon. I then trephined just beyond the apex of the fracture, so as to reach the point of greatest depression. I first removed a three-fourths inch button and then enlarged the opening so as to easily get under the inner plate, which we found depressed over a much larger area than was the external plate, the lines of fracture not corresponding in the two plates. The dura was found extensively torn, and on raising the depressed area, which was easily done, the blood flowed very freely from under the membranes through this wound. Bleeding was so free that it was not deemed wise to close the wound entirely. The scalp was replaced and closed everywhere, except immediately over the opening into the skull.

The patient's general condition was excellent. He was examined carefully before and after the operation by Dr. Eskridge, who from this time on saw him frequently with me. Dr. Eskridge's notes, given herewith, fully describe the mental phenomena which were now one of the marked features of the case.

The wound was dressed on the third day and was found doing well. On that day his temperature fell to normal and never rose above it again. The wound, which had been left open, began to close quite rapidly, but the pulsating brain could be seen at the bottom of it at all times. The patient went on without a bad symptom of any kind, and at the meeting of the State Medical Society, on June 20th, he was taken before the members and the wound exhibited. The brain could be seen pulsating over a very small area.

The patient continued to improve and apparently felt quite well in every particular until the morning of July 4th, when he was taken suddenly with a severe choleraic diarrhea. This, after a few hours, completely prostrated him. It was a form of diarrhea of which there were then many cases about the city. The patient never rallied from this prostration, but died on the 8th of July, seemingly from an entire loss of recuperative force.

On the following day a post-mortem examination was made and the conditions thoroughly examined. The wound in the skull was found completely closed, except a small orifice about a sixteenth of an inch in diameter. New bone seemed completely formed, making a translucent diaphragm across the opening. The line of fracture, both in the internal plate and in the external plate, was distinctly visible, the area of fracture in the internal plate being very much larger than that in the external. The membranes were found completely healed and showed no signs of ever having been injured, and the brain beneath was perfectly normal and healthy. The entire brain was very anemic, but no gross lesion was found.

MENTAL PHENOMENA, BY DR. ESKRIDGE.

I am indebted to the courtesy of Dr. Rogers for the privilege of studying the interesting mental phenomena of the case he has reported in this paper.

That the patient's confused mental state may be the better understood, I will first state facts in the history of the patient, especially those surrounding the accident and extending over his amnesic period, as they really occurred, and refer to his story as he gave it to Dr. Rogers on his admission into the hospital, reporting circumstances as they seemed to occur to him in his blurred conscious state; and finally, I shall try to show the relation between the real and the supposed occurrences, or the structure on which his delusions were founded.

William D., forty-six years of age, of England, single, a miner, came to Colorado fifteen years ago. His family history, so far as I was able to learn, is negative. His health during childhood was excellent, and he denied any venereal disease. He was not a "steady drinker," but indulged in alcohol to great excess periodically for a number of years. He stated that when he indulged in alcoholic liquors he did so on account of an overpowering desire for alcohol.

About June 4th or 5th an explosion occurred in the mine in which he had been accustomed to work, and several men were injured, but D. was not in the mine on the day of the explosion. On June 6, 1893, he fell in the mine and slightly injured his nose, but the next day he felt but little inconvenience from the fall. On June 7, 1893, at 10 A.M., he left Calumet, Col., on a freight train and reached Salida at 11 A.M. Between this hour and 2.45 P.M. he drank six glasses of beer. Before leaving Salida at 2.45 P.M., with two or three companions, he purchased a bottle of whiskey, and from this bottle he took three drinks before reaching Pueblo, during two or three hours' ride. After leaving Pueblo he felt a desire to urinate and went to the water-closet; but finding it closed, he went out upon the rear platform, from which he fell.

The remainder of the patient's experience on the nights of June 7th and 8th; his story, as told by himself on reaching the hospital, together with the treatment and subsequent surgical progress of the case, are related by Dr. Rogers, under whose care he remained until he died, nearly a month after his admission into the hospital.

He rode on a passenger train from Salida to Denver.

To prevent a break in the history of the case, and to save the reader the trouble of referring to the first part of this report, I shall have to repeat some things already given by Dr. Rogers.

D.'s Account of Himself a few hours after the Injury to his Head.

(For this I am entirely indebted to Dr. Rogers, who has kindly allowed me to use his notes.)

On reaching the hospital the man seemed to be perfectly conscious, and stated that there had been an accident the day before in the Calumet coal-mine, and his head had been slightly injured by a fall, but that he knew the injury was not severe and he would be all right in a few days. When asked by Dr. Rogers why he had not left the train at Pueblo and gone into the company's hospital there, he replied that "The men wanted me to do this, but I would not do it, as I preferred coming to Denver." In Dr. Rogers's own words: "He answered every question about the journey and about the accident rationally, and was quite positive that the statements he made were correct; still he was not dogmatic. His story seemed so rational and so well connected that I telephoned again to the railroad company for assurances as to how the accident had happened." He said that his head had been examined.

(It is probable that the examination here referred to was that made by the police-surgeon on his reaching Denver.) He was quite positive that he had not been on a passenger train, but had ridden all the way from Salida on a freight train. He seemed conscious of the day and the month. He stated that he had no friends in Denver, and nothing more than acquaintances in Colorado, miners with whom he had been working, and that most of his near relatives in England were dead. He appeared rational all the next day.

I saw him for the first time on June the 8th, a few minutes before the operation at 5 P.M., but I had no opportunity to inquire into his mental condition. The physical condition was as given by Dr. Rogers. Some time during the day subsequent to the operation, June 9th, he awoke, seemed confused, looked around the ward, and said, "Where am I?" On inquiry, I found that his mind was almost a complete blank. He could give no account of himself, seemed utterly bewildered, and would relapse into a semi-stupor immediately on being left alone. On June 10th, 11th and 12th, his mental condition seemed to be improving, but his answers to questions were so contradictory as to be wholly unreliable. On June 13th and 14th he was much brighter and gave a consecutive account of his early history, his occupation, and his habits; but while he appeared to respond to impressions made upon him at the time, he retained no memory of them a few minutes afterward. He was not aware that he had been injured on a train, that he had been operated upon, or that he had been in the operating-room at all, although he had been taken into the operating-room several times since his entrance into the hospital.

On June 15th he was quite bright and answered questions coherently, but he remembered absolutely nothing from the time he reached Salida until he found himself in the hospital yesterday. He did not remember yesterday afternoon that he had been in the hospital all day, but on the 15th he was conscious of having been in the hospital one entire day before the 15th. He thought he had been in the hospital longer than this, but he said he only inferred this, as he remembered absolutely nothing that occurred two days before. When he was taken to the operating-room on the 15th, he remembered that he had been in that room once before, but he could not tell when he had been there. I was informed that he had been in the operating-room on the 14th.

He gave an account of his journey in a freight car from Calumet to Salida; thought he drank something while in Salida, but of this he was not sure. He spoke of his fall in the Calmumet mine, and of the accident to his nose, of the explosion that had occurred in the mine a few days before his fall, and of the injury of several of the miners; but of his boarding a passenger train at Salida for Denver he had no remembrance.

On June 16th he was still improving, and remembered quite distinctly of drinking in Salida, but was still under the impression that he came all the way to Denver in a freight car.

On June 18th, at 8 A.M., he remembered that he had talked with a large man in the ward about mining several days ago. On inquiry of Mr. Le Strange, the man with whom he had talked, this was found to be on Tuesday, June 13th. A few hours later he remembered having had his head dressed in the operating-room the day before he had the conversation with Le Strange. At 7 P.M. of the same day (June 18th), he remembered having been in the hospital one week ago, June 11th. This fact he recollected during the afternoon, and at my evening visit he stated that he was in a certain bed on that day on the opposite side of the ward. This, on inquiry, I found to be true.

On June 20th he could give the number of drinks of beer that he drank while in Salida, and tell what he and his companions did while there from 11 A.M. till 2.45 P.M.; he mentioned purchasing a bottle of whiskey in Salida, and taking three drinks out of it before reaching Pueblo, and said the last thing which he remembered on that day, June 7th, was going to the water-closet at the rear end of the car to empty his bladder, and finding the closet occupied he went out upon the rear platform of the car. After this all was a blank. He was not positive whether he rode on a passenger or freight car from Salida to Denver, but supposed it must have been a passenger car.

His memory was carefully inquired into daily, and sometimes several times daily, from June 20th till the beginning of his fatal illness, July 4th, but nothing further was remembered by him.

Occurrences on which D.'s delusions were founded.	*D.'s delusions.*
1. An explosion in the Calumet mine in which several miners were injured on June the 4th or 5th.	1, 2 Believed that his head had been slightly injured in a mine explosion, and that he had not been severely injured by a fall from a train.
2. D.'s falling in the same mine on June 6th, and injuring his nose.	
3. Travelled from Calumet to Salida on a freight train, and drank heavily at Salida.	3. Believed he had ridden all the way from Calumet to Denver on a freight train, and that he had not been on a passenger train at all; and all his answers to questions in relation to the journey based on the belief of his having come all the way in a freight train.
4. Prejudice of the miners against the company's hospital in Pueblo.	4. He said the men wanted him to get off at Pueblo and go to the company's hospital there, but he refused, as he preferred coming to Denver to be treated.

The separate and distinct accidents—the one, the explosion in the mine in which several miners had been injured, although D. was not in the mine at the time; and the other, D.'s falling in the same mine a day or two subsequently to the explosion, by which he had injured his nose—in his confused mental condition were not separate in his own mind, and as the explosion had probably made a greater impression upon his mind in its normal condition than the trivial accident by which he had been slightly injured, he attributed his head-injury to that accident which had made the greater impression upon him at the time of its occurrence. He did not realize that he was severely injured, although the wound was in a different portion of his person than the one really received at the time of his fall, but contended that he was only slightly disabled and would be all right in a few days.

His firm belief that he had ridden all the way from the Calumet mine to Denver on a freight train, and had not travelled the greater portion of the distance, from Salida to Denver, in a passenger coach, can be accounted for either on the theory of temporary retrograde amnesia, extending back from the time of the injury to the time of his arrival in Salida on a freight train from Calumet, or from the effect of his free indulgence in beer soon after he reached Salida, thus clogging his mental powers so that he was scarcely able to distinguish the difference between a coach and a box car. That alcohol played some part in his temporary retrograde amnesia becomes the more probable when we recall to mind the fact that his actions during this period of his temporary amnesic state were the last to be recollected.

Things that were correctly remembered during his most profoundly amnesic state were events long past, as, for example, that he was born in England and that most of his near relatives were dead.

As to certain circumstances relating to his own personal condition and environments, he realized that he was a miner and that he had no intimate friends in Colorado, his only aquaintances being miners with whom he had been accustomed to labor.

The total amnesic period extended from June 7th, at 11 A.M., until June 14th, at 5 P.M. Of this period, eleven hours, from 11 A.M. until 10 P.M., are of the retrograde type, and six days and nineteen hours are of the anterograde. It is possible, and even probable, that he might have remembered something on June 14th, before 5 P.M., but at my morning visit, at 8 o'clock, he did not, and Dr. Fish, one of the hospital residents, had been unable, between my visits, to find out that he remembered anything of the occurrences of the day before. Besides this complete amnesic period shading off, both before and after the accident, there was at first a greater or less length of time during which he only remembered imperfectly. During these incomplete ante-amnesic and post-amnesic periods memory was the worse the nearer the complete amnesic state was approached in point of time, and best the longer the interval of time that had intervened between the state of complete amnesia and the time at which his memory was investigated; so that soon after the amnesia ceased to be complete, memory was only reliable for things relating to himself, such as being in the operating-room and having his head dressed, his conversation about mining, his being in the hospital ward, etc.

The permanent amnesic period began just immediately preceding his fall from the train, when he went upon the rear platform of the passenger coach, and continued until June 11th, a period of four days, all of which was of the anterograde type. During the twenty-three days that intervened between the 11th of June and the beginning of his fatal illness, July 4th, this period of complete amnesia was not encroached upon by his being able to recall a single incident that had occurred at any time of this period.

As to the manner in which D.'s memory returned for events occurring during his temporary amnesic state, it may be noted that at 8 A.M. of June 18th he remembered that some days before he had talked with a man in the ward about the Calumet mine. On inquiry of the patients in the ward I found that the conversation was held with a miner by the name of Le Strange, on June 13th, just five days before. About 12 M. of June 18th he remembered that he had been dressed in the operating-room. On looking up the records of his case I found that this occurred on Monday, June 12th, six days before. At 7 P.M. of the same day he remembered that he was in bed on the other side of the ward several days ago, and this fact came to his consciousness sometime during the afternoon. I ascertained that he had occupied a bed on the other side of the ward on June 11th.

It will be seen that for events occurring after the accident memory manifested itself first for periods furthest from the time of the occurrence of the injury to his head, and that each registration of memory was for events that had taken place, in point of time, at periods nearer and nearer the time at which he had sustained the injury. Further, the things that his memory was first able to recollect were those relating to himself, either directly or indirectly.

On examining into the manner in which the retrograde period of amnesia was obliterated it was found that he was first able to give the number of drinks of beer that he had taken in Salida, what he and his companions did while there, from 11 A.M. until 2.45 P.M., including the purchasing of a bottle of whiskey to take on the train with them. He next remembered getting into a car for Denver, but never had any distinct idea whether it was a coach or a freight car. The next day he remembered taking three drinks on his way from Salida to Pueblo. The last thing that he was able to remember occurred just a few minutes before the accident. He said that he remembered feeling a desire to urinate, going to the water-closet, finding it occupied, and then going to the rear platform.

Here again the things first remembered were most remote from the accident and those last recalled to his mind occurred just prior to it. Everything that he remembered during this period was something relating to himself. It is important to bear in mind that the thing remembered as occurring nearest to the time of the accident was something relating to his personal discomfort and means taken to relieve this.

As to the diagnosis of amnesia. If a person after coming out of an amnesic condition should be able to recall anything that took place during the time of the existence of the amnesia the memory for such occurrences seems to be, in the majority of instances, accurate and reliable; but if any portion of the events thus recollected should prove to be false, the cause for the inaccuracy, if thorough investigation is made, will be found in the environments of the subject or in the history of his acts previous to the occurrence of the accident, or other causes which produced the amnesia.

In the case just given, D. was never able to remember clearly that he came to Denver in a passenger coach and not in a freight car. The explanation of this discrepancy is found in the fact that he rode from Calumet to Salida in a freight car, and then became partially intoxicated before leaving Salida in a passenger coach for Denver.

Other things being equal, the history of this case shows that events occurring furthest from the time when the amnesia begins are remembered before things occurring in point of time more nearly related to the beginning of the amnesia. This rule seems to hold good in

all forms of amnesia, and when it is modified the cause may be found in the difference in intensity and duration of the impressions upon the individual made by the different events at the time of their occurrence.

Another point in the diagnosis of amnesia is that personal feelings, such as hunger, pain, uncomfortable sensations, and means resorted to relieve them, will be recalled more readily than mental impressions, especially those of an intellectual character. The fifth conclusion in my paper entitled "Retro-anterograde Amnesia" (*The Alienist and Neurologist*, July, 1892) is "Personal feelings and emotional states are more stable in memory than the results of the intellectual faculties."

Ribot tersely states that "feelings form the self; amnesia of the feelings is the destruction of the self."

The diagnosis of periods of complete amnesia, which remain complete and are unassociated with periods of partial amnesia, is most difficult. As a rule, such a condition is suggestive of feigning. Most persons who feign amnesia pretend to remember nothing. That states of complete amnesia, unassociated with partial amnesia, do occur I have verified in certain cases of epilepsy. Each of such cases requires a careful study.

Dr. W. P. Munn, in an editorial article entitled "Unreliability of Ante-mortem Statements," in the *Denver Medical Times*, on learning the facts in the case reported in this paper, took issue with the rule of the courts in allowing the admission of ante-mortem declarations as evidence in homicidal or murder cases.

An imaginary case might be instanced. Suppose that D. had had an altercation with someone and had in consequence received a slight wound about the face or head, and he should shortly afterward accidentally have seriously injured himself by a fall, striking his head against some unyielding substance, which produced the same amnesic condition in which D. was found on entering the hospital. Under such circumstances the altercation would have been more impressed upon his mind than the fall from which death might result, and he would naturally have attributed his wound to the blow inflicted by the man with whom he had had trouble.

At first thought this supposititious case seems to militate against the value of ante-mortem declarations. But we most remember that the law provides that an ante-mortem statement, to be of any value, must be made by the person making it, when he believes himself fatally injured, without any chance (even though that should be small) of recovery, and usually while he is in imminent danger of speedy death.

So far as my experience goes with head-injuries, all persons who have been rendered amnesic by them have regarded their wounds as slight and have expressed the belief that they would soon be all right again. I have records of some eight or ten cases of amnesia produced by injuries to the head, and in all of them the firm belief of the trivial nature of their injuries has been expressed.

Dr. Cusco, the inventor of the speculum known by his name, died recently at the age of seventy-five years. He was, early in his career, a brilliant surgeon, and he contributed to the literature of ophthalmology and gynecology.

FOUR CASES OF OPIUM-POISONING IN WHICH POTASSIUM PERMANGANATE WAS ADMINISTERED.

By WALTER L. PYLE, A.M., M.D.,
RESIDENT PHYSICIAN IN THE EMERGENCY HOSPITAL, WASHINGTON, D. C.

Having had, within the last year, a number of cases of attempted suicide by morphin-poisoning, after the publication of Dr. Moor's article in the *Medical Record*, February 17th, on the antidotal action of potassium permanganate in morphin-poisoning, a natural interest was felt to try its efficiency in our cases, which as a rule have been the least amenable to treatment of any of our emergency-cases. This, however, is generally due to the length of time after the ingestion of the alkaloid that the patient is admitted. It is of course an easy matter to rid the stomach of lethal doses of morphin within a few minutes after ingestion, and combat the subsequent symptoms, but only one who has labored with a case several hours old can appreciate the difficulty and work required to combat the effects of the absorbed poison. It was in such cases that we were particularly desirous of testing the antidote, as therein its greatest value would lie, particularly in cases of attempted suicide, in which the dose is usually taken in a locked room, or in some place not readily accessible, or in which early discovery is not likely to be made. Any remedial measure within reason is worthy of trial; in fact, one so extreme as tracheotomy and artificial respiration by means of wind-bellows should be considered advisable in a case not responding to other measures.

Through the courtesy of my chief, Dr. George Byrd Harrison, I am able to present the following cases:

Case I.—James S., a white, male clerk, fifty-seven years of age, was, at 7 A.M., April 11th, heard to go into his bath-room and return to his bed-room, and lock the door. Being accustomed to sleeping late, having recently been ill, he was not disturbed until about 1.30 P.M. After getting no response to repeated knocks on the door, his room was entered by the window, and he was found unconscious in his bed, with an empty vial of morphin-sulphate pills, gr. ⅛, by his side. A physician was hastily summoned, who administered atropin, and called the hospital-ambulance. The man was brought in about 2.30 P.M. Just how long after taking the morphin he was admitted we could not say, but as he usually arose before 9.30 A.M., we have good reason to believe that it was before that time. Assuming this correct, he reached the hospital five hours after the alkaloid was taken. He was in a state of collapse, his body cold, his face almost purple, and his pulse, heart-action, and reflexes were absent. His pupils were contracted to the size of pin-points, and altogether the case looked hopeless. The stomach-pump was employed and the gastric contents removed, and replaced with a solution of potassium permanganate, 6 grs. to 6 oz. of water. This was removed, and a similar solution re-introduced. Continued hypodermatics of strychnin to a total of gr. $\frac{1}{10}$, and atropin to gr. $\frac{1}{20}$, caffein to grs. 6, were given. Artificial respiration was practised, and the man was given several hot foot-baths, and catheterized.

The permanganate was given in the arms hypodermatically, but the enfeebled circulation rendered this, as well as all other hypodermatic administration, rather

inoperative. Faradization was tried, with no avail. About 4.30 P.M., about two hours after admission, we were somewhat encouraged by the man's condition. The conjunctival reflexes returned, as well as the reflexes of the soles of the feet. The condition remained the same, although constant friction and massage rendered the circulation more appreciable. Anal dilatation was tried, but about 9.20 P.M. cyanosis returned, respirations were abolished, and a fatal issue ensued.

CASE II.—Harry M., a white male, an ex-pugilist, twenty-two years of age, in a fit of despondency after a debauch, in which he admits having taken repeated doses of morphin sulphate, at 4.15 P.M., April 16th, took three teaspoonsful with suicidal intent. The ambulance was called shortly after he fell in the street, and he arrived at the hospital at 4.45, thirty minutes after taking the drug. Artificial respiration was practised, and hypodermatic injections of atropin were administered in the ambulance. On arrival at the hospital his respirations were shallow, and not over two a minute—virtually slight gasps. His pulse was slow and full, his pupils pin-point in size, and his face and lips cyanosed. His forehead was cold, and bore a profuse perspiration.

Artificial respiration was continued by Sylvester's method. The contents of the stomach were removed by the pump, and a solution of 6 grs. of potassium permanganate to the pint of water was introduced, and it in its turn removed and replaced by 8 oz. of a half gr. to the ounce solution. Repeated hypodermatic injections of strychnin, caffein, and atropin were given, as in the previous case. The feet were placed in pails of hot water, and then douched with cold. We then gave, hypodermatically, five injections of one grain to one ounce solution of the permangate, three in the arm and two in the leg. Friction and massage were vigorously practised, and the chest and face were alternately lashed with hot and cold towels.

After twelve minutes of this treatment the man regained consciousness, and was given a pint of strong, hot coffee. He continued well for about ten minutes, and then suddenly again became asphyxiated and cyanosed. There seemed to be a spasmodic closure of the larynx. The treatment was continued, the tongue was drawn forward and the throat cleansed. Anal dilatation was also tried. Finally a hypodermatic injection of atropin, gr. $\frac{1}{60}$, was given directly over the larynx, and some signs of respiration returned. The man gradually improved, the cyanosis disappeared, and the reflexes rapidly returned.

Consciousness was regained again after twenty minutes' vigorous treatment. The man was given 4 ounces of the solution, and this was followed by copious draughts of strong, hot coffee. As he seemed to be doing well, he was dressed, walked about, and constantly awakened, as he was about to fall asleep every other minute.

Shortly after midnight he was taken to the hospital-ward and allowed to sleep for about half an hour. During this time his respirations had been strong and full, about twelve to the minute, and after being awakened easily he was allowed to sleep all night. The next morning he felt well enough to dress himself, and complained of nothing but a little soreness and weakness, naturally resultant upon such vigorous treatment, in which the energies of the whole hospital-corps were well-nigh exhausted. On the following day he was discharged perfectly well.

Another interesting feature of this case was the sensation of intense itching which developed. This, in itself, kept him from falling asleep for quite half an hour.

CASE III.—Nettie H., a white female, twenty-five years of age, a prostitute, while on a debauch took half an ounce of laudanum with suicidal intent. The dose was taken about an hour before the ambulance was called. Meanwhile an attending physician, who was immediately summoned, had induced her to drink about two grains of the permanganate in solution, and had administered atropin sulph. gr. $\frac{1}{60}$. On admission she was cyanosed, her respirations were shallow and slow, and about eight per minute. The pupils were contracted, but not to the size of a pin-point; consciousness was lost, the pulse was slow and full, and the conjunctival reflex was present.

The stomach-pump was employed, as in the previous cases, being preferable to any emetic, particularly one of central action, which very often fails to act; indeed, apomorphin I have seen act almost identically in the same manner as morphin, producing narcosis rather than emesis.

The gastric contents were removed and replaced by 8 grs. of permanganate in ℥viii of water, slightly acidulated. Five syringesful of this solution were also given hypodermatically, and stimulants, as in the foregoing cases, were administered. After fifteen minutes of treatment the woman regained consciousness, but lapsed into stupor, attributable, no doubt, to alcoholism. She was taken to the ward, showed no dangerous symptoms, in fact, none other than those generally subsequent to a debauch, and was discharged the following day.

CASE IV.—Sadie H., a female mulatto, twenty-one years old and a prostitute, at about 9 P.M., May 3d, bought a mixture of glycerin, f℥ij, and laudanum, f℥ij, took the contents, entire, outside of the drug-shop, and fell on the street on her way home. She was picked up, placed in a carriage and brought to the hospital, arriving about fifteen minutes after taking the mixture. On admission she was unconscious; her pupils were contracted, but respiration and cardiac action were but slightly affected. The reflexes were considerably lessened. The stomach-pump was immediately employed, and the woman regained consciousness sufficiently to drink a solution containing six grains of the permanganate. Apomorphin, gr. $\frac{1}{10}$, was then given hypodermatically, and the contents of the stomach, *i. e.*, the permanganate solution, were ejected, being light-brown in color.

In a half-hour after admission the woman was well enough to be taken home in a carriage by friends, and little the worse for her dangerous experiment.

Epileptic Colonies.—At the last business meeting of the Allegheny County Medical Society, a series of resolutions was passed strongly commending the so-called colony system as the best known plan of caring for the indigent epileptics of this State. Drs. C. C. Heisman, T. M. T. McKennan, and T. D. Diller, were appointed a committee to urge the State Society at its coming meeting in Philadelphia to adopt the same resolutions, and take measures to bring the matter before the Legislature.

PATHOLOGIC NOTE.

TWO CASES OF RUPTURE OF THE ESOPHAGUS.[1]

German Hospital, Philadelphia, Pa.

SERVICE OF L. WOLFF, M.D.

[Reported by ARTHUR J. PATEK, M.D., Resident Physician.]

IT would be difficult to find a more typical case of rupture of the esophagus, with the classic symptoms pertaining thereto, than the one about to be reported. Interest is centered in this case, not because of its conforming in its symptom-complex to the requirements of the lesion; not because of rarity of occurrence, for rupture of the esophagus is not so uncommon; but because of the peculiar circumstances surrounding the case, which are more or less mysterious and leave much room for doubt and speculation.

CASE I.—F. H., a German, thirty-two years old, weighing over two hundred pounds, is said to have been a man of good habits and to have indulged freely in athletics of a mild character. Though an actor by profession, he is said to have used stimulants very moderately, more than equalizing this moderation, however, by a liberal indulgence in food. More noticeable than the quantity of food taken was the excessively rapid manner of its ingestion. The man had been, as far as it has been possible to ascertain his previous history, entirely free from any dyspeptic annoyance. None of his associates had ever heard a complaint of illness on his part, nor had he ever consulted an intimate friend of his who was a physician. Moreover, no medicine of any kind was found on his person or in his room. This unanimous expression of opinion, coming from the man's constant and intimate associates, must certainly receive some consideration in summing up the merits of the case.

On Thanksgiving day of 1893 the patient claimed never to have been in better health, and partook of a hearty dinner. An equally hearty meal was indulged in with friends in the evening, and as the man was in the habit of lunching freely between meals, it is safe to assume he may have done so on this day also. At 7.30 in the evening, while behind the scenes at the theater, he suddenly complained of a sense of fulness in the epigastrium, remarking that possibly a rich dish of which he had partaken may have disagreed with him. Very shortly thereafter he gave a distinct cough, and, a sense of nausea probably overcoming him, he inserted a finger into his mouth to induce emesis, then rushed to a basin near by, leaned over it, and in the act of vomiting cried out in German in great agony: "Something has broken. I heard it and felt it. Air! Doctor!"

The physician who was immediately summoned found the man in a state of collapse, with a feeble, running pulse, cold sweat, pallor, and suffering great agony, the pain being referred principally to the region of the stomach and back. A hypodermatic injection of morphin was administered, but gave no relief. Two hours thereafter the face and eyelids were noticed to be puffy. The patient became gradually worse during the night, suffering greatly from dyspnea and thoracic and abdominal pains. Several times fruitless attempts at vomiting were made. Urine was entirely suppressed. The patient was removed to the German Hospital at 10.30 the next morning, and was found in the following condition: Cyanosis was marked; orthopnea was profound; the pulse was almost imperceptible; the surface was cold—in fact, showing all the signs of collapse. In addition there was a noticeable puffiness of the face and eyelids, which proved to be due to interstitial emphysema. This emphysema extended down the neck as far as the clavicles, and was more marked anteriorly. He passed twenty ounces of urine, which was the first since the previous day. As the patient was in a moribund condition an accurate examination was out of the question. The signs of an extensive effusion in the left pleural cavity were, however, perfectly clear. Over the upper lobe of the left lung percussion elicited a tympanitic sound, and over the right lung there seemed to be normal resonance. The orthopnea was so intense as to preclude the possibility of a more satisfactory examination. The patient died two hours after his admission.

An autopsy was held four hours after death. With the first incision into the pleural cavity there came a gush of gas, indicating the existence of a pneumothorax. The odor emanating from the cavity was of the pungent character so peculiar to vomited matter. No gas escaped through the opening into the right chest-cavity. Upon removal of the breast-plate the left pleural cavity was found filled to fully two-thirds of its capacity with a grumous, brownish fluid, in which were floating many shreds of tissue that proved to be particles of partially masticated meat. The left lung was completely atelectatic. The right, though apparently normal in appearance and crepitant in part upon opening the chest-cavity, collapsed before its removal. It is quite likely that a small amount of pneumothorax existed here also. The pleural cavity on the left contained about three quarts of fluid, which was removed after a thorough examination had been made for the presence of a hard foreign body; the seat of rupture was then searched for.

On the left side of the cardiac extremity of the esophagus, just anterior to the diaphragm, a longitudinal rent, about one inch in length, was discovered. The finger, introduced into the opening, entered the stomach, and pressure on the stomach forced fluid matter into the pleural cavity through the rent. The esophagus, with the stomach attached, was removed. A thorough examination, macroscopic as well as microscopic, was made, with following result: The mucous membrane of the esophagus was smooth and glistening and in every respect perfectly normal; the stomach was in the same condition; the edges of the esophageal rent were clearly defined; there was no sign of ulceration of the mucous membrane, with the exception of a very small round area a quarter of an inch in diameter, opposite the line of rupture, which seemed to be devoid of epithelium. Antemortem or post-mortem maceration from contact with the gastric contents would be a sufficient explanation of this abnormality.

Rupture of the esophagus *per se* is not an uncommon accident attending pathologic conditions of this viscus. Spontaneous rupture of the esophagus is, however, so

[1] Read at the meeting of the Philadelphia Pathological Society, March 8, 1894.

rare an occurrence as to have called forth many a doubt as to the possibility of its existence. Reginald H. Fitz,[1] in an exhaustive study, collated all reported cases of spontaneous rupture of the healthy esophagus extant in medical literature, and found that since the first case (that of Boerhaave in 1724) there had been reported but eight cases, including one he reported, making a total of nine in over one hundred and fifty years. In a minute and thorough analysis of these nine cases Fitz throws out all but two—his own and that of Meyer—as instances of spontaneous primary rupture.

Zenker and von Ziemssen, in an article in Ziemssen's *Cyclopedia*, discountenance even the claim of Fitz as to the spontaneity of the two cases he reports, and give the following reasons: The normal esophagus cannot possibly be torn by the violence of its own contractions, inasmuch as the mucous membrane during contraction is more relaxed even than normally. It was shown that it required a direct weight of ten kilograms to rupture the esophageal wall when stripped of its external muscular coat, the mucous membrane alone, therefore, bearing the strain; and that the cases of Meyer and Allen, in each of which the rupture occurred in an effort to dislodge a piece of food that had become fixed in the esophagus, fall under this criticism, as the efforts at contraction could not possibly have ruptured the relaxed mucous lining, though the muscular coat have been torn, no force from without or within being, it is claimed, even a fraction of that which was successfully employed experimentally. Moreover, as the condition of the mucous membrane below the tear was in each case that described by King as the incipient stage of esophagomalacia, viz., absence of epithelium, the authors find themselves justified in concluding that all cases of so-called spontaneous rupture of the esophagus find their origin in a rapid esophagomalacia brought about by special circumstances.

It is difficult to meet the arguments of Zenker and von Ziemssen; but nevertheless several points present themselves for consideration. The experiment with which these authors wish to refute the possibility of spontaneous rupture seems an extremely fallacious one, as force exerted in the longitudinal axis of the esophagus by a dead weight is not of the same nature as that exerted in a fit of vomiting, as in the latter there is a *vis a tergo*, and consequently a momentum not experienced in the former, and a transmission of force not only longitudinally, but radially as well. Moreover, as the longitudinal muscular fibers predominate, the cohesiveness of the muscular tissue will permit the application of a greater amount of force with impunity when applied longitudinally than when exerted radially or laterally, and therefore the longitudinal rents from over-distention may readily follow the forcible ejection of a large quantity of gastric contents. There has been but one case reported in which a transverse rupture existed.

However, without granting the force of Ziemssen's argument against spontaneous rupture, it seems doubtful if even the two cases of Meyer and Allen, as reported by Fitz, can stand the test of criticism. In the case of Meyer, in which the rupture took place following efforts to remove a bolus of food, distinct reference is made to an ulcerated surface, and, more than this, there is a history pointing to an existing esophageal stricture.

The case of Allen, for which Fitz claims emphatic spontaneity, and in which the rupture was caused by the impaction of a foreign body, loses ground because of this very fact. A minute injury to the esophageal wall may have been sustained sufficient to have weakened it and permit of rupture by unsuccessful efforts at vomiting.

Since Fitz's report, three other cases of so-called spontaneous rupture of the esophagus have been reported. None of these, however, can bear criticism. The case of Dr. Tändler[1] occurred in a patient suffering from general septicemia; that of Stanley Boyd was in a patient suffering from Addison's disease, and, as is acknowledged, in view of the lack of symptoms during life, the rupture probably occurred either just before or after death. The case reported by Adams[2] was discredited by the report made upon it by the committee of the Pathological Society of London.

Though there is thus a total of thirteen reported cases of so-called spontaneous rupture of the esophagus, including the present one, it can be claimed for this that it is probably the only one not affected by any of the arguments advanced to disprove the spontaneity of such rupture. This statement is based on the fact that the patient had no illness that could in any way have had an influence on the cause of death; also, that from the presence of the classic symptoms (sudden onset, with pain and collapse, dyspnea, cyanosis, interstitial emphysema, suppression of urine) the rupture took place *intra vitam*; and that the perfectly normal condition of the esophagus and the clearly defined rent preclude the possibility of a pathologic condition prior to the accident. It may further be stated that, for these several reasons, spontaneous rupture of the esophagus is more clearly demonstrated in this case than in any previously reported.

While the case just detailed clearly illustrates rupture of the esophagus from within outward, the following case is of interest in this connection, as showing the reverse order—rupture from without inward.

Case II.—J. C., a colored man, thirty-nine years old, was admitted to the hospital on October 20, 1893. He had been married for four years, but had had no children. Only a scant history could be elicited, and what was learned had rather a negative bearing on the condition under consideration. Up to within nine months the patient's health had been good. He denied absolutely any history of syphilis. He was not given to excesses of any kind, and had worked hard at manual labor all his life. In the spring of 1893 he had had a severe cough, which persisted during the summer, though it did not prevent the man from pursuing his occupation. Two weeks prior to admission the cough had become quite aggravated, and there was much complaint of severe pain in the right side of the chest. For several days the patient was in a state of mild delirium. He applied to the Dispensary of the German Hospital for treatment of his cough, and was immediately admitted to the wards. Examination revealed the following condition: The pulse was fair in quality, and equally strong on both sides; the pupils were equal; dyspnea of

[1] American Journal of the Medical Sciences for January, 1877.

[1] Deutsche Zeitschrift f. prakt. Med., Leipzig, 1878, v, p. 63.

[2] Trans. Pathological Society, London, 1878, xxix, p. 113.

moderate severity existed. No dysphagia was complained of, though, the appetite being poor, the man restricted himself to a soft diet. The general state of health was fairly good.

On physical examination a pulsating tumor was detected on the right side of the chest, between the second and third ribs and just below the sternal insertion of the cartilages. There was a decided bulging here, though not of great degree. No bruit could be distinguished; the second sound of the heart was much accentuated; the first seemed quite normal.

One morning, ten days after admission, the patient was seen arranging his bedspread. Two hours afterward, when an attempt was made to rouse him, it was discovered that he was dead.

Upon post-mortem examination, the abdomen was found much distended, and the gastric area dull on percussion. An aneurism of the ascending arch of the aorta, corresponding to the area of visible pulsation observed before death, and containing soft clots, was found. The transverse arch appeared only slightly dilated. In the upper part of the descending aorta another aneurism was found. This was likewise filled with soft clots, and opened into the esophagus. The dilated stomach was incised in situ, and was found to contain a large blood-clot in the shape of an exact mold of the stomach. It was removed in two portions: the lower piece—a mold of the body of the stomach—was 9 inches long, 6 inches wide, and 4 inches thick; the smaller clot, which was a cast of the pylorus, measured 4 by 3 by 2 inches.

This case is particularly worthy of note, because of the dearth of symptoms, both subjective and objective, referable to the aneurism of the descending arch. In spite of the existence of two large aneurismal dilatations of the aorta, one of which was continuously encroaching upon and eroding the esophagus, no pressure-symptoms manifested themselves at any time. Even the erosion of the sternum occasioned few subjective symptoms; nor was there any dysphagia to point to the existence of a second internal tumor. Furthermore, neither pupils nor pulse presented the irregularities so commonly met with in aneurisms of the thoracic aorta.

NEW DEVICE.

A UTERINE IRRIGATING TUBE.

BY FRANCIS L. HAYNES, M.D.,
LOS ANGELES, CAL.

SEVERAL years since I devised the irrigating tube here pictured, and which has since been used by my associates and myself with great satisfaction in more than one

thousand cases. Its great merits are: (1) that it can be introduced very readily through a cervix that is but moderately dilated; (2) that it is almost impossible to obstruct the outflowing current; (3) that it is readily sterilized by the ordinary methods; (4) it is not materially affected by any antiseptic solution.

MEDICAL PROGRESS.

Primary Sarcoma in a Nine-months-old Child. — COHN (*Berliner klinische Wochenschrift*, 1894, No. 11, p. 266) has reported the case of an infant, nine months old, that came under observation on account of a swelling in the right temporal region that had been noticed for two weeks. For a week the right eyeball had been prominent and for a few days there had been vomiting. The child, though pale, appeared well nourished. The tumor was found to be attached to the bone, but not to the overlying skin; it extended anteriorly to the upper margin of the right orbit, posteriorly to the lobule of the ear; its surface was smooth and its consistence soft, in places yielding a sense of fluctuation. Further examination disclosed the presence of five additional isolated tumors, as large as cherries, behind the left ear, and one at the vertex of the skull. All appeared to have the same consistency and constitution. Puncture of the largest, however, failed to disclose the presence of fluid. On digital exploration of the mouth, the right retro-pharyngeal space appeared encroached upon. The liver extended two inches below the costal arch in the mammillary line; its surface was smooth, its margin sharp. The apex of the spleen was palpable below the left costal arch. In the depth of the right lumbar region a spherical tumor could be felt and which was separable from the liver. The urine did not contain albumin or morphologic elements. The subsequent course of the case was only noteworthy for the rapidity with which the tumors increased in size. The eye became further protruded, until its movements were greatly interfered with, and finally the cornea was lost by suppuration. The antrum of Highmore was ultimately invaded and a hard prominence became evident in the hard palate. The occipital and deep cervical glands became enlarged. The tumor in the right lumbar region increased correspondingly in size, extending beyond the middle line. A few days before death it was possible to distinguish that this mass was made up of an upper, larger, and a lower, smaller part, separated by a distinct fissure. Death took place from exhaustion, two and a half weeks after the child came under observation. Upon post-mortem examination the mass in the right lumbar region was found to consist of a homogeneous, soft, spongy neoplasm of the right adrenal body, in places whitish, in other places reddish in color, and below which was the right kidney, in the cortex of which were also multiple small new-growths. The glands around the hilus of the kidney were enlarged and coherent. The left kidney was enlarged and contained numerous nodules in the cortex and on its surface. The left adrenal, as well as the pancreas and the spleen, was normal. The liver was tilted upward and forward by the enlargement of the right adrenal. An adventitious nodule was found in the fissure for the round ligament. The surface of the left ovary presented two tiny nodules. The mesenteric glands were slightly enlarged and, on section, grayish-

red. Upon the outer aspect of the thorax, corresponding with the osteochondral junctions of the fourth, fifth, and sixth ribs on the right side, were small, pale, soft tumors. On the inner surface of all of the ribs on the right, with the exception of the first and the ninth, at the osteochondral junction, there were distinct nodular swellings, while the inner periosteal lining of the corresponding ribs was thickened diffusely and homogeneously throughout its whole extent. The thymus gland was normal. Histologic examination showed the tumor of the right adrenal body to be a medullary sarcoma, containing in part round cells, in part polygonal cells with large nuclei. In many places, under high powers of the microscope, fatty metamorphosis was distinguishable.

Non traumatic Subcutaneous Emphysema.—BROCKBANK (*Lancet*, No. 3684, p. 858) has reported the case of a youth, seventeen years old, who came under observation on account of a slight cough and of swelling of the face and chest. It was related that four days previously, on awakening, the patient had felt a pain in the left mammary region, with a point of maximum intensity about one inch outside and below the nipple. The pain was sudden in onset and not preceded by coughing. It seemed to come from the back, was sharp, and restrained breathing. After the pain had continued for some hours it was suddenly observed that the right cheek had become swollen. The breathing had by this time become difficult, and there was a desire to cough, which was restrained by the intense pain about the nipple. The left cheek soon became swollen, the eyelids a little later, and, finally, the front of the neck and the chest became involved. The patient was now suffering from great dyspnea and much distress. An incision three-quarters of an inch long was made down the center of the manubrium sterni, and air could be heard to escape. This was followed by considerable relief, but the swelling did not decrease much, and the patient felt ill and was short of breath. After a little while the swelling permanently subsided. On physical examination there was found to be impairment of the percussion-resonance at the apex of the left lung, but no abnormal auscultatory phenomena could be detected. There had been an attack of acute left-sided pleurisy eight years before, and the youth had suffered with repeated abscesses at different times. There was a family history of pulmonary tuberculosis, but tubercle-bacilli could not be found in the sputum. The first sound of the heart was impure and low-pitched at the apex; the second was accentuated. At the aortic cartilage there was a faint systolic murmur, the second sound being normal. It is believed that as a result of ulceration through a bronchus of a suppurating mediastinal gland air found its way into the subcutaneous tissues; the opening closed in a short time and the air was absorbed.

Return of Knee-jerks in Posterior Spinal Sclerosis.—At a recent meeting of the Association of German Physicians of Prague, KRAMER (*Wiener medizin. Presse*, 1894. No 11, p. 424) presented a case of progressive paralysis complicated by posterior spinal sclerosis in which after a long absence the knee-jerks had returned. Reference was also made to two other cases of the same kind that had terminated fatally and in which careful post-mortem examination failed to disclose any anatomic basis for the unusual phenomenon. In these cases the knee-jerk returns in association with apoplectiform or epileptiform attacks, or even spontaneously, remaining present for a long period, at times upon one side, at other times upon the other side, to disappear again or to continue until death takes place. The explanation offered is that with the slight amount of muscular tonus ordinarily present the few remaining intact fibers of the posterior columns are unable to complete the reflex, but that with an increase of the muscular tonus, such as occurs in connection with apoplectiform or epileptiform attacks, a tap of the patellar tendon is sufficient to induce such stimulation of the anterior horns as to bring about the reflex action.

Peptonuria.—In an extensive series of observations covering 121 cases of 49 different diseases and including 537 individual examinations, ROBITSCHEK (*Zeitschrift f. klin. Medicin*, Band xxiv, Hefte 5, 6, p. 556) found that peptonuria occurs when, as a result of some morbid process, peptone enters the blood in solution and is eliminated by the kidneys. As far as could be determined the normal puerperal state is the only physiologic condition attended with the existence of peptonuria. As a rule, the existence of peptonuria is an indication of the occurrence of tissue-disintegration in some part of the body. The manifestation is, however, of but subordinate significance, occurring, as it does, in the most varied conditions and at different stages of the same disease, without apparently influencing the ordinary course of the disease. As a symptom, however, and in conjunction without other manifestations, peptonuria may prove a valuable aid in diagnosis and prognosis—*e. g.*, being absent from meningitis and acute articular rheumatism. In the present status of the subject "pyogenic peptonuria" is the only variety to which notable significance is to be attached.

The Relative Weight of the Liver and the Spleen in Mammals.—From personal observations, together with the results of the work of other investigators, RICHET (*Archives de Physiologie Normale et Pathologique*, 5e sér., t. vi, No. 2, p. 232) has arrived at the conclusion that in the different species of mammals the volume of the liver varies with the relation between the weight of the body and the extent of exposed surface. In a general manner it may be said that the volume of the liver is proportional, on the one hand, to the extent of exposed surface when the animal is large, and, on the other hand, to the bodily weight when the animal is small. In man, and in all animals in which the liver is large in relation to the extent of exposed surface, this fact is to be explained by the necessity of increased chemic combustion to supply the deficiency due to the absence of a natural protective covering for the integument. It was found that the weight of the spleen in the various mammals is proportional to that of the body, being on an average 2 grams per kilogram, with a maximum of 3.8, in man, and a minimum of 0.54, in the rabbit.

Acute Puerperal Cellulitis and True Pelvic Abscess.—At a recent meeting of the Philadelphia County Medical

Society, DR. CHARLES P. NOBLE reported seven cases demonstrating:

1. That in the puerperal state, pelvic cellulitis and true pelvic abscess occur as the result of septic inflammation.

2. That inflammation may spread from the vagina or uterus along the pelvic lymphatics to the broad ligaments, without involving the Fallopian tubes.

3. That peritonitis can be set up by the spread of inflammation from the broad ligaments to the peritoneum, without involvement of the Fallopian tubes.

4. That very extensive pelvic exudates and intraperitoneal adhesions can be absorbed.

Toxins in the Urine during Constipation.—At the recent International Medical Congress, SPALLACI (*Le Mercredi Mèdical*, 1894, No. 15, p. 175) reported that the inoculation of rabbits and frogs with extracts obtained from the acid urine of individuals suffering with constipation of from seven to eleven days' standing, gave rise to stupor, muscular weakness, general tremor, tetaniform contractions, hypothermia, followed by hyperthermia and rapid death; phenomena more profound than those induced by the injection of extracts of urine passed in the absence of constipation.

THERAPEUTIC NOTES.

Senecio Jacobœa for Functional Amenorrhea.—Having learned that common ragwort (senecio Jacobœa) made into tea, was extensively employed in many parts of England in the treatment of various menstrual disorders, MURRELL (*British Medical Journal*, No. 1735, p. 619) prepared a 1 : 10 tincture, of which he ascertained the medicinal dose to be two drams. He also prepared a 1 : 1 liquid extract, of which he ascertained the dose to be twenty minims. He administered one or the other preparation four times daily to women suffering from menstrual derangement, and found that it answered well in cases of amenorrhea. He also used an active principle known as senecin, the minimum dose of which is two grains three times a day. It is believed that senecio aureus has an action similar to that of senecio Jacobœa. The drug was found useful in cases in which the menstrual function, having been performed regularly for some years, was suddenly suspended as the result of exposure to cold. In the majority of cases the period is not reëstablished until the drug has been taken for from ten days to two weeks, but sometimes the desired result is brought about considerably earlier. In cases in which the amenorrhea is associated with anemia senecio fails, but if after giving iron for a suitable period menstruation does not occur, senecio may answer better. Senecio answered admirably in cases of amenorrhea following parturition, when anemia was not a prominent symptom. The drug also proved useful in some cases in which menstruation had not yet been established. It is believed that senecio not only anticipates the period, but that it also increases the discharge. In many cases it relieves the accompanying pain, and not infrequently the headache from which some women suffer at such times. In one instance the administration of the drug was coincident with the disappearance of a profuse leukorrhea, from which the patient had suffered for months. The opinion is further expressed that senecio deserves to rank as an emmenagogue with potassium permanganate and manganese dioxid.

Injections of Mercuric Chlorid in the Treatment of Echinococcus of the Liver.—BLUMER (*Corresp.-Blatt für Schweizer Aerzte*, 1894, No. 7, p. 216), has reported the case of a woman who had suffered with an echinococcus of the liver for fifteen years, attended with jaundice, thirst, diuresis, itching, and emaciation. Exploratory puncture, followed by aspiration, gave exit to five and one-half quarts of a homogeneous, yellowish, emulsion-like fluid, but in the course of a few days the cyst had resumed its previous proportions, with a return of troublesome symptoms. After the lapse of several weeks the cyst was again punctured, but it could not be entirely emptied, as the canula repeatedly became obstructed by flakes. After about an ounce of fluid had been removed, five drams of a 1 : 1000 solution of mercuric chlorid were injected into the cavity of the cyst. As the swelling did not become notably reduced in size a third puncture was made, a larger trocar being employed, four quarts of homogeneous, dirty-amber fluid evacuated, and an ounce of mercurial solution again injected. The tumor, nevertheless, rapidly increased in size, but did not reach its former proportions. The general state of the patient now notably improved, and the condition gave promise of being on the way to gradual subsidence.

The Injection and Congelation of Oil for the Control of Muscular Spasm.—CORNING (*New York Medical Journal*, No. 802, p. 449) proposes for the control of troublesome muscular spasm the injection into the affected muscles of an oily substance having a solidification-point a little above the temperature of the body. The method was successfully employed in one case of violent clonic spasm of the splenius capitis muscle. The injected fluid consisted of oil of theobroma to which a sufficient amount of paraffin was added. The injection was made by means of a large syringe, armed with a stout, hollow needle, 800 minims of the fluid being used. It is recommended that the injection be made while the muscle is extended, even though it be necessary to administer an anesthetic for the purpose. The oil should be distributed as well as possible throughout the affected muscle. After the oil, made liquid by warming, has been injected, it is hardened by the application of an ether-spray or an ice-bag. Too much should not be attempted at one sitting. Supplementary injections may be made after the first at intervals of three or four days.

For Sea sickness.—

THE DIAGNOSIS OF HYSTERIA.

IT has been claimed by French observers that nations are exempt from hysteria in inverse proportion to the candor and intelligence of their medical writers. This is a sweeping assertion, so far as intelligence is concerned, because some of the nations whose medical writers state that they are exempt from grand hysteria are not devoid of intelligence, but so far as candor is concerned we are disposed to regard the claim as true. It is certain that an extraordinary prejudice and ignorance are displayed occasionally by writers in the English language, both in this country and in Great Britain, regarding both the literature and the clinical phenomena of hysteria. This has led, and still leads, to the erroneous reporting of atypical cases of the grand neurosis under artificial and inexact terms, and to the claim that such cases are "heretofore undescribed." Our American literature furnishes numerous examples of this, which if collected, digested, and critically examined would probably surprise many and convince some that our assertions here are not unfounded. We recall a recent glaring instance in which even an ordinary hysteric stigma was reported under a false title in a prominent American periodical as heretofore undescribed, whereas there exists a special French monograph on the identical subject, illustrated with numerous cases.

We are impelled to think that in Great Britain this prejudice is even more marked, and that the attitude of some writers there is that of persistently refusing to see or to be taught. We are not unmindful of the contributions of British writers to the subject of hysteria. We recall BRODIE'S classic (almost forgotten at home; nowhere so appreciated and cited as in France) and the recent contributions of PAGE and of THORBURN. But these writings only emphasize by contrast the fact that the average British writer does not, and often will not, recognize hysteria in its most palpable forms. It is within a comparatively recent period that REYNOLDS, in his *System of Medicine*, asserted that heredity has no influence in causing hysteria, and that GOWERS affected to think that hysteria in his native island was something radically different from this neurosis in France. The lack of power of systematic description, of what we may call the nosologic instinct, is especially conspicuous in writers on this subject across the sea. Their papers are confused and confusing; they lack the arrangement, the accuracy, and the convincing power that come only from a writer who has thoroughly mastered and *believes in* his subject.

We are inspired to these reflections by the perusal of a paper in the *St. Bartholomew's Hospital Reports* on "Two Cases of General Spastic Rigidity." The cases were quite remarkable, but not, as the observers appeared to think, of a kind unheard of, even in England. The first case occurred in a girl, thirteen years of age, and followed a trauma and an attendance at a "demonstration" meeting in Hyde Park. The patient had extreme spastic paralysis affecting all the muscles of the body, right-sided paresis, pyrexia for three weeks, dysphagia, dysphasia, impaired consciousness at times, loss of control over sphincters, emotional condition, whining voice, inspiratory noisy laugh, and progressive and extreme emaciation. There were no bedsores. The sensory conditions and the eye-grounds were not critically studied, nor is any note made of hysterogenous zones. There were twitchings and occasional tremor of a wide rhythm. Attempts at suggestion, hypnotism, and the use of esthesiogenic agents were not made, but reliance was placed on mercury and potassium iodid. Anorexia of a truly hysteric type was present and led to extreme wasting. The patient had a markedly neurotic

family history—an uncle and a great-aunt had been insane and the maternal grandmother was subject to "fits." The case resembled in some respects the cases of *anorexia nervosa* reported some years ago by GULL, although the authors of the paper do not recognize this fact. The conspicuous hysteric stigmata of the case must be recognized by all students who are at all familiar with the literature of hysteria, although the case is not critically reported. In view of this fact, it is curious to read the authors' comments "that at first many of the symptoms strongly suggested the idea that there was an hysterical basis for them; but the presence of fever, right-sided paresis, and wasting, with mental clouding, soon disposed of this view"(!). Hysteric pyrexia is now well recognized, and such common stigmata as right-sided paresis, and wasting, with "mental clouding," do not dispose of the view at all. No satisfactory explanation of the pathology of the case is offered, but the whole affair is left in an exceedingly doubtful and confused state.

The second case, also in a girl of thirteen years, followed the death of the patient's mother, thus illustrating the fact that the death of near relatives is a very common cause of grave hysteria in children. The onset was marked by a convulsive attack, which, as is well known, is often the immediate exciting cause of the permanent stigmata in children. Then followed, in natural sequence, stupor, paraparesis, slight nocturnal pyrexia, universal rigidity of the voluntary muscles, trismus, peculiar emotional mental state, delusions, hallucinations, insomnia, whining voice and dysphasia, inspiratory laugh, extreme emaciation, loss of control over the sphincters, absence of bedsores, increased reflexes, tremor, and sweating. Sensation, it is stated, was not affected, nor were the visual fields contracted, but considerable doubt remains as to the accuracy and thoroughness of the tests. But even discounting the absence of sensory stigmata, surely there remains in the foregoing list enough of the typical hysteric symptoms to mark the case indelibly. If it was not hysteria, what was it? Why cast doubt upon the diagnosis of such a typical case of hysteric paralysis and anorexia? Why deny to it its proper name? Why call it by another name, which is not a name, but only the label of a symptom? Why devote two pages, as do the authors, to an ineffectual and not very intelligible effort to explain the case away? We cannot answer these queries in the light of modern science. The work done in France under the guidance of CHARCOT, with its intelligibility, its reasonableness, its luminous description, its accuracy of diagnosis, its universal applicability, its successful therapy, alone furnishes the argument against, the commentary upon, and the condemnation of, all such loose, confused, and misguiding reports. The assumption by the authors that these cases were instances of some hitherto unheard-of and mysterious type of meningitis is entirely unfounded and cannot be entertained for a moment. The hint that they were, likewise mysteriously, "functional," as distinct from hysteric, is a suggestion in pathology so crude as to relegate it to the level of the ideas that marked the infancy of the science, when men talked of vapors mounting from the uterus to the brain. Finally, the assertion that the diagnosis of these cases is not clear, an assertion made by both these authors, is directly in the face of some of the most scientific clinical work of the present century, which has been done, too, within a day's journey of London.

The necessity for the correct diagnosis of hysteria transcends in importance to-day almost any other strictly clinical subject in medicine, and even in surgery. The science of diagnosis is the basis upon which rests all our medical and surgical art. The complexity of modern life, the vast increase in populations, and the corresponding increase in the neurotic element permeating all social strata, bring the subject of hysteria and the hysteric factor in disease constantly into the foreground of practice. Its insidious approach, its ubiquity, its counterfeit presentment of all other pathogenies, will continue to be observed and noted by the wise in all departments of clinical work. In this aspect, the merits of the work and the permanence of the standards of the eminent French neurologist, who has just deceased, must continue to meet an increasing recognition, and will constitute, perhaps, his most enduring hold upon fame.

THE TEACHING OF SANITARY SCIENCE IN NON-MEDICAL SCHOOLS.

REFERENCE was made in a recent number of THE NEWS to the defects in the instruction in physiology as given in common schools. The object of this instruction is essentially sanitary, as the legislation directing it was avowedly promoted by temperance organizations, with the hope that the principles thus instilled into youthful minds would

lead to abandonment of the use of alcoholic beverages. It has been unfortunate that the end has been allowed to justify the means, and that a strictly scientific presentation of the facts of physiology has not been made the requisite for the text-books adopted.

Much is expected by the promoters of such methods, and time alone will show whether satisfactory results are to be obtained; but there can be little doubt that books alone will not accomplish much, for children require to be taught and not merely given reading lessons. At a meeting of the Michigan State Board of Health, lately, DR. BAKER, well known in connection with the work of that Board, brought forward the question of establishing chairs of sanitary science in the two State schools in which teachers are educated. He pointed out that instruction in hygiene is compulsory in all schools receiving State aid, and yet no provision is made for the training of persons to carry on this instruction. The questions thus raised will very likely extend to other States, and it will be worth inquiring briefly into the plans suggested.

As regards the public schools, it must be said that the text-book is one of its familiar demons, and a dangerous one. Not only does much corruption, in a simply financial way, surround this department, but these influences operate also to endanger the merit of the works chosen. In the higher institutions not under public control, especially in medical schools in which the individualism of the instructors is best preserved, the merit of the text-book secures it a pretty fair field, but the books used by the public schools are usually selected by managing boards notoriously composed largely of persons neither highly educated nor familiar with teaching work, and the basis of selection is sometimes not safe for publication. If there is to be generally diffused instruction in sanitary science by teachers specially trained and employing text-books specially prepared, it will be by no means easy to secure a satisfactory method. There will be need of a graded series, the simplest essays being adapted to the youngest pupils.

No task in education is more difficult or more perilous than to instruct school-children in applied sciences, especially in those sciences that are not exact. The main objects of the lower schools are to train developing minds in methods of study, and to teach fundamental branches, such as language, geography, and mathematics. Upon such topics there is substantial agreement everywhere. It is expected also that schools shall have regard to morals and manners, but it is doubtful if either is much looked after. On the so-called "common branches" there is little difficulty in securing competent teachers, and little liability to erroneous teaching. All text-books on English grammar are in substantial agreement; the methods of involution and evolution are taught in pretty nearly the same manner in all arithmetics; and although atlases may differ in artistic merit and freshness of information, the essential facts of geography will be presented in all.

When, however, a progressive science is to be taught, a grave difficulty arises. New discoveries in hygiene are continually occurring, either widening our field of information or demonstrating the error of former views. It is essential that a teacher should keep in touch with these changes, and this can only be done by steady perusal of the literature of the science. Few common-school teachers, however, will give such attention, but will rely on the text-book. This, even at its highest development is sure to be behind the times, and the cheaper forms are likely to be prepared by professional school-book writers, who are mere compilers.

The institutions at which DR. BAKER suggested that normal courses in sanitary science should be given are the State Normal School and the State Agricultural College, and it is not unlikely that a demurrer will be entered to the plan to develop such teaching entirely within non-medical schools. The study of hygiene involves much medical knowledge, and sometimes requires a degree of freedom of discussion and familiarity with physiology not usual in lay-schools. It seems more logical to regard properly educated physicians as the safest instructors in this science and to discourage the general teaching of it by others. The workers in the science are almost all medical graduates, and it is to be properly studied, not by means of a single chair at some State school, but at a properly equipped institute of hygiene conducted under the auspices of a medical college.

It is hoped that the day is not far distant when the importance of systematic instruction in medical jurisprudence and sanitation will lead to the establishment at some of the better-equipped American medical schools of a comprehensive course leading to a degree in these branches, and thus develop a class of experts from which courts, and health-boards,

and school-boards may draw for competent witnesses, workers, and teachers in these fields.

Meanwhile the crude methods of instruction in hygiene, as in that of anatomy and physiology, go on in the schools, doubtless with but little practical result. The child recites in school-hours that alcohol and tobacco are injurious, and goes home to observe his parents drinking beer and his older brothers smoking. The influence of example destroys the influence of the text-book, and the harvest is uncertain.

EDITORIAL COMMENTS.

The Prevention of Tuberculosis.—There are in the City of Philadelphia (and in every large city) hundreds of families, including thousands of individuals, that receive *gratuitous* medical treatment. This service is largely rendered through the out-patient dispensaries, through dispensaries that furnish physicians for home-treatment, and through the district physicians of Bureaus of Charity. Among this class of patients are many that are tuberculous, and unable, for obvious reasons, even under the intelligent direction of the attending physician, to carry out proper measures of disinfection and prophylaxis. While there may have been justification for the desire to avoid antagonism by taking a too radical step in making obligatory the registration of all cases of tuberculosis, surely such an objection cannot be applied in connection with a class in the community confessedly without resources to adopt such measures as current knowledge concerning the diffusion of tuberculosis and other infectious diseases makes incumbent upon the individual, and in the failure of the individual upon the municipality and the State. If statistics were available, it might be possible to prove that this class includes actually the greater number of all tuberculous persons, for tuberculosis prevails most amid the conditions to which these persons are exposed: crowding, filth, want of sunshine and fresh air, vicious habits, food and clothing deficient in quantity and defective in quality, and ignorance. We wish to call attention here to dangers of such magnitude that they need be only mentioned to be realized, and to urge the notification of the Bureau of Health of all cases of tuberculosis in which proper prophylaxis and disinfection cannot or will not be carried out. These very cases illustrate, too, the need, the urgent, the immediate need, of hospitals for tuberculosis, where adequate isolation and therapeutic management can be practically carried out.

Good News from Texas.—A personal letter from Austin, Texas, brings to THE MEDICAL NEWS a message that should greatly encourage all who are enlisted in the war against quackery. Wherever one man is found with the courage to lead the fight, he will find the overwhelming majority of the profession behind him. The allies of quackery may make much noise and bluster, but they can never prevail in an assemblage of physicians. At its last annual meeting, just held, the Texas State Medical Association passed resolutions instructing the delegates to the San Francisco meeting of the American Medical Association to oppose any change in the Code of Ethics. This was almost good enough in itself, but the good men in Texas went further. On motion of DR. DAVID CERNA, of the Texas University Medical Department, Galveston, resolutions deprecating the advertising of nostrums in medical journals, and condemning the course of the *Journal of the American Medical Association* were carried after a lively debate, in which a great deal of fierce eloquence was exhausted in opposition. DR. CERNA, however, stood firm, and the motion to amend by striking out the special censure of the *Journal of the American Medical Association* was tabled, and the original resolutions passed by an overwhelming majority.

We repeat, then, that the good men are everywhere in the majority—Pennsylvania, Missouri and Texas. The American Medical Association itself has formally declared against the unholy alliance between the *Journal of the American Medical Association* and the nostrum-venders, and all that is needed to secure the final and complete triumph of the right is the courage to stand up and be counted.

Carolina Physicians and Nostrums.—We are gratified to note that our North Carolina colleagues have taken a positive stand in regard to the nostrum-question. In an admirable paper read before the Medical Society of Guilford County, DR. W. P. BEALL (*North Carolina Medical Journal*, vol. xxxiii, No. 4, p. 182) makes a cogent plea for the absolute rejection of the nostrum, and although a number opposed formal action and a few made confession, the following resolution was adopted by a large majority:

"*Resolved*, That the members of the Guilford County (N. C.) Medical Society pledge themselves to abstain from the use or indorsement of any manufactured drug or medicinal preparation which is offered directly for sale to the public, or any combination of drugs the formula of which is not submitted to our approval, and that we call upon our medical brethren throughout the country to unite in abating this growing evil which threatens our profession, both from an ethical and business point of view."

The traditions of an honorable and noble profession demand the suppression of the nostrum.

The Minority Report.—In remarkable contrast with the work of the majority of the Committee on Revision of the Constitution, By-laws, and Code of Ethics of the American Medical Association, the minority report, signed by DR. H. D. DIDAMA and published in *the Journal of the American Medical Association*, for April 21, 1894, is a straightforward, practical, scholarly and sensible production. We trust that the minority report will prevail overwhelmingly. It advises that no change be made in the Code of Ethics, and the changes that it suggests in the Constitution and By-laws all tend to improve and elevate the Association, better its work and strengthen its influence for good. The report of the majority of the Revision Committee tends to destroy time-honored safeguards against immoral and dishonest conduct, while endeavoring to avoid the revelation of overt opposition to the rules of morality and honor; but the report of the minority seems influenced only by a sincere desire to to make the Association truly representative of all that is good in the profession of medicine and openly and

irreconcilably antagonistic to all that is bad in the environments of the profession. The lines are now clearly drawn, and those who desire to preserve the good repute and honor of the profession will vote for the minority report.

SELECTIONS.

HOW TO PUT A STOP TO HEREDITARY CRIMINALITY.

On several previous occasions we have called attention to the stupidity which characterizes society's present method of dealing with habitual criminals. During the last few years the view has been steadily gaining ground that impulse to crime is an inherited taint; that the criminal is an atavistic creature no more to be blamed for his acts than the child of syphilitic parentage to be called to account for his unlovely skin, or bones, or teeth; and yet every year several hundred thousand habitual criminals, who have been convicted several times of brutal crimes, are allowed to go forth from the prisons to sow a crop of several hundred thousand children, who will be born criminals, and who will in due time prey on society, and require in turn to be imprisoned at society's expense. The whole tendency of science at the present day is to prevent rather than to go on from generation to generation treating disease. Thus have cholera, the black plague, smallpox been almost made to disappear from off the earth, and before many years we will be able to say the same of diphtheria, scarlet fever, measles, and consumption. Why should not the physician in charge of social disorders take the same preventive measures? Why go on eternally imprisoning and executing the aberrant race of criminals, when, by a simple and painless operation, an end could be put to the breed forever? Aseptic castration applied to every man or woman convicted twice of deadly assault or highway robbery, to every man convicted twice of rape or other abominable crime, would forever remove from them the power to inflict their beastly character upon thousands of innocent babes condemned from their birth to a childhood of misery and a youth of crime. There is nothing cruel or savage about the idea; for it is not to be compared with judicial murder which society fully justifies for her own protection. On the contrary, castration would be an ideal punishment, for all treatment of criminals should be directed to the sole object of preventing crime in the future rather than to have revenge for it in the past, and it would probably in most cases convert the criminal into a gentle and useful member of society. Not only would castration empty our prisons in a generation or two by the lack of supply of criminals, but even the immediate effects upon the diminution of crime in our day would be very marked, for the deterrent effect of this penalty would be even greater than the penalty of death itself. In our former article we quoted from the criminal statistics in England, showing that one criminal alone left behind him nearly one hundred descendants to occupy the prison-cells. We feel sure that this remedy has only to be more fully considered in a truly philanthropic light in order to receive the approval of our legislators and of public opinion at large. Without castration, society must, for its own protection, continue to treat cruelly and unjustly unborn generations of wild beasts in human form. It would be more merciful to them as well as to their innocent victims if the criminal class should, by the above means, forever cease to be.—*Canada Medical Record.*

AN INSCRIPTION.

According to a newspaper report, one of Allegheny's philanthropic Select Councilmen proposes to present a drinking-fountain to that fair city. As all well-regulated fountains should have an inscription, we would suggest the following:

Erected to the memory of 161 citizens who drank of this water and died of typhoid fever during the year 1893. This water is warranted to be drawn from the Allegheny River at a point where the discharges of eighteen sewers of Fittsburg are mingled with the stream, and each drop contains on an average 200 bacteria.

These 18 sewers, we might add, drain an area of 7000 acres—more than two-thirds of the entire territory of Pittsburg, exclusive of the South Side. Some of them pour their contents into the river a short distance above the influent pipes of the Allegheny water-works, while others are situated irregularly for five miles above, so that the entire volume of water must become contaminated by the Pittsburg sewers, not to mention the surface drain from upper Allegheny and the numerous towns along the Allegheny and its tributaries. The discharges from the West Penn Hospital patients find their way into the river at a point that is specially well adapted for transference into the Allegheny reservoir, and as many fever-patients are treated there during the summer and fall months, when the stage of the water in the river is usually low, the prevalence of fever and death in Allegheny is to be expected, and the source of the infection is not difficult to trace.—*Pittsburg Medical Review.*

MEDICO-LEGAL WISDOM.

The New York Medico-Legal Society has some decidedly queer legal members. One of these, ex-Judge Abram Daly, recently appeared in advocacy of a bill emasculating the medical practice act in favor of "Christian Scientists," clairvoyants, etc. He advanced the following "reasons":

If "Christian science" did not cure, at least it did no injury. It was as unjust for the legislature to say how a man should be cured as it was for a railroad company to say that a man should travel on their road. He said that one daughter of his had been cured by a clairvoyant, who had diagnosticated her case after a physician had failed. He mentioned another case, of a daughter who had died because of an incompetent physician. He was in favor of the bill because of the freedom of practice it accorded. The fighting among doctors was such that it was necessary that more freedom be had.

It is a little difficult to see how self-respecting physicians can remain members of a society which admits such aberrant intellects.—*The Medical Standard.*

Dr. Ritter v. Hacker has been made Professor of Surgery in the University of Vienna, and temporarily conducts the clinic and delivers the lectures in place of Billroth, deceased.

REVIEWS.

Operative Surgery. By Th. Kocher, M.D., Professor at the University, and Director of the Surgical Clinic at the Berne University. With 163 illustrations. 8vo, pp. 279. New York: William Wood & Co., 1894.

Although Professor Kocher's writings are wholly unknown to the vast majority of surgical readers in this country, his name has by frequent quotation become so familiar to all that a book by him carries with it no slight prestige. The present volume is a translation—by whom does not appear. Unfortunately it is a very bad translation, marred by many inelegancies of style and obscurities of expression. We judge it to have been prepared by someone ignorant of anatomy, because of the frequent use of unrecognized words and the retention of many anatomic terms that should have been rendered into the equivalents known to English-speaking students.

Notwithstanding these grave defects, this work will be found of much interest, as setting forth the methods of a man who has had a large experience and who is evidently an independent thinker, accustomed to the unquestioning acceptance of his views. Its scope is limited, embracing only the strictly manipulative part of operations, without even descriptions of instruments. Its teachings are allied to those of the modern school of German surgery.

With regard to incisions, the author lays down the general rule that they should be made along the borderlines of nerve-distributions; so that in abdominal sections, for example, he prefers keeping to the median line instead of opening along the outer margin of the rectus muscle, because in the latter case the nerves supplying the muscle are divided. Again, he insists upon following in each region certain "lines of cleavage" of the skin, along which he claims that union takes place more readily; these are set forth in elaborate diagrams. We cannot but think that such refinements of detail are shown by the daily experience of many surgeons to be needless.

It seems somewhat in contrast with this that we find ourselves advised, for the exposure and removal of tumors of the base of the skull, to divide the hard and soft palate by a median incision, and to chisel away the horizontal plate of the palate with a portion of the vomer. The expediency of any interference whatever in cases of this kind is open to doubt.

The directions given for some of the operations on the trunk are at variance with those usually accepted. Thus our author prefers a transverse lumbar incision for nephrectomy; and recommends extending it forward, opening the peritoneum, and passing in the hand, so as to determine by palpation the condition of the opposite kidney. And he says that by extending a left lumbar incision forward, the exposure of the spleen can be effected. Surely an anterior section would be for either purpose as safe, and more satisfactory. A transverse incision is prescribed for suprapubic cystotomy. For castration, the direction given is "a transverse incision along the inguinal canal one finger's-breadth above Poupart's ligament, running in a median direction downward parallel to the median third of the ligament;" or, when the testicle is adherent or the seat of larger tumors, "a transverse incision in a frontal direction at the lower end of the scrotum." We fail to see why the testicle should not be approached directly in either case; but from the diagrams it would seem that the author's ideas are correctly rendered in the text.

Very full directions are given for finding the vessels and nerves in the various regions of the body.

For amputations in the continuity of the limbs, the oval method is preferred.

On page 225 the author states that he has resected "one-half of the pelvis," with the head of the femur; and that the patient "could walk without a cane, though he limped badly." We think that the mechanism of this walking should have been very fully explained, if possible.

As a text-book for students, this book seems to us to be of little value. But the experienced surgeon will find it interesting and profitable to become acquainted with methods which are unfamiliar to him, even if he should not see reason for adopting them in preference to those which he has learned to follow.

Department of Agriculture. Eighth and Ninth Annual Reports of the Bureau of Animal Industry for the Years 1891 and 1892.

The first seventy pages of this report are devoted to a description of the workings of the Bureau for 1891. It is stated that export cattle, after having been inspected, are marked with a numbered tag in the ear, which serves for their identification. By this means every animal can be traced to the very farm on which it was fed.

In the inspection of pork microscopic examinations are made of two samples of muscular tissue from each animal, and thus protection is afforded against trichinæ.

Experiments were made with the milk of two tuberculous cows. Eight guinea-pigs were inoculated and two fed with the milk. About seven months later, when killed, the animals were in good condition, and only one pig showed tubercles. Tubercle-bacilli were found in the milk of one cow shortly before death. The autopsies on the cows showed "extensive generalized tuberculosis," but no tuberculous lesion could be detected in the udders.

These reports are interesting, as they "thus favor the position of those who maintain that tuberculosis of the udder is necessary to an infection of the milk when the disease is not too far advanced." It is stated in reference to the udder that "when the tubercles are just beginning to form it may be wholly impossible to detect their presence during life by simple palpation of the bag." No one will dispute this, for the same statement might almost be made when examining it after death, for no tissue masks small tubercles better than that of the cow's udder, and one cannot be sure of the absence of tubercles unless every portion has been examined microscopically.

In the report for 1892 Dr. D. E. Salmon has a very good account of the successful treatment of lumpy-jaw, or actinomycosis in cattle, with potassium iodid. The effects of this drug on the ray-fungus are remarkable, large lumps being removed in a short time.

The paper is concluded with concise reports of numerous autopsies and eight plates showing cuts of cattle treated.

The next one hundred and twenty-eight pages are devoted to the best paper on Texas fever that has ever been written. After an historic review, the disease is traced step by step, all statements being backed by scientific investigations. All the recent methods are utilized in the examination of the urine, blood, etc. One cannot but admire the thoroughly scientific manner in which the etiology of this disease has been elucidated. In the examination the corpuscles were enumerated at different stages of the disease, and one is astonished at the tremendous fall in the number of red blood-corpuscles; thus, at page 200, the disappearance is spoken of as being at the rate, in one case, of nearly 1,000,000 per c.mm. a day for three days. No note is made of the percentage of hemoglobin. The different forms of the microörganism found in the blood in this disease are beautifully illustrated by colored plates. This organism has been named pyrosoma bigeminum. The cattle-tick, the chief if not the sole carrier of the disease, receives careful attention. This paper on Southern cattle or Texas fever, reflects great credit on the writers, Drs. Theobald Smith and F. L. Kilbourne.

The report ends with a copy of the laws for the control of contagious animal diseases.

An Illustrated Encyclopedic Medical Dictionary. By Frank P. Foster, M.D., and Collaborators. Vol. IV. New York: D. Appleton & Co., 1894.

Upon receipt of the final volume of Dr. Foster's great work we were at once struck by the fact that the last fourteen letters (Minn.–Zyth.) of the alphabet are included in the single volume, while the first twelve letters took three equally large volumes. We regret the condensation. Only a small proportion of the operations, of the signs and symptoms of disease, of parasites, of tests, of stains, etc., are included that should have found place in an "encyclopedic" work.

We also feel compelled to regret the rigid exclusion of eponymic terms, the personal nomenclature of disease, operations, symptoms, etc. However objectionable this tendency of naming facts may be, and we are second to none in acknowledging it, the lexicographer is primarily a historian, and for the convenience of his reader he should chronicle a fact so persistently common as this one. Elsewhere the good reasons against the practice may obtain. In excluding eponymic terms, the fact itself is often excluded, as, *e. g.*, Heberden's, Parrot's, and Schmidt's nodes, Neisser's method, Murphy's button, Neale's lung, many operations, Pajot's law, etc. Schönlein's Disease is not referred to by this title either under Schönlein, Disease, or Peliosis.

We note also a few other omissions that have caught the eye: Direct and Indirect Ophthalmoscopy; Mounding of Muscle; Paradoxic Deafness, Temperature, and Knee-jerk; Mururé; Alkaline Tide and Acid Tide; Toric Lens; Toxosozin; Hypertrophic Pulmonary Osteoarthropathy; Phantom Aneurism, Stricture, and Cell; Phaneroscope; Picro-saccharimeter; Pilastered Femur; Piperazin; Pithing; Pitre's method; Peach-fever; Pocketing; Plate-culture; Weismann's theory and his terms as to heredity; Mounting and Mounting-media, etc. A typographic error occurs in the word myeloplast. The important distinction between *sanitarium* and *sanatorium* is not made. To spell septum, *sæptum*, not even noting the fact by a cross-reference, seems ultra-conservative and reactionary. It seems strange and unpatriotic to omit from the list of spirits our American friend *spiritus frumenti*. We also regret a large number of failures in the cross-references, as, *e.g.*, *Syringomyelia*. The failure to find it under the cross-references results in non-definition of the word. In the two definitions *Salvatilla Vein* is located in two different parts of the hand.

But even if such almost unavoidable errors were far more numerous than they are, we maintain that they should be pointed out in no captious or hypercritical spirit; it would be wrong to mention them except as coupled with praise and gratitude for the noble example of American scholarship offered in the work as a whole by Dr. Foster and his collaborators. The somewhat strange omission of biologic terms from among the list of "collateral sciences" may not too much detract from our praise and the congratulations we sincerely offer upon the completion of a work so highly valuable to science and so frightfully onerous to the editors. We have here, as in no other completed English word-book of the kind, a gathering of systematized medical knowledge which must long remain a gift to the profession for which we may well be proud and for which we cannot be too thankful.

Politzer's Text-book of the Diseases of the Ear and Adjacent Organs. For Students and Practitioners. Translated by Oscar Dodd, M.D., Assistant Surgeon at the Illinois Charitable Eye and Ear Infirmary; Clinical Instructor of the Eye and Ear in the College of Physicians and Surgeons, Chicago. Edited by Sir William Dalbey, F.R.C.S., M.B. Cantab.; Consulting Aural Surgeon to St. George's Hospital. With 330 original illustrations. Philadelphia: Lea Brothers & Co., 1894.

Owing to the advances made in otology during the past few years, considerable difference is to be found between this and former editions. Much of this advance is due to the labors of the author himself, and we are glad to note that he has given us the results of his investigations upon the hearing, in a considerably enlarged chapter.

In the discussion of adhesive processes attending catarrhal otitis media, the various operative procedures suggested receive full attention. While the author's experience with these, particularly those of synechotomy of the crura of the stapes, and of excision of the whole membrana tympani, with extraction of the malleus and incus, has been somewhat extensive, he wisely declines to pass judgment as to their respective merits.

Further observation is necessary to demonstrate in precisely which cases we can hope for relief through operation.

A long chapter is devoted to suppurative otitis, and mention is made of influenza as a causative factor.

Intra-cranial diseases of otitic origin receive due attention, and the main directions for surgical treatment are given.

The essential points of difference, both in course and treatment, between primary and secondary inflammation of the mastoid, are well brought out.

A short description is given of the diseases of the nose and naso-pharynx and of their influence upon aural disease.

Numerous new illustrations have been added; the arrangement is much better than in former editions, and the translation is uniformly commendable.

HOLDEN'S MANUAL OF THE DISSECTION OF THE HUMAN BODY. Edited by JOHN LANGTON, Surgeon to, and Lecturer on Anatomy at, St. Bartholomew's Hospital, etc. Sixth edition, revised by A. HEWSON, M.D., Demonstrator of Anatomy, Jefferson Medical College, etc. 311 illustrations. Small 8vo., pp. 803. Philadelphia: P. Blakiston, Son & Co., 1894.

A MANUAL for dissectors bears somewhat the same relation to a text-book on anatomy as that of a volume of clinical lectures to a didactic work on surgery. Each has its legitimate sphere, its special arrangement, and its appropriate style. Among its numerous competitors, Holden's *Manual* has always found a high place, its appreciation by students being shown by the demand for successive editions. As now issued, the book has been reduced in size by the employment of smaller type, and is thus rendered more convenient for use in the dissecting-room. We do not note any changes in the text.

While, as a rule, we are in favor of retaining the old-fashioned anatomic nomenclature, as has been done in this work, we think it would be well if the simplification of compound terms should be universally accepted, as, for instance, by dropping the word *mater*, and using only *dura* and *pia*. And, except in a very few time-honored instances, we would abandon the use of proper names in designating parts. What idea is suggested to anyone by "the valve of Hasner," or "the ampulla of Vater?" Why should the recto-vaginal pouch be called "the pouch of Douglas," or the lower end of the posterior sheath of the rectus abdominis muscle "the fold of Douglas?" Why should the student be required to burden his memory with these and like meaningless terms?

The illustrations in this work are drawn from very various sources, and are of all grades of merit, not only artistically, but as explanatory of the text.

A CLINICAL TEXT-BOOK OF MEDICAL DIAGNOSIS FOR PHYSICIANS AND STUDENTS, based on the most Recent Methods of Examination. By OSWALD VIERORDT, M.D., Professor of Medicine at the University of Heidelberg, etc. Authorized Translation, with Additions, by FRANCIS H. STUART, A.M., M.D. Third revised edition, with one hundred and seventy-eight illustrations, many of which are in colors. Philadelphia: W. B. Saunders, 1894.

THE favorable opinion we have expressed concerning previous editions of this work must be repeated in regard to the present edition. It is one of the most useful books in medical literature. The translation is not always smooth and the proof-reading is not yet perfect, for on page 142, *inspiration* is printed for *expiration*. No other error of the kind, however, was found in the course of our reading of the new edition and the drawbacks noted are, after all, slight. The peculiar value of the book lies in the fulness with which methods of examination are described, and the remarkably rich discussion of the significance of symptoms and signs, and of their association. Merely to read a page or two is an education in methods, and reference to the work for special points will always be found helpful.

A PRIMER OF PSYCHOLOGY AND MENTAL DISEASE. By C. B. BURR, M.D., Medical Superintendent of the Eastern Michigan Asylum, etc. Detroit, Michigan: George S. Davis, 1894.

THIS is the kind of a book that it is customary to damn with faint praise. It is a book of definitions. For those who need definitions in psychiatry it will be useful, and for those who are satisfied with them it will be sufficient. It is simple, intelligible, and harmless. Dr. Burr writes in his preface that "the association of the concept embarrassment and the concept commiseration, has produced the judgment to write this unambitious little book." This explains all. For those not acquainted with psychologic phraseology, it may be well to translate that Dr. Burr means to say that he has written his primer as a quiz-book for the members of a training-school class. It is a good book for its purpose.

THE YEAR-BOOK OF TREATMENT FOR 1894. A Comprehensive and Critical Review for Practitioners of Medicine and Surgery. In a series of twenty-four chapters, by eminent specialists. 12mo., pp. 497. Philadelphia: Lea Brothers & Co., 1894.

IN convenient form for ready handling and quick finding, well-indexed both as to authorities and subjects, this publication presents in well-digested articles, by authorities competent to judge and to choose, most that has been of value in the therapeutic literature of the year. The term treatment is liberally interpreted, including operative as well as medicinal measures, while bacteriology and hygiene have not been neglected. A "Selected List of New Books, New Editions and Translations" is a useful addition.

REPORT OF THE SURGEON-GENERAL OF THE ARMY TO THE SECRETARY OF WAR FOR THE FISCAL YEAR ENDING JUNE 30, 1893. 8vo, pp. 231. Washington: Government Printing Office, 1893.

THE report of the Surgeon-General deals largely with business matters, as well as with the discipline and sanitation of the army. Embodied in it there is an interesting account by Capt. L. A. Lagarde of a series of experiments as to the effects on the human frame of missiles of larger or smaller caliber, moving with greater or less velocity. This portion of the book is illustrated by fifteen plates, containing twenty figures—excellent specimens of wood-engraving.

About ninety pages are taken up with statistical tables. The composition of these, in any private printing-office, would have involved great expense. Possibly this is not a matter of consequence under the arrangements by which government work is done, but the result does not seem to us to be of such value as to justify the outlay of time and labor.

CORRESPONDENCE.

ENUCLEATION OF THE UTERUS.

To the Editor of The Medical News,

Sir: I have read with much interest the article in your Journal of May 5, 1894, by Dr. Paul F. Mundé, on the above-named subject.

It is, however, very pleasant for me to know, that to Dr. Mundé himself we owe the idea of enucleating the uterus from its peritoneal envelope, and thus reviving the old operation of Langenbeck.

In regard to the operation of Langenbeck, I will quote again from my second article (The Medical News, February 24, 1894), his description, which seems to me to show that his operation was a real enucleation.

"*Abstract of Langenbeck's method.* 'I now come to that portion of the uterus which, seen from the front, was inserted into the peritoneum as into a cloth. I also separated very accurately the substance of the uterus from the peritoneum, without cutting it, because otherwise the intestines might have protruded, and constantly drew out the uterus. I continued this separation to the upper rounded border of the fundus uteri, and then cut the uterus out of the peritoneum, in such a way that a small piece, which seemed to be perfectly healthy, remained connected with the peritoneum. This was consequently a true enucleation of the uterus out of the peritoneum, so that the latter, in connection with the vagina, formed an empty bag.' The ovaries, which Langenbeck thought he had removed, were found at the autopsy."

Dr. Mundé is perfectly correct in his statement of the difficulties of the operation in younger women, who have not reached the menopause. It is certainly a delicate piece of dissection to free the anterior surface of the neck of the uterus from its peritoneal attachments (more especially at that point which is immediately over the internal os uteri), but I venture very respectfully to dissent from the very high authority of Dr. Mundé, when he says that it cannot be done. As he justly says, my first case being in a woman of seventy-two years of age, was a very favorable one for the operation. The comparative ease with which the operation was performed on account of the relaxed condition of the peritoneal coverings probably made me more enthusiastic in advocating this method, than if my first operation had been upon a younger woman.

On February 23, 1894, I performed the same operation upon a woman, forty years of age, in whom the menstrual function was still active. The difficulties in this case, though much greater than in the first case, were not insurmountable, and the cancerous womb was successfully enucleated. The great difficulty met with in this last operation was the continual oozing of blood, which so obscured the field of operation as to render very difficult the careful dissection that is absolutely necessary in this operation.

The cardinal rules to be observed by the operator are, to use only the scissors curved on the flat, and not the knife during the operation, and to cut always toward, and never from the body of the uterus. During some portion of the time of operation an ordinary retractor was used to aid in peeling off the peritoneum from its attachments to the uterus.

I would like to refer Dr. Mundé to a paper read by Dr. John B. Deaver, before the Philadelphia Academy of Surgery, March 5, 1894, and published in The Medical News, April 21, 1894, pp. 446–448. On page 446 he says: "There is no doubt that the method of enucleation (of the uterus) is the ideal one, and should be adopted when the case is suitable for it." Further down on the same page he says (speaking of enucleation of the uterus): "I think this should be the operation of choice, in the early stages at least."

Dr. J. H. Wyethe, of Oakland, California, has kindly sent me a printed report of four cases, entitled "A New Method of Enucleation of the Uterus," and read by him before the Medical Society of the State of California, in April, 1892.

These four cases were operated upon during the years 1888 to 1890, and were all enucleations of large portions of cancerous wombs; in all these cases, however, a portion of the outer walls of the uteri was allowed to remain, so they can scarcely be called complete enucleations. The profound respect I feel for the immense experience and surgical skill of Dr. Mundé renders me very loath to differ with him in this matter. I feel compelled, however, to express my sincere conviction, which is, that in cases of cancer of the cervix uteri (especially when the disease is not too far advanced, and in old persons), the operation of enucleation of the uterus presents many and very great advantages, in the absence of shock and hemorrhage, over every other method of operation.

Respectfully,

Robert Reyburn.

HISTOLOGY OR OBSTETRICS?

To the Editor of The Medical News,

Sir: The requirements which the Committee of the Association of American Medical Colleges has decided upon seems, to say the least, very curious to me, when I see, *e.g.*, that 100 hours are required for histologic work, while I fail to see that a student should have attended half a dozen cases of labor.

Now I have spent many an hour on histologic work, but I cannot see that my patients are any better off on that account. On the other hand, every case of labor I have attended during my student-life has been of the most obvious service to my patients.

I, for my part, do not think that ever so many laboratory hours will make up for such glaring deficiencies in schools, and who would attend a school with a curriculum of four years that does not furnish such opportunities in obstetrics?

Respectfully,

Chr. Sihler.

Cleveland, O.

QUININ-IDIOSYNCRASY.

To the Editor of The Medical News,

Sir: Noticing the article of W. J. J. Paris, M.D., in The Medical News of April 14th, p. 419, I am impelled to report that I have in my practice two ladies who also suffer from an idiosyncrasy to quinin. Even grain-doses occasion much distress, with erythema, associated with severe dyspnea and other manifestations. In experi-

menting with them, I learned that by giving aromatic chalk and opium powder in combination with the quinin, no evil effects followed. My plan is to give the drug in small doses, say two or three grains, with double the quantity of the aromatic chalk and opium powder, repeated every hour or two hours until cinchonism is produced. I would cordially commend this plan in similar cases.

Respectfully,

F. W. Chitty.

Olar, S. C.

NEWS ITEMS.

The American Orthopedic Association will hold its eighth annual meeting at Washington, D. C., May 29, 30, 31, and June 1, 1894. The following program is announced:

"The Treatment of Severe Forms of Club-foot, by Edmon Owen, London. "Tarso-Clasis for Club-foot," by Nicholas Grattan, Cork. "The Abuse of Phelps' Operation for Club-foot." by James E. Moore, Minneapolis. "Phelps' Method for Talipes Varo-equinus," by H. P. Kaptyn, Abcande, Holland. "Phelps' Method for the Cure of Club-foot in Adults," by Wm. E. Wirt, Cleveland. "Phelps' Method of Treating Severe Forms of Club-foot," by Dr. Cordua, Hamburg, Germany. "The Place of Traction in the Treatment of Club-foot," by Newton M. Shaffer, New York. "Elastic Traction in the Immediate Treatment of Club-foot," by Bernard Bartow, Buffalo. "Some Observations on the Anterior Transverse Arch of the Foot and its Obliteration as a Cause of Metatarsalgia," by Joel E. Goldthwait, Boston.

"Final Results in 100 Cases for Operation of Deformities following Hip-joint Disease," by V. P. Gibney, New York. "The Treatment of Hip-disease and the Application of Lateral Traction," by Robert W. Lovett, Boston. *a*. "The Question of Priority in the Application of Lateral Traction to Relieve Intra-articular Pressure in Hip-joint Disease." *b*. "The Presentation of New Knee and Ankle Splints." *c*. "The New Improved Celluloid Corset." *d*. "An Original Operation for Wry-neck," by A. M. Phelps, New York. "Blanchard's Hip Splint," by Wallace Blanchard, Chicago. "What Results should we try to Attain in the Treatment of Hip-joint Disease," by Reginald Sayre, New York.

"Cases of Hoffa's Operation for Congenital Dislocation of the Hip-joint," by E. H. Bradford, Boston. "Lorenz's Operation for Congenital Dislocation of the Hip," by A. Lorenz, Vienna. "Congenital Dislocation of the Hip," by T. Halsted Myers, New York. *a*. "The Results in Talipes Varo-equinus after Phelps' Operation." *b*. "The Limits of Operative Treatment in Congenital Dislocation of the Hip," by Sigfred Levy, Copenhagen. "Congenital Dislocation of the Hip," by L. A. Weigel, Rochester.

"Peculiar Nervous Symptoms occurring in Pott's Disease of the Spine," by Leroy W. Hubbard, New York. "Relief of the Spondylitic Spine from the Concussion of Walking," by John C. Schapps, Brooklyn. "Spondylitis," by A. J. Steele, St. Louis.

"The Treatment of Old Neglected Cases of Deformity following Poliomyelitis," by S. L. McCurdy, Dennison. "Observations on Rachitic Distortions of the Neck of the Femur in Adolescence, and its Significance," by Royal Whitman, New York. "Infantile Apoplexy and Paralysis, and some of their Consequences," by W. J. Little, England. "The Etiology of Deformities in Knee-joint Disease," by A. E. Hoadley, Chicago. "The Care of the Bony Frame in Infancy and Childhood," by J. B. Ransom, Dannemora, N. Y.

"Diseases of the Knee-joint," by J. D. Griffith, Kansas City. "Excision of the Knee for Relief of Crippling from Infantile Paralysis," by Ap Morgan Vance, Louisville.

"The Treatment of Lateral Rotary Curvature of the Spine by Non-restorative and Developmental Methods," by B E. McKenzie, Toronto. "The Improved Machine for Treating Scoliosis," by Max Schede, Hamburg. "Scoliosis," by A. B. Hosmer, Chicago.

"Excision of the Sac in Spina Bifida," by DeForest Willard, Philadelphia.

"On the Application of the Principle of Extension in the Treatment of Wry-neck," by Mr. William Adams, London, and Mr. R. W. de Sante, London. "Lorenz Osteoclast," by F. S. Coolridge, Chicago.

"A Case of Ankylosis of the Jaw in a Child; Resection; Recovery, with Good Motion," by Dillon Brown, New York.

"Excision of the Wrist-joint by a New Method," by Herman Mynter, Buffalo. "Disease of the Shoulder-joint," by W. R. Townsend, New York. Title to be announced, by W. J. Taylor, Philadelphia. Title to be announced, by W. O. Plimpton, New York. "Fixation and Traction in the Treatment of Fractures into Joints," by Ansel G. Cook, Hartford. Title to be announced, by James Kerr, Washington, D. C.

Flat-foot. *a*. "Its Etiology and Mechanism of its Production," by Newton M. Shaffer, New York. *b*. "Pathology, Prognosis, and Mechanical and Surgical Treatment," by T. C. Morton, Philadelphia. *c*. "Gymnastic Treatment," by H. Augustus Wilson, Philadelphia. Royal Whitman, New York; Sidney Roberts, Philadelphia; J. D. Griffith, Kansas City; Roswell Park, and others will take part in the discussion.

Rachitic Deformities, *a*. "Etiology, Clinical History, and Lesions," by A. Jacobi, New York. *b*. "Its Various Manifestations, Diagnosis, Differential Diagnosis, and Prognosis," by Benjamin Lee, Philadelphia. *c*. "Mechanical and Constitutional Treatment," by Samuel Ketch, New York. *d*. "Operative Treatment," by De Forest Willard, Philadelphia.

Paralytic Deformities, *a*. "Etiology, Clinical History, and Pathological Conditions producing them," by E. H. Bradford, Boston. *b*. "Varieties, Diagnosis, Differential Diagnosis, and Prognosis," by E. G. Brackett, Boston. *c*. "Mechanical Treatment," by John Ridlon, Chicago, and Joel Goldthwait, Boston. *d*. "Operative Treatment, Paralytic and Rachitic Deformities," by DeForest Willard, Philadelphia.

The American Association of Genito-urinary Surgeons will hold its eighth annual meeting at Washington, D. C., May 29, 30, 31, and June 1, 1894. The following papers are announced:

"Modification of Bigelow's Operation for Stone in the Bladder, designed to meet Cases in which the Prostate is Enlarged," by George Chismore, of San Francisco. "The Treatment of Hypertrophied Prostate," by J. William White, of Philadelphia. "A Suggestion as to

the Best Method of Removing Fibro-adenomatous Growths from the Prostate," by Samuel Alexander, of New York City. "Report of some Cases of Rupture of the Urethra," by Francis S. Watson, of Boston. "Remarks on the Treatment of Cystitis," by Gardner W. Allen, of Boston. "Treatment of Imperfect Transition of the Testes," by Samuel Alexander, of New York City. "Aëro-urethroscopy with a New Instrument," by William K. Otis, of New York City. "New Instruments and Apparatus," by F. Tilden Brown, of New York City. "Stone in the Bladder; Choice of Operation," by William H. Hingston, of Montreal. "Urine-leakage and Stricture-formation," by John P. Bryson, of St. Louis. "The Possibility of Overcoming Permanent Stricture of the Deep Urethra without Resort to External Urethrotomy," by J. Blake White, of New York City. "The Surgical Aspect of Impotence," by Edward R. Palmer, of Louisville. "Epithelioma of the Penis," by Edward Martin, of Philadelphia. "The Hygiene of Circumcision," by W. Frank Glenn, of Nashville. "The Question of Surgical Interference in Tuberculous Kidney," by John P. Bryson, of St. Louis. "Brief Report of a Case of Cystitis and Pyelonephritis due to the Colon Bacillus, requiring Nephrectomy," by F. Tilden Brown, of New York City. "Report on Irrigation of the Bladder and Urethra without a Catheter," by George E. Brewer, of New York City. "Catheterization of the Ureters in the Male," by William K. Otis, of New York City. "Exhibition of Calculus from the Kidney," by Edmund E. King, of Toronto. "Some Infrequent Symptoms of Disease of the Urinary Tract," by Alexander W. Stein, of New York City. "The Relationship of Syphilis to Stricture of the Rectum," by Robert W. Taylor, of New York City. "Two Cases of Syphilis having a Bearing on the Question of the Period during which the Disease is Communicable," by James Bell, of Montreal. "Excision of the Initial Lesion," by Edmund E. King, of Toronto.

A general session of the Congress will be held under the direction of the American Association of Genito-urinary Surgeons, on May 31st, from 2 to 3.30 P.M. There will be discussed the question of "Nephritis in its Surgical Aspects." The discussion will open with a paper by Edward L. Keyes, of New York City, followed by a paper by George M. Sternberg, Surgeon-General United States Army, on "The Bacteriology of Nephritis," and by George Chismore, of San Francisco, L. Bolton Bangs, of New York City, and Francis S. Watson, of Boston.

The American Laryngological Association will hold its sixteenth annual congress at Washington, D. C., May 30, 31, and June 1, 1894. The following is the scientific program:

President's Address, by D. Bryson Delavan, of New York. "Nasal Polypus: Its Association with Ethmoiditis, and its Treatment by Resection of the Middle Turbinated Body," by W. E. Casselberry. "Papillary Hypertrophy of the Nasal Mucous Membrane compared with Papillary Fibroma or Papilloma," by Jonathan Wright. "The Use of Metallic Electrodes in the Treatment of Nasal and Post-nasal Disease," by Clarence C. Rice. "Observations on some of the Results of Cutting Operations on the Nasal Septum," by Thomas R. French. "Some Comments on the Surgery of the Antrum of Highmore," by W. H. Daly. "*a*. A Case of Odontoma invading the Antrum of Highmore and corresponding Nasal Fossa, with the Application of an Improved Method of Anesthesia adapted to Operations in the Mouth. *b*. A Case of Foreign Body (gold coin) engaged in the Ventricles of the Larynx," by A. W. de Roaldes. "Foreign Bodies in the Larynx, with Report of a Case," by Charles M. Shields. "Three Cases of Papilloma of the Larynx," by Charles H. Knight. "Report of a Case of Sarcoma and of one of Epithelioma of the Larynx," by Arthur Ames Bliss. "A Case of Laryngectomy by a Novel Method," by H. L. Swain. "Two Cases of Tumor of the Epiglottis," by J. Solis-Cohen. "Singers' Nodes," by F. I. Knight. "*a*. A Case of Cyst of the Larynx. *b*. Pharyngo-mycosis," by C. F. Ingals. "Exudative Pharyngitis," by W. C. Glasgow. "A Case of Sarcoma of the Tonsil," by A. W. Watson. "Importance of an Early Diagnosis of Malignant Tumors of the Throat," by J. W. Gleitsmann. "On Neurasthenic Throat, with Illustrative Cases," by W. P. Porcher. "Contribution to the Study of the Etiology of Rheumatic Affections of the Body due to Tonsillar Diseases," by H. L. Wagner.

On June 1st, at 2 P.M., in the general session of the Congress, a discussion on "The Surgery of the Accessory Sinuses of the Nose" will be conducted under the auspices of the Association by Drs. Bosworth, Bryan, Mackenzie, and Roe.

The American Physiological Society will hold its annual meeting in Washington, on May 29th, 30th, and 31st. The following papers and demonstrations are announced: "The Physiologic and Therapeutic Action of Nuclein," by V. C. Vaughan. "Remarks on the Qualitative Determination of Ptyalinogen and Pexinogen," by J. W. Warren. "Some Points on the Chemistry of Muscle," by G. N. Stewart. "Demonstration of the Effect of Calcium Salts on the Contractility of the Heart," by W. H. Howell. "Circulation Time in Organs," by G. N. Stewart. "A Study of the Volume-Changes in Muscle During Activity and Rest," by G. W. Fitz (introduced by Prof. H. P. Bowditch). "Exhibition of Plethysmographic Curves During Sleep," by W. H. Howell (for Messrs. Bardeen and Nichols). "On the Employment of Cerebral Pressure as a means of Anesthesia," by G. T. Kemp. "On the Pleuro-cardiogram and the Nature of the Cardio-pneumatic Movements," by S. J. Meltzer. Exhibition of a new Canula-coupler (modification of the old French form), by G. T. Kemp. "The Effect of Fatigue on the Rate of Transmission of Nerve-force," by H. P. Bowditch. "Preliminary Note on Cerebral Centers of the Bladder," by Isaac Ott. "Some Facts Bearing on the Action of Strychnin on the Spinal Cord," by A. R. Cushny. "On Respiratory Paths in the Spinal Cord," by W. T. Porter. "Experiments upon Reflex Vaso-constriction and Vaso-dilatation," by W. H. Howell (for Mr. R. Hunt). "Preliminary Report of Experiments on Reflex Time of Winking," by W. P. Lombard (for Mr. D. P. Mayhew). A Short-circuiting Commutator, affording making or breaking induction-shocks, by W. P. Lombard. 1. Hand-rest to be used with Ergograph; 2. Non-oxidizable Mercury Key, by W. P. Lombard (for Mr. Sidney P. Budgett.

Meetings of Philadelphia Medical Societies:

Ohio State Medical Society.	May 16–18	Zanesville, O.

The American Otological Society will hold its twenty-seventh annual meeting at Washington, D. C., on the 29th of May, in connection with the third triennial Congress of American Physicians and Surgeons. The following papers are announced: "Otitic Brain-abscess; Opening of Mastoid, Tympanum, and Skull; Evacuation of Abscess; Hernia Cerebri; Evacuation of another Abscess; Recovery," by H. Knapp. "Five Deaths following Suppurative Otitis, with Two Autopsies," by F. M. Wilson. "The Conservative Treatment of Mastoid Inflammation," by Ralph W. Seiss. "Remarks on the Treatment of Chronic Purulency of the Ear," by Samuel Sexton. "Chronic Tympanic Vertigo (so-called Ménière's Disease): its Relief by Surgical Liberation of the Stapes," by Charles H. Burnett. "The Value of Middle-ear Operations as a Means of Improving the Utility of the Organ of Hearing," by Edward B. Dench. "Statistical Studies of the Foramen of Rivinus and of the Axis of the External Meatus in their Relations to Intratympanic Surgery," by B. Alex. Randall. "An Insufflator for Applying Powder to the External Auditory Canal," by Walter B. Johnson. "Exhibition of Photographs of the Temporal Bone and Membrana Tympani," by Gorham Bacon.

Prof. J. Arnold, of Lille, an eminent French hygienist, died recently, at the age of sixty-four years, from an attack of infectious pneumonia. He contributed many papers to the literature of medicine and hygiene. His principal works were upon typhus, malaria, and pulmonary tuberculosis. He was one of the callaborators of the *Archives de Médecine*, of the *Gazette médicale de Paris*, and of the *Annales de Hygiène*. He was an ardent advocate of cremation of the dead.

ORIGINAL ARTICLES.

ACUTE APPENDICITIS.[1]

BY JOHN B. DEAVER, M.D.,
OF PHILADELPHIA.

With Remarks in Opening the Discussion.

BY J. M. DA COSTA, M.D.

HISTORY.

MORE than sixty years ago Albers, of Bonn, first described, under the name of typhlitis, localized inflammations about the cecum, of four varieties:

1. Stercoral typhlitis—stagnation of fecal matter in the cecum, with subsequent irritation.

2. Simple typhlitis—catarrhal inflammation due to a multitude of causes.

3. Perityphlitis—extension of the inflammation of the mucous membrane to the external coat of the cecum and the surrounding parts.

4. Chronic typhlitis.

Previous to 1820 Dupuytren recorded observations calling attention to the connection between abscess of the right iliac fossa and disease of the cecum. In 1827, Husson and Dance described the disease more in detail. In 1824, Louyer and Villermay gave the first description of a fatal peritonitis due to perforation of the appendix. Melier, in 1827, reported four cases, three of which were cases of perforative appendicitis with fulminating peritonitis; the other a case of relapsing appendicitis. He laid especial stress upon two distinct symptoms in the perforative cases, namely, more or less severe abdominal colic and fixed pain localized in the right iliac fossa. Melier not only described the causes, character, and consequences of appendicitis, but foresaw the possible advantages of operation in this affection. He says: "If it were possible to establish with certainty the diagnosis of this affection, we can see the possibility of curing the patient by an operation. We shall, perhaps, some day arrive at this result."

Subsequent memoirs of Ménière and Albers, advancing the notion that the lesions occupied the cellular tissues of the right iliac fossa, caused Melier's theories to be lost sight of. Later memoirs of Bodart, Favre, Forget, and of Leudet, added new facts to those established by Villermay and Melier.

Thus little by little the view that the grave and fatal forms of typhlitis are due to perforation of the appendix gained ground, and that the benign and curable forms are due to an inflammation of the cecum and the cellular tissues which surround it. The theory still counts a few advocates, but fortunately they each year grow fewer and fewer. This much-vexed question has been restored to the status to which Melier had advanced it by the surgeons and physicians of the United States. They have demonstrated by early operation that inflammation of the right iliac fossa is invariably due, primarily, to disease of the appendix vermiformis.

Hancock, in 1848, operated upon one case, and advocated early operation. This met with no encouragement. In 1867, Willard Parker, of New York, first proved that early operation would save 75 per cent. of the cases. Dr. R. F. Noyes, in 1883, reported 100 operations, 90 per cent. of which had been performed in America.

An article in the *American Journal of the Medical Sciences*, by Reginald Fitz, published in 1886, "On Perforative Inflammation of the Vermiform Appendix," marks the epoch of the present status of this much-discussed trouble. Fitz collected 209 cases of typhlitis and perityphlitis, and 257 cases of perforative appendicitis. His conclusions have been summarized by Talamon as follows: "He showed that the symptoms are the same in the latter as in the former class of cases. He studied with care the consequences of perforation. He established the fact that the peritonitis is not always generalized, but that it may be circumscribed under the form of an encysted purulent collection. He gave the characters of the tumor formed by this localized peritonitis, the different modes of the evacuation of the pus, the complications that may supervene if the disease is left to itself. He insisted on the frequency of fecal concretions as a cause of perforation of the appendix. He concludes in favor of early surgical interference."

In a second paper published by Fitz, in 1888, he advanced the radical but sound theory that the diseases described as typhlitis, perityphlitis, paratyphlitis, appendicular peritonitis, and perityphlitic abscess, are all varieties of one and the same affection, namely, appendicitis.

ANATOMY.

The vermiform appendix is a narrow musculomembranous tube ending in a blind extremity, and

[1] Read before the College of Physicians, May 2, 1894.

is the atrophied remnant of the elongated cecum. It is present in man and in some of the higher apes only. The elongated cecum persists in other mammalia. It is attached to the inner and posterior wall of the cecum, the point which originally was its apex.

The appendix may arise from the apex of the cecum, be a direct linear continuation of the colon, and thus afford an example of the fetal type. It may arise from the lower end of the cecum, under which ciscumstances it is unequally divided by the anterior longitudinal band, that portion to the right of the band being larger, while that to the left, though smaller, constitutes the true apex of the cecum. This is the type of cecum usually found when there is an increased development of the anterior wall, which rotates the apex posteriorily and to the left, thus bringing it into close relation with the ileo-cecal junction. Finally, it may arise from the lower end of the cecum, appearing between two bulging sacculi and posterior to the inferior angle of junction of the ileum with the cecum.

In cases of non-descent of the cecum the appendix will hold a corresponding abnormal position, when it may lie to the left of the median line. Lennander mentions the case of a boy of sixteen, in which the cecum and the appendix, which was nine inches long, were found lying against the spleen in the left hypochondriac region.

The length of the appendix varies from one to nine and a half inches, the average being four inches. When the appendix is long, the cecum as a rule is small. Its diameter is that of a goose-quill or about as thick as a large earthworm (Holden). The appendix is hollow and has an opening of communication with the cecum, which is usually guarded by a valve of mucosa.

The left or under layer of the mesentery joins with the serous covering of the appendix, which may be complete or incomplete, forming the mesentery of the appendix or the meso-appendix. In the majority of instances the appendix has a peritoneal covering throughout its entirety. When only a portion of the appendix is included in a peritoneal investment, it is the base or root that is destitute. The root of the appendix being uncovered makes this part of the organ extraperitoneal. If perforation should take place with this disposition of peritoneum, we can clearly see how infection of the postperitoneal connective tissue would occur and result in the formation of an abscess which would be extraperitoneal. Perforation of the appendix between the layers of the meso-appendix would cause infection of the postperitoneal connective tissue.

The meso-appendix is triangular in shape, the base corresponding to the free margin, and the sides to the appendix and the mesentery. It is attached to the proximal one-third or two-thirds of the appendix, leaving the tip free, or it may be attached along its entire length, as I have usually found it. Sometimes it may be altogether absent or exist in so slight a degree as to be practically absent.

It consists of two layers of peritoneum between which run the appendicular artery and vein, and the lymphatics, in addition to some fat. Occasionally the meso-appendix contains a considerable amount of fat which, when operating for its removal, renders it more liable to be torn in the delivery of the appendix. The mobility of the appendix depends upon the extent of the attachment and the width of the meso-appendix.

The meso-appendix may have a hole in it through which the small intestine has been known to herniate and become strangulated. The iliac vessels have been known to pass through the layers of the meso-appendix. In the female it has a prolongation which is lost in the broad ligament; this is described by Clado as the appendiculo-ovarian ligament.

The shape of the appendix varies in accordance with the length of the meso-appendix. When it is short the appendix will present an abrupt curve. If the meso-appendix is shortened in several places it may present a corkscrew shape.

The appendix will occupy one of eight positions in the majority of all cases. Dr. Bristow suggests a very simple method of classification of the positions and directions of the appendix. It consists in locating a central point in the right iliac fossa which represents the attachment of the appendix in its most common position. From this central point are drawn lines radiating in eight different directions. Fowler has modified this method by substituting the initial letters of the points of the compass for the numbers. The central point is located by drawing a line from the anterior superior spine of the ilium to the umbilicus. A point on this line from two to two and one-half inches within the anterior spine will correspond to this central point.

The appendix may occupy either of the ileo-cecal fossæ, more likely the inferior or the sub-cecal fossa. In the event of its occupying the two latter fossæ, it would sometimes constitute a retroperitoneal hernia of the appendix. Again, if it should occupy one of these fossæ and the mouth of the fossa close over it, it might be regarded by the operator as being absent. Suppuration due to inflammation of the appendix so walled in would be circumscribed. Other abnormal positions of the appendix are met with, namely: (*a*) when it lies behind the peritoneum, below the cecum and adherent to its under surface, in contact with its muscular wall, and

covered by the peritoneal coat of the cecum; (*b*) adherent to the peritoneum along the right border of the cecum and ascending colon; or (*c*) adherent to the peritoneum at any point in the neighborhood of the cecum; and (*d*) in the inguinal canal.

When the appendix lies postcecal and postcolic, suppuration, the result of appendicitis, may simulate a lumbar or a perinephric abscess.

The normal positions of the appendix are five:

1. When it lies under the inferior layer of the mesentery directed toward the spleen.

2. When it lies on the ileo-pectineal line or projects into the pelvis. In this position it may become adherent to the bladder. Only in this position is rectal examination of value.

3. When there is a long meso-appendix, it may lie to the right of the cecum and the ascending colon, running upward parallel to the colon over the kidney and toward the right lobe of the liver.

4. When it lies in front of the colon and cecum.

5. When it lies under the cecum.

Usually the width of the meso-appendix accounts for the other three positions by allowing more motion to the organ.

ETIOLOGY.

The theory that appendicitis is due to a foreign body in the appendix—for example, seeds, pits of the smaller fruits, pins, buttons, etc.—has been accepted etiologically in a certain proportion of cases, and fecal concretions for the balance. Recent writers upon this subject have taken exception to this theory, basing their arguments on the fact that cases of appendicitis, with or without perforation, have occurred in which no foreign body could be found. They also present cases in which normal appendices have been found, while performing abdominal section for other conditions, as well as in post-mortem reports, in both of which fecal concretions or inspissated mucus was contained within the appendix without evidences of inflammation, and when there had been no history of symptoms of appendicitis. In every case of appendicitis these observers have demonstrated the presence of the bacterium coli commune in pure cultures or associated with pyogenic organisms. They have grown pure cultures of this bacterium from the walls of an inflamed appendix in which perforation had not occurred, and have also grown pure cultures from the interior of the appendix, and from the pus of an appendicular abscess. This bacterium is normally found within the colon and the appendix; still it has been proved that under favorable conditions—as, for example, inflammation of the appendix—it takes on pathogenic and pyogenic properties. The bacterium coli commune has been grown in pure cultures, or associated with other pyogenic microörganisms, from the exudate of peritonitis, from the pus of a septic pneumonia following a perforative general peritonitis, and also from the spleen and liver of such cases.

From the number of cases in which I have found foreign bodies, it is my judgment that in the majority of cases of perforative appendicitis there is a direct relation between the presence of the concretion and the other causative agents. From the fact that so many cases of appendicitis follow so closely upon the ingestion of improperly masticated and hastily swallowed indigestible food, I cannot help thinking that there is a direct relation of cause and effect between them.

I would classify the causes of appendicitis under two heads—predisposing and exciting.

Predisposing Causes.—*Age.* 15 per cent. of all cases occur under fifteen years of age, but the disease is most common between the ages of ten and thirty. The earliest stage in which I have met with the disease was in a child under two years.

Sex. Males are more prone to the disease than females.

Constipation, from its tendency to provoke catarrhal inflammation.

Tuberculosis, when secondary to the involvement of the cecum. Should the disease be most pronounced in the appendix, it is likely to be followed by a result similar to that of acute perforative appendicitis. The appendix being a rudimentary organ, and therefore of lower vitality than the cecum, is more likely to suffer from pathological processes.

By far the most frequent cause is a *previous attack*, a history of which cannot always be obtained on account of its mild character.

Exposure to cold and wet. I have met with two cases illustrating these agencies. In one the attack was provoked by taking a cold shower-bath after coming out of a warm bath; the other was the result of wet feet.

Traumatism, such as from violent exercise or sudden blows. The former is more likely to cause the disease if it immediately follows the taking of a heavy meal. As I have already stated, the rapid ingestion of indigestible food is an exciting cause.

Exciting Causes.—*The introduction of foreign substances*, such as fecal matter, pits, or enteroliths, when associated with the ever-present bacterium coli commune, is the most frequent exciting cause of appendicitis.

PATHOLOGY.

In considering the pathology of acute appendicitis there is a great difference of opinion as to the cause in localized abscesses of the peculiar offensive odor which the pus possesses; whether this odor is due to a commingling of the gases of the bowel which

are intimately admixed with the pus, or whether it is the result of decomposition of the contents of the abscess. I believe this odor to be entirely fecal, as we find that abscesses occurring elsewhere in connection with the bowel will possess the same characteristic odor which is found in the appendiceal abscess.

Cases which take on the gangrenous type of inflammation may lead to the destruction of the cecum at the base of the appendix. I have seen several such cases during the past year.

Tuberculosis has been found in my experience to be one of the remote causes of suppurative appendicitis.

The rôle which the bacterium coli commune plays in the production of peritonitis lies in the fact that the appendix is a hatching-bed for this dangerous form of bacterium. It can rest within the cavity of the appendix and multiply with perfect impunity, not being in the direct channel of fecal circulation, and irrespective of the fact that intestinal antiseptics may have been administered.

The appendix in an acute inflammatory condition is enlarged, congested, and hard; its peritoneal coat is thickened and at times covered with flakes of lymph. The mucous lining is habitually thickened, not infrequently being almost equal to all of the other coats. Within it presents corrugations, at times irregular ulcerated areas, and in subacute cases may rarely be the seat of small mucous cysts. If perforation has not already taken place there may be seen a dark spot of softening, containing within its tissues colonies of the bacterium coli commune. If perforation has taken place, the tissue surrounding the opening of communication will extrude through it.

In perforation of an appendix in which there is a fecal concretion, the perforation usually takes place at the situation of the concretion. There may be gangrene of the entire walls of the organ, leaving a direct communication with the bowel; or only of the outer coat, leaving the mucous membrane intact. If the appendix be turned upon itself and its inflamed end be in contact with the cecum, ulceration at the spot of contact will occur. I have recently operated upon a case in which such a condition of affairs was present.

On several occasions, while washing out the abscess-cavity I have seen a gangrenous appendix that had ulcerated off appear in the wound.[1]

CLINICAL HISTORY.

Acute appendicitis is usually ushered in suddenly by a severe pain which may be peri-umbilical or epigastric. The character of the pain is paroxysmal and colicky, varying in intensity. Coincident with the pain there is vomiting, first of the contents of the stomach, later of bile-stained material. The colic now subsides, and the pain shifts to the right iliac fossa and becomes constant. There may be a point of greatest intensity, or it may be diffused. The abdominal muscles of the right side are contracted and rigid. There is but little fever. The attack may terminate here with a gradual subsidence of all the symptoms; or on the other hand, this attack may be followed directly by a return of the abdominal pain, and vomiting which is incessant and uncontrollable. The entire belly-wall becomes tense and rigid, though the more so on the right side. The patient takes on the typical and anxious expression of the Hippocratic face, and symptoms of collapse appear, with sweating, and cold and blue extremities, death finally supervening from diffused septic peritonitis.

In another type, the pain, which at first has been diffused, concentrates itself in the right iliac fossa. The accompanying rigidity of the muscles of the right side is replaced by a swelling which in some instances presents to the touch a doughy sensation, and in others that of a hard mass the contour of which is not constant.

The fever, which up to this time has been of a moderate degree becomes pronounced, with a decided rise in the evening and remission in the morning. While this symptom usually indicates pus, absence of a rise of temperature does not necessarily preclude the possibilities of the presence of pus. This I have demonstrated many times by operation to the skeptical attending physician, who has pinned his faith to the thermometer, which instrument is of but little value in the majority of this class of cases.

SYMPTOMS.

Pain. The initial symptom is pain. This usually follows the ingestion of a hearty meal of indigestible foods, improperly masticated and hastily swallowed, particularly when eaten at night. The character of the pain at the outset is paroxysmal and colicky. So far it simulates an attack of acute intestinal indigestion. The term appendicular colic has been applied to this initiatory pain. To this, however, objection has been raised, as the cause of the pain is inflammatory and not functional. While acknowledging the cause of the pain to be inflammatory, yet I am convinced that it may be paroxysmal in character; otherwise how can we explain the wave-like exacerbations so vividly described by an intelligent patient. Palpation over the affected area excites and intensifies this peculiar, wave-like, characteristic pain. Fowler, who in a recent article upon appendicitis has taken exception to the term

[1] Microscopic and bacteriologic examinations are being made by Drs. Stengel, Abbott, and Kneass, and will be published at a later date.

appendicular colic, offers as an argument the absence of poor development of the circular muscular fibers of the appendix, and from this argues the inability of the appendix to cause this colicky pain by expulsive efforts. I must take exception to Fowler's statement, particularly regarding the absence of circular muscular fibers in the appendix, as this organ possesses a continuous circular muscular coat. I will, however, grant that the circular muscular fibers are not always as well developed as the longitudinal, but I am convinced that the appendix possesses sufficient contractile power to cause a colicky pain by its expulsive efforts. The study of pathological appendices cannot be relied on for histological facts. The dissection of normal appendices proves the presence of circular muscular fibers. The irritation arising from a simple catarrhal inflammation of an appendix in which there is no fecal concretion or foreign body, is capable of giving rise to expulsive efforts which cause the colicky pain and which may be likened to similar efforts of an inflamed rectum or bladder.

Location of pain. The primary pain is referred most frequently to the umbilicus or peri-umbilical region; next in order of frequency to the epigastrium; and last of all to the region of the appendix. After the occurrence of localized peritonitis in the right iliac fossa the pain is here located. I have observed two cases in which the pain was referred to the left iliac fossa, in neither of which, as demonstrated by operation, did the appendix occupy the corresponding position. In one the appendix hung down into the pelvis and in the other it was retrocecal.

Rigidity of the abdominal walls. This, next to pain, is one of the most reliable signs. It is usually confined to the right side of the abdomen, being most marked over the inflamed region, and immediately follows the localization of pain in this locality. In some instances the rigidity is so pronounced that it operates against deep palpation, and in addition makes the percussion-note of higher pitch.

Vomiting. Coincident with the onset of the initial pain there is vomiting of the contents of the stomach. This usually does not persist in favorable cases, while in unfavorable cases it is persistent and uncontrollable. The ejecta consist first of the contents of the stomach, later of bile, and finally, if intestinal paresis supervene, consequent upon a septic peritonitis, of stercoraceous matter. When the material rejected becomes stercoraceous, it is thrown off by regurgitation, indicative of a fatal termination.

Constipation. Constipation is present in the majority of cases of appendicitis, yet in a few diarrhea ushers in the attack. Obstinate constipation early in the disease is due either to intestinal paresis, the result of infection, or to the indiscriminate use of opium.

The temperature and the pulse-rate bear no direct relation to the gravity of the attack. We may have early perforation and gangrene of the appendix with but a moderate rise of temperature; on the other hand, there may be a decided rise with a simple catarrhal inflammation of the appendix. The pulse in the former class of cases more nearly corresponds to the gravity of the attack. A sudden fall of temperature to the normal or below normal is not by any means ground for a favorable outlook, as too often it indicates the lull which immediately precedes the storm of destruction, in the shape of perforation or a ruptured abscess. This is in accord with the statement that I have already made, namely, that the thermometer is a most untrustworthy instrument in determining the severity of a case.

Tenderness is one of the most valuable and constant of all the signs or symptoms. It is always present, although if the appendix be postcecal and the rigidity of the abdominal walls marked, it is difficult to elicit, requiring deep palpation. Sometimes it can be elicited through the rectum or vagina. In vaginal or rectal palpation in the female, the possibility of a right-sided pyosalpinx and salpingitis must be borne in mind. In rare cases the tender spot may be located in the loin, only to be discovered by deep palpation. After the advent of suppuration the tenderness becomes general in the right iliac fossa and loses its extreme severity. Frequently after the remission which follows the sudden sharp primary attack, tenderness and rigidity alone remain to tell the attending physician that trouble still exists in the right iliac fossa. The point of greatest intensity is usually over the inflamed appendix, but to this rule there are exceptions. I have recently met with a case in a young adult male, in which the point of greatest tenderness was to the left of the left rectus muscle, a little above the level of the anterior superior spine of the ilium. By rectal examination a small but very sensitive mass occupying the recto-vesical space was detected. The operation demonstrated the appendix occupying this position. The point of greatest intensity usually corresponds to the so-called McBurney's point.

I recall two cases in which the point of greatest tenderness was immediately above the middle of Poupart's ligament. This, as demonstrated by the operation, corresponded to the angle of curve in the appendix; in both cases the origin was from the postero-external aspect of the base of the cecum, descending in front of the latter as far as the apex, where it curved abruptly upward.

Distention may be due to several causes: to mechanical obstruction, to paralysis of the intes-

tines, to septic causes, to obstinate constipation, and consequent collection of gas. Richardson points out the possible differential diagnosis by means of auscultation between distention due to accumulated gas from mechanical causes, and that to paralysis of the intestines the result of infection—the sounds of peristaltic action being clearly heard in the former condition but not in the latter. The distention may sometimes be limited to the right side of the abdomen; here only those portions of the gut in relation with the inflamed area are affected. This local distention may be marked, because the still functionally active intestine will force more gas into the affected portion. If the peritonitis become diffused, the abdomen is flat and its walls rigid and hard. This appears early and arises from the complete paralysis of the intestinal canal preventing the entrance of gas. A distended abdomen associated with marked and uncontrollable vomiting is an ominous combination of symptoms.

Tongue. The tongue is furred, and if diffused peritonitis occur may become dry, associated with a deposit of sordes upon the teeth.

Urine and bladder. The urine is usually diminished in amount, and contains albumin and indican. Several theories have been advanced to explain this diminished and albuminous urine. The most tenable of these is that there is a decreased activity of the glomerules of the kidney, due to the general fall in the arterial tension. Frequency of urination is often a prominent symptom from the first, being most probably due to disturbance of the sympathetic nerves, and when the inflamed appendix occupies the pelvis, to irritation of the bladder directly communicated thereto. In peritonitis involving the serous coat of the bladder, retention of urine may occur, necessitating the use of the catheter.

Respiration. Respiration plays a comparatively unimportant part in the symptomatology of appendicitis, yet I have noticed early in the attack a voluntary limitation in breathing, the patient thus favoring the tender side. If the distention is pronounced the respiration is correspondingly labored, while if there is active peritonitis the respiration is thoracic. In advanced cases of appendicitis with a diffuse peritonitis, a symptom that I have also noticed is a peculiar reflex condition of the pharynx, which the patient speaks of as a difficulty in swallowing.

Leukocytosis. According to Richardson, leukocytosis is an invariable symptom in perforative appendicitis. In one case he deferred operation for twenty-four hours on account of the absence of this symptom, the patient dying a few hours after the draining of an extensive general infective peritonitis.

DIAGNOSIS.

Ordinarily, I regard the diagnosis of appendicitis as simple. The suddenness of the attack; the pain referred either to the peri-umbilical region or right iliac fossa; the occurrence of nausea and vomiting coincident with the pain; and tenderness over the site of the appendix, are pathognomonic. One of the greatest sources of error is the masking of the symptoms by the use of large doses of opium in some form.

The ushering in of an acute attack of appendicitis simulates very closely that of an attack of bilious colic, the pain being peri-umbilical or epigastric, and associated with vomiting. Shortly the pain becomes localized and more intense in the iliac fossa, when we should at once suspect more serious trouble. Owing to the fact that appendicitis follows some hours after the ingestion of food, the vomited matter consists of partly digested material, and is often bile-stained. The pain and tenderness cause the patient to voluntarily assume the dorsal decubitus with thoracic respiration, to favor the affected side. Palpation reveals decided rigidity of the abdominal walls, most marked on the right side, and particularly over the right iliac fossa. While it may be slight, yet the experienced sense of touch cannot fail to recognize it. Tenderness is a most important and reliable diagnostic sign. It is always present, and corresponds to the point of greatest intensity of the inflammation, which is the appendix. This may correspond to McBurney's point, or when the appendix holds an anomalous position its location will be governed by that of the organ—as, for example, when the appendix occupies the pelvis. The point of greatest tenderness is elicited by rectal palpation. Between the disease and the extent and intensity of the tenderness there is a close relationship. When the tenderness continues to increase it shows the progressive tendency of the attack; while if it decrease without the administration of opium, it is indicative of a favorable termination of the attack. I have recently operated upon a case in which the greatest tenderness was elicited by rectal examination, and where there was also a distinct point of tenderness to the outer side of the left rectus muscle; this was explained by the presence of adhesions, indicative of Nature's effort to circumscribe the purulent collection.

Fulness. Fulness in the right iliac fossa appears late, after inflammatory exudate and adhesions are formed; coupled with this a doughy feeling may be present, indicating the presence of pus, though this is not a reliable diagnostic sign. Accompanying fulness there may be edema of the abdominal walls. Excessive circumscribed tenderness I have come to regard as a more reliable sign of the presence of pus than either doughiness or edema.

When the appendix lies over the psoas magnus or iliacus muscles, flexion of the thigh may be an early sign. Another cause for flexion of the thigh upon the abdomen is rigidity of the anterior abdominal wall due to peritonitis, this, however, being a later manifestation.

Distention. In simple appendicitis the distention, if at all present and not due to mechanical causes, is confined to the seat of the inflammation. Distention occurring in connection with appendicitis is due to peritonitis, and its extent corresponds to the area of inflamed peritoneum. Mechanical obstruction due to constipation, or the use of opium causes distention, which differs from that of septic peritonitis in being functional, and can be differentiated by auscultation. Functional distention simply occasions discomfort, while that of septic paralysis is indicative of a grave type of the disease. Distention may also be due to acute mechanical intestinal obstruction, such as bands. In some early cases of perforative appendicitis in which the general peritoneal cavity is not yet walled off, and septic peritonitis supervenes, we may not only not have distention, but instead may have a scaphoid or retracted belly, due to profound paresis of the intestinal canal, which would prevent the admission of gas.

Only in cases of appendicitis with circumscribed peritonitis are we likely to detect the presence of a mass. Even under these circumstances rigidity of the overlying abdominal walls may mask this sign, unless it occupy the pelvis, when it can be detected by rectal or vaginal examination. If the patient be a female, right-sided pyosalpinx or salpingitis must be excluded. Rectal examination should be confined to the use of the finger. The introduction of the hand, I maintain, is unjustifiable, as it endangers adhesions and the rupturing of abscesses. Examination under ether will not throw sufficient additional light on the diagnosis of an obscure case to warrant the administration of the anesthetic.

The advent of suppuration may or may not be accompanied by a chill.

The temperature in appendicitis is so variable and inconstant that it is of little value except in the differential diagnosis between it and some other conditions in which it is characteristic.

Percussion over the diseased area will give a flat or resonant note depending upon the appendix.

In a doubtful case in which it would seem to be impossible to differentiate, rather than introduce an exploring or aspirating needle, either of which procedures under these circumstances I regard as most unsurgical and attended by no little danger, I would advise an exploratory incision.

Differential diagnosis. Appendicitis may be confounded with the following conditions:

1 *Bilious colic or acute indigestion.* The onset of the attack of appendicitis is somewhat similar to that of an attack of acute indigestion, differing, however, in the character of the vomited matter, and in the fact that the pain soon becomes located in the right iliac fossa, and is accompanied by tenderness.

2. *Hepatic colic.* In hepatic colic the painful area is usually higher in the abdomen, referred also to the shoulder, and most severe over the region of the gall-bladder, and usually followed by jaundice.

3. *Floating kidney.* From floating kidney with a twisted pedicle, appendicitis may be diagnosticated by the presence of blood in the urine, a history of a movable tumor prior to the attack, a depression in the right loin corresponding to the site of the kidney, and possible symptoms of uremia.

4. *Intestinal obstruction.* In intestinal obstruction the onset is more abrupt, and the pain, which at first was remissive, is referred to the seat of the obstruction, more commonly to the umbilicus; there is absolute constipation and inability to pass flatus, and vomiting occurs early and soon becomes fecal. With the onset of peritonitis regurgitant vomiting occurs, and there is absence of fever unless the patient survives long enough to allow inflammation to set in. Invagination is the most common form of obstruction in children, while obstruction from bands and volvulus are more common in adult life. Tumors from these forms of obstruction are more common to the left of the linea alba. When obstruction is the result of invagination, blood and mucus will be discharged from the rectum, and upon examination through this avenue a tumor may be felt. The early development of peritonitis in acute intestinal obstruction is marked by great distention of the abdomen. Shock and collapse appear early in obstruction, but not in appendicitis, unless it may be of the fulminating type, and even then collapse does not occur as early.

5. *Pyonephrosis.* From abscess of the kidney appendicitis differs, first, in that the pain in the former radiates to the groin and testicle with retraction of this latter organ. Tenderness is elicited on pressure over the kidney. There is irritability of the bladder and diminished excretion of urine, which contains pus and possibly some blood. In the absence of urinary symptoms, abscess of the kidney, and particularly if it be a floating kidney, is necessarily more difficult to differentiate. In the latter instance, however, the tumor will be movable. I have recently operated on a case of acute suppuration of the kidney in which the urine was normal, and the diagnosis was made on the anatomic situation of the swelling. Nausea, sometimes with vomiting, is not an inconstant symptom.

6. *Perinephric abscess.* When the appendix holds a retrocecal position and an abscess forms, it may

be mistaken for a perinephric abscess, but the absence of intestinal disturbance will be sufficient to clear the diagnosis.

7. *Nephritic colic.* To differentiate between nephritic colic and appendicitis is at times difficult, owing to the fact that in the latter condition there is in rare and exceptional cases pain referred to the umbilicus, retraction of the testicle, associated rectal and vesical tenesmus, and painful micturition. This error, however, could only occur in the early stages of appendicitis, as the symptoms of the later stages are so entirely dissimilar. I recall the case of a physician, in which the diagnosis of renal colic had been made, and in which the ureter was supposed to have been ruptured by the passage of a calculus. The autopsy revealed a gangrenous and perforated appendix with diffuse suppurative peritonitis.

8. *Hepatic and perihepatic abscess.* Appendicitis can only be confounded with abscess of the liver or about the liver when, late in the disease, a circumscribed collection of pus is in close relation with this organ, and when the appendix is postcecal and points toward the liver. The previous history, the hectic temperature of hepatic or perihepatic abscess, and the pain referred to the shoulder will be sufficient to establish the diagnosis.

9. *Entero-colitis.* In this disease the colicky pain is more marked, and there is present a mucous diarrhea and extreme collapse.

10. *Neuralgia of the right iliac fossa.* Neuralgia of the right iliac fossa is a condition associated with localized intermittent pain, which is relieved rather than increased by deep pressure. A case has been reported by Shrady of a medical man whose appendix was removed under these circumstances.

11. *Extra-uterine pregnancy.* From extra-uterine pregnancy the diagnosis is made by a history of pregnancy; and along with the rupture of the sac and production of a pelvic hematocele, there is profound collapse followed by a discharge of blood and decidual shreds.

12. *Typhoid fever.* From typhoid fever appendicitis can be differentiated by the frequency of the pulse, the absence of the characteristic temperature, the coated tongue with red border, epistaxis and headache. The presence of spots does not necessarily indicate typhoid fever, as spots may be present in septic conditions.

13. *Hip-joint disease.* The presence of the characteristic deformity, inability to execute the normal movements of the joint, pain referred to the knee, arching of the lumbar spine when the limb is brought into the fully extended position, and absence of intestinal symptoms, should settle the diagnosis.

14. *Abscess of the abdominal wall.* Between abscess of the abdominal wall and that caused by appendicitis, there should be but little difficulty in arriving at a correct conclusion. If the collection is in the superficial fascia it will be circumscribed, while if between the abdominal muscles it is likely to be diffused. The purely local character of the abdominal abscess, the swelling moving with the abdominal walls, the absence of intestinal symptoms, the presence of local and constitutional evidences of pus, coupled with the history of the case, should be enough to render a differential diagnosis possible.

(To be concluded.)

SUICIDES.

By CARL JOHNSON, M.D.,
of Denver, Colorado;
Lecturer on Gynecology at Denver University Medical College.

In the performance of my duties as Police Surgeon during the past fourteen months I have treated forty-six cases of suicide and attempted suicide. They were very nearly equally divided as to sex: twenty-four were females, and twenty-two males.

The cause of the attempt was ascertained in thirty-seven cases. Ten were on account of lovers' quarrels. The greater part of these were among the class known as "kept women." Only one was a public prostitute. Eight were due to poor health, combined in five instances with poverty. Three were well-marked cases of melancholia. Two wanted to die because they could not quit drinking. Four were on account of trouble between man and wife. Seven were out of work and out of money. One had no money to defend himself against a charge of larceny, of which he claimed to be innocent. One was a mother who had just heard of the death of her child in Kansas, and had no money to enable her to go to its funeral; and one man, who knew himself to be impotent, married a young lady, and tried to do away with himself after several months of wedded misery. At least three-fourths of the cases were partly under the influence of liquor at the time of making the effort at self-destruction.

In twenty-eight cases opium or some of its derivatives was taken. Three took strychnin. One took "Rough on Rats," which is composed principally of crude arsenic. One took half an ounce of fluid extract of cactus grandiflorus; one took an ounce of carbolic acid; one drank several ounces of a saturated solution of chloral hydrate; and one tied a bottle of chloroform around her neck in such a way that the open mouth of the bottle was in contact with her nostrils. One took two ounces of "bromidia," and one disappointed young man chewed up a seltzer glass and swallowed it. Three attempted to suffocate themselves with illuminating gas. One of these claimed to have blown out the

gas accidentally, but the surroundings and circumstances all indicated that it was intentional.

Another, a boy of sixteen, buckled a strap around his neck so tightly that he was comatose when discovered. This boy, who was an epileptic, had made a previous attempt in the same unique manner, had also jumped head first into a well, and thrown himself in front of a moving train, without injury each time. One severed his radial artery with a sharp-pointed harnessmaker's knife. One tried to shoot himself, and one was lying on the floor dead when found, having probably taken hydrocyanic acid. In addition to this one, five of the cases ended fatally.

Three of the fatal cases were due to opium, one to strychnin, and one to chloral hydrate. One of the fatal opium-cases, an old man, recovered from the direct effects of fifty grains of morphin, but died ten days later from inanition and exhaustion as an indirect result of the attempt.

The case classed as death from strychnin should, perhaps, be classed as a death from an unknown cause. This man had repeatedly threatened to kill himself. He was suddenly taken sick, and I was sent for, and found him with well-marked symptoms of strychnin-poisoning. A stomach-tube was inserted, and his stomach well washed out. He recovered in a few hours, and said he had gone to a drug-store, called for ten cents worth of morphin, and taken it. He had presented no symptoms of opium-poisoning. A few days later he was taken sick with symptoms of gastritis, from the effects of which he died in about two weeks from the time I was first called to see him. I have never arrived at a satisfactory conclusion in regard to this man's death. The onset of the gastritis was not sudden enough to indicate that he had again attempted suicide by taking an irritant poison, unless it was taken in small and repeated doses, which would be very unusual for a suicide.

I have related this case at length to call attention to the fact that the gastritis might possibly have been caused by undue violence in the passage of the stomach-tube, and to emphasize the fact that too much care cannot be used in the passage of this instrument. The stomach-tube was used in twenty-three of these cases, and in no other instance could any bad effects be referred to it. I have used the lever stomach-pump, manufactured by Tiemann & Co., with a lisle-thread-tube. The ordinary soft-rubber-tube, with a funnel at the top, is almost useless for the treatment of suicides. I have on two occasions passed the tube down the trachea instead of the esophagus, but the mistake was discovered before any damage was done by simply placing the finger over the end of the tube, when the current of air accompanying respiration could easily be felt. This is a precaution which should always be taken before fluid is introduced. I know of a case in this city in which a man who had taken morphin with suicidal intent was actually drowned by this unfortunate method of pulmonary irrigation.

In the twenty-eight opium-cases reported the preparations taken were as follows: Morphin, 20; tincture of opium, 5; powdered opium, 1; aqueous extract of opium, 1; and one smoked opium, taking a large dose of morphin soon afterward. The smallest doses taken were half an ounce of the tincture of opium in one case, and three and one half grains of morphin in another. The largest dose was the entire contents of a dram-bottle of morphin. This quantity was taken in several cases. In all of the cases the drug was taken by the mouth.

I shall confine my remarks on treatment entirely to cases of opium-poisoning, as these are seen to be by far the most common. The symptoms are practically the same, no difference being observed, whatever the preparation of opium taken. Morphin in solution and the tincture of opium act more quickly than the solid forms, such as morphin pills and powdered opium.

The first stage of opium-poisoning is one of increased nervous excitability. I think that the small percentage of successful suicides by this agent is due largely to this condition. The patient becomes talkative and excitable, and if he engages in conversation with anyone he almost always betrays the fact that he has taken poison, thus allowing early treatment to be instituted. When a large dose is taken, this stage may be very short. Its duration is from ten or fifteen minutes to three or four hours. The second, or the stage of somnolence, is ushered in by a feeling of drowsiness, and the patient goes into a condition very closely resembling sound sleep. This soon gives way to the third, or stage of narcosis. The patient is now entirely insensible to pain, the pupils are small, the face has a purplish hue, the respiration is slow and snoring, but usually not stertorous. The pulse is either strong and nearly normal, or rapid and weak. The skin is relaxed and moist, but the perspiration is rarely profuse. I am aware that these symptoms do not agree in some respects with those given by the authorities on toxicology, but I have given them as noticed in my own cases. As to the differential diagnosis, the contracted pupils, exceedingly slow respiration, and cyanotic face, are usually sufficient to establish a diagnosis.

The case mentioned in which chloral hydrate was taken puzzled me greatly. When I was called the patient, a woman of thirty-five, was lying asleep. I aroused her, and she muttered a few words, turned over, and went to sleep again. The pupils were normal or slightly dilated, the pulse about normal, but rather weak, and respiration normal. I ex-

pressed the opinion that she was only drunk, as her breath had a distinct odor of alcohol. I was told that she had been drinking, but she had told her friends that she was tired of life, and was going to "take a dose." I gave her a hypodermatic injection of apomorphin, and, to my surprise, it failed to act. After waiting about ten minutes I tried to arouse her, but failed. The pulse became weaker and rapid, the respirations more shallow, and she died within half an hour of the time I was called.

Repeated injections of strychnin and digitalis had no effect either on the pulse or on the respiration. The countenance was natural, and the rhythm of the respiration was uninterrupted and noiseless to the last. I did not make a diagnosis until after death, when I found a bottle of a strong solution of chloral hydrate from which several ounces had been taken. The temperature of the patient was not taken.

A curious fact which has been noted by both my colleague, Dr. Wheeler, and myself in opium-poisoning is that several fatal cases have, after being unconscious for a long time, opened their eyes, moved their hands, and shown other signs of returning consciousness, dying almost immediately afterward. The patients have been pulseless and in a dying condition when this phenomenon occurred.

The first step in treatment is, of course, to empty the stomach. If the patient is still conscious or can be aroused, I depend on apomorphin hydrochlorate for this. I give one-fifth of a grain hypodermatically. This drug deteriorates if kept too long, and should be replaced by a new supply occasionally. As soon as the apomorphin has been given I have the patient drink as much water as he can be prevailed upon to take. Free emesis occurs in from one to ten minutes. I believe that any patient seen early enough to induce vomiting in this manner by apomorphin will recover. In fact, most of them require no further treatment, unless it be simply to keep them awake if they show a tendency to go to sleep. The dangerous cases—those that require energetic treatment—are so profoundly influenced by the narcotic that the cerebral centers fail to respond to the irritation of the apomorphin.

If the case is too far advanced for apomorphin to be of service, I proceed to pass the stomach-tube, attach it to the pump, and inject about a quart of hot water. I leave this in for a few minutes, to allow it to dissolve whatever solids there may be in the stomach, and then withdraw it by reversing the pump. This is repeated several times, or until the water removed from the stomach is clear. In the meantime I have had prepared a quantity of hot, strong coffee. I now inject one or two quarts of this into the stomach. This procedure is almost invariably followed by an improvement in the respiration and a lessening of the cyanosis. The coffee acts as a physiologic antidote to the opium, although I believe the heat which is conveyed from the distended stomach to the solar plexus and diaphragm, and perhaps to the heart itself, to be more beneficial than any direct action of the coffee. I have used hot water when coffee could not be obtained, and the difference in the result was not appreciable.

I have often used coffee so hot that I could not bear my hand in it in this manner without bad after-effect, and consider it one of the most efficient remedies at our command for stimulating the heart and respiratory organs in these cases. The coffee is pumped out as often as it becomes somewhat cooled, and replaced with hot coffee. I wish to lay stress on the importance of having the stomach fully distended with the hot fluid, as I think this to be an essential point.

It must be admitted, however, that this procedure is not without danger. If a gastric ulcer should be encountered it might result in serious hemorrhage, or even rupture of the stomach. I have supplemented this method in a few cases by rectal injections of coffee. I have found it difficult to induce the rectum to retain enough to distend the transverse colon, where it seems to me it would be of the most benefit. This difficulty might be obviated by injecting the fluid more slowly than I did or by using a rectal tube.

The galvanic current I have not had an opportunity of using, as a portable galvanic battery is not easily obtained. I hope at some future time to be able to make a report of cases treated with the aid of the chlorid-of-silver galvanic battery now on the market, which is easily carried to the bedside. I have used a strong Faradic battery for two purposes: First, for stimulating the respiratory muscles. To do this I place the positive pole between the shoulders, and move the negative pole from side to side along the anterior attachment of the diaphragm. I have failed to perceive much benefit from its use in this manner.

The principal use I make of the current is in keeping the patient awake. I leave the positive pole as before, and touch the negative pole to the patient's lips, nose, ears, or eyelids as often as necessary. I have been able to keep patients awake in this manner when walking and slapping had failed. I regard the time-honored custom of walking and abusing a patient until he is exhausted as entirely unnecessary, and believe that it actually lessens the chances of recovery. It has seemed to me that if a healthy person who had taken no opium was put through the same treatment that these unfortunates are often compelled to undergo he would die of exhaustion. Much less, then, could a person whose vitality is already lowered by the action of a powerful narcotic

be expected to withstand the added depression following the severe treatment so often persisted in.

The endeavor should be to save the strength of the patient, not to exhaust it. I always put the patient to bed, cover him up, put dry clothing on him if, as is usually the case, cold water has been thrown on him, and depend on the battery to keep him awake as described. In the absence of a battery, pulling the nose is nearly as efficient as walking the patient, and does not exhaust him.

As for drugs, I rely largely on strychnin sulphate. I give a twenty-fifth of a grain hypodermatically, and in extreme cases repeat this dose every ten or fifteen minutes, until there is twitching of the muscles or the breathing becomes spasmodic in character. Even after it is pushed to this extent the effects wear off rapidly, and it needs to be frequently repeated. I am convinced that I have saved several cases which would have died had not this drug been used. I usually give $\frac{1}{100}$ of a grain of atropin, and repeat it twice at intervals of fifteen or twenty minutes. I think the importance of this remedy has been over-estimated. It certainly dilates the pupils, and theoretically it counteracts the systemic effects of opium, but I have failed to notice any decided beneficial effects from its use.

I have at times used digitalis, and I believe it to be of some benefit when the heart's action is weak. It has the disadvantage, however, of being slow in its action, even when given subcutaneously. I therefore depend largely on the more transient heart-stimulants, whose action begins more promptly. In a few cases I have given hypodermatics of aromatic spirit of ammonia. This is a very good diffusible stimulant, but has the objection of frequently causing an abscess at the point of injection.

When the patient has not been under the influence of liquor prior to taking the opium I sometimes give whiskey or brandy subcutaneously with good results. If the unconsciousness is long continued the catheter should be passed to prevent the possibility of reabsorption of the poison from the urine. I have frequently heard "morphin fiends" make the assertion that an overdose of opium would be counteracted by cocain. Acting on the suggestion I gave a man in the last stage of narcosis a quarter of a grain of cocain hydrochlorate every ten minutes until I had given him three doses. His pulse became very weak and rapid, and he died in a few minutes after the last injection. I have made no further experiments with cocain. In another case to which I was called a physician who had preceded me by an hour and a quarter had treated the case solely by the subcutaneous injection of the tincture of iodin—for what purpose I cannot conceive. The man died soon after my arrival.

I believe the responsibility for a large percentage of the suicides in this city rests with the newspapers. A suicide written up in a sensational manner, accompanied, perhaps, by a picture of the deceased, is usually followed by a number of attempts by others within a short time. There are at all times in every city a number of poorly balanced individuals who need only the suggestion conveyed to them in this manner to determine them to make an effort to end their existence.

CLINICAL LECTURE.

EXTRA-ARTICULAR ABSCESS NEAR THE HIP—COMPOUND FRACTURE OF THE LEG; SIMPLE FRACTURE OF THE THIGH—PARAPLEGIA DUE TO POTT'S DISEASE.

A Clinical Lecture delivered at the Buffalo General Hospital.

BY ROSWELL PARK, A.M., M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF SURGERY IN THE UNIVERSITY OF BUFFALO.

EXTRA-ARTICULAR ABSCESS NEAR THE HIP.

THIS patient is a boy, four years of age, whose trouble dates back two weeks, when his mother took him out for a short walk on a chilly night. During the walk he was taken with nose-bleed and vomiting, and he appeared to be thoroughly chilled. After reaching home fever succeeded the chill, and within a short time there developed pain, swelling, and other symptoms of inflammation about the left hip. Ever since then the child has been peevish, complaining in a general way of pain, and with evident tenderness about the hip. Dr. Bernard Bartow has seen the patient, and I will ask him to give you the further history of the case.

DR. BARTOW: All I recall as bearing upon the diagnosis and indications for treatment are the acuteness of the trouble to which Dr. Park has referred; the fact that the child was previously well, except for an attack of whooping-cough, and the evidences of trouble in or about the hip-joint, as shown by pain on motion, the malposition of the limb, and later the swelling of the hip. The child was treated at first by a physician who made a diagnosis of rheumatism. Later, as the symptoms did not abate, another physician was called, who applied a blister and made the diagnosis of hip-joint disease. The acute development of the trouble excludes the ordinary chronic form of tuberculous hip-joint disease. Owing to the pain which digital examination caused, I have not decided as to the exact nature of the swelling.

DR. PARK: Such a history suggests several diseases to be differentiated from one another; inflammation somewhere in the bone, the shaft of the femur, head, epiphysis, or about the acetabulum; an acute synovitis taking on the purulent form; or an extra-articular inflammation with abscess-formation. These are among the more probable explanations of the trouble. If there were inflammation of bone coming on suddenly in this location, there would be not merely an ostitis, but an

osteomyelitis. The symptoms have not approached the severity of those of acute osteomyelitis. The child will allow himself to be lifted, and, after pacifying him, I could move the hip and jar the thigh-bone without causing complaint. The slightest attempt at such manipulation in acute osteomyelitis would have caused intense agony. I think we must conclude that if there is anything of the nature of ostitis it is localized and slight. The movement of the joint, to which the child submitted, makes it improbable that a synovitis exists, although we may imagine that at this stage the tenderness has passed away. But what has principally attracted both Dr. Bartow's attention and my own is the swelling and pain at the outer and posterior aspect of the joint under the gluteus maximus. For the sake of a more careful examination the child has been chloroformed in spite of the persistence of the whooping-cough, as I believe that the condition about the hip is a sufficiently urgent demand for exploration, and, if need be, surgical interference. It seems to me that, beneath the thick gluteal covering, I find fluctuation. Further exploration should be made, and we will disinfect this region preparatory to incision. The red marks which you see on the buttocks are due to an early scald, and have no significance for our present purposes. With reference to the etiology of the abscess—if there be an abscess—it must be due to the entrance of bacteria, and it is interesting to note that the child has recently had several little abrasions of the toes. Even slight injuries of the feet are sometimes followed by the conveyance of micro-organisms to the groin and neighboring parts by the lymphatics, followed by the development of abscesses.

Not because I am afraid of the result of an incision, but because in ordinary private practice, in which most of you will engage, caution is necessary, I will illustrate to you the preliminary use of the exploring-needle and syringe to make sure of the presence of pus. A little thick pus is withdrawn, confirming our diagnosis. Now, on making a free opening with the knife, I find quite a large abscess-cavity deep down beneath the muscles of the buttocks. Notice that I have followed the general rule applying to all operations in this region, to make the incision as far as possible from the anus. It is necessary to make a counter-opening to provide for free drainage, and this I do on a level with and a little to the outside of the tuberosity of the ischium. While I come down to periosteum, I do not find bare bone indicating bone-disease, nor is the capsule of the joint distended, as it would be if there were an effusion in the synovial sac. The pain, fever, and general symptoms which the child has manifested can be accounted for by this extra-articular collection of pus. The cavity is disinfected as thoroughly as possible with the hydrogen dioxid spray, which causes a frothing and bubbling at both orifices. A tent of zinc oxid-gauze is inserted, and over the wounds will be applied a simple antiseptic dressing.

FRACTURE OF TIBIA, FIBULA, AND FEMUR.

This patient is a boy, ten years old, who, three and a half months ago, was knocked down by a horse, and sustained a compound fracture of both bones of the leg and a simple fracture of the upper portion of the femur. His condition was so serious on account of the extensive laceration of the soft parts and the shock that we were prevented from doing what we wished to do. Traction could not be applied to the lower fragment of the femur on account of the condition of the leg. By dint of a good deal of effort—for the boy was hard to control—the fractured bones of the leg were held in place and have united. There remains a little ulceration marking the site of the laceration of the soft parts. The fracture of the femur has resulted in some angular deformity nearly as high as the trochanter, and there is a somewhat unsightly projection at this point. The operation to day is to relieve this deformity. Whether there is simply a projection to be chiselled off, or whether it will seem best to make a Macewen osteotomy, break the bone, straighten it, and apply traction, I cannot determine at present. The leg will now allow the application of a traction-apparatus. Examining the parts under complete anesthesia, I find that there is an excessive deposit of callus all around the bone at the site of the fracture. It is not, however, an exostosis in the proper sense of the word. Under these circumstances, if nothing were done to remedy the deformity, Nature would probably try to relieve the interference with muscular movements by developing an adventitious bursa, a "cyst of new formation," to enable the muscles to slide over the projection. I see no indication for rebreaking the bone, as the contour of the limb will be sufficiently restored if I cut down and remove some of the excess of callus with the chisel. At a later date it may be expedient to hasten the healing of the ulcer on the leg by skin-grafting.

[The removal of the callus was done as indicated and the wound dressed aseptically.]

PARAPLEGIA FROM POTT'S DISEASE.

This case illustrates the results of pressure upon the spinal cord, due, not to injury, but to the insidious progress of disease. The patient is a little girl, aged eight, whose mother has brought her to the hospital to seek relief. Sensation is not entirely gone, for the child feels when I tickle the sole of the foot. So far as any volitional effort is concerned, she makes none, so far as I can discover, to raise the leg, though there is a slight reflex from the irritation of the foot. Holding her upright, she cannot aid in the least in maintaining her position. Even as she sits on the table she supports herself with her hands. She complains of pain, particularly at night. The explanation of these symptoms is found on inspecting her back. There is a marked gibbosity of the dorsal spine, technically called a kyphosis. It is not quite regular, and it does not straighten out when I lift her by the shoulders. The intermittent pain, felt especially at night, is an almost constant feature of such a disease. Without calling the child's attention to the movement, I press down on her head. Rather to my surprise she makes no complaint of pain. If the disease were in the cervical region the slightest pressure on the head would certainly cause pain. From the rigidity of the spinal muscles, from the care with which the child protects herself from every jar, there is no difficulty in determining that properly directed pressure would cause pain. The diagnosis is Pott's disease of the spine, or tuberculous spondylitis. Now, what relation has this disease of the bones to the paralysis? Simply

the relation of cause to effect. The spinal canal has a very slight backward curvature in the dorsal region, but when it is kinked by the giving way of carious vertebræ its lumen is closed very much as a rubber tube would be collapsed by bending. The paraplegia is simply the compression-paralysis of Pott's disease.

What can be done for its relief? Drugs will do little except to promote better nutrition and to regulate excretion. The muscles of the legs and the lower part of the body are idle, and they will atrophy unless they are permitted or made to work. We can cause them to contract and to receive proper nutrition by electricity and massage. To permit them to perform their natural function at the will of the patient we must straighten out the kink in the spinal canal, or, at least, prevent its becoming worse, and thus allow the spinal cord to adapt itself to its new surroundings. This I can effect by putting on a plaster-of-Paris jacket, with a jury-mast to keep the weight of the head off the dorsal vertebræ. The possibility of operation must be considered. On purely theoretic grounds it would be comparatively easy to cut down on the site of the compression and remove the pressure. Practically, the operation would not be of great difficulty to the surgeon, but it would be a very serious danger to an emaciated, cachectic patient like this. There is not only the shock of the operation, but the drain on the vitality, of a slow recovery, and the liability to septic infection. Moreover, the success of the operation is not certain. If there be nerve-degeneration, there is less to be hoped for from the relief of pressure. It is difficult to say whether the degeneration of nerve-tissue has yet occurred. If the compression of the spinal cord had occurred rapidly, even with this degree of paralysis, there would not be the same reason to fear serious degeneration. I have not, however, absolutely given up the idea of operating, but I shall first try the conservative plan, which we should prefer in the case of our own children.

PATHOLOGIC NOTE.

DUPLICATION OF THE SPINAL CORD, AS A RESULT OF POST-MORTEM INJURY.

BY E. D. BONDURANT, M.D.,
ASSISTANT SUPERINTENDENT OF THE ALABAMA INSANE HOSPITAL, AT TUSCALOOSA.

RECENT studies of the artefacts of the nervous system by Van Gieson, some of the results of which were presented at a meeting of the New York Neurological Society in June, 1892, and subsequently embodied in a series of articles in the *New York Medical Journal*, place in an entirely different light many of the heretofore recorded cases of congenital abnormality of the spinal cord. Van Gieson, after an exhaustive review of the cases of malformation of the cord reported prior to 1892, together with an experimental study of the subject, including the examination of a large number of cords unwittingly injured during removal, and others in which it was attempted by intentional bruising and rough treatment to reproduce some of the appearances previously regarded as of ante-mortem origin, reaches the conclusion that of the thirty-one cases of supposedly congenital malformation recorded from 1878 to 1892, only six are instances of true developmental defect; the remaining twenty-five, including cases of heterotopia of the gray and white substances, and several instances of most remarkable doubling of the cord, reported by Fürstner, Zacher, Drummond, Schiefferdecker, Feist, Kronthal, and others, being nothing more than topographic alterations in the nervous tissues produced by bruises and other injuries inflicted during unskilled or careless removal of the cord from its bony canal, or by rough handling after its extraction.

When it is considered that the literature of these pseudo-malformations had attained to quite respectable proportions, and that the misconception of their true nature, passing unchallenged for many years, had already given rise to erroneous conclusions as to the frequency of spinal-cord malformations in general, and of their influence in the causation of disease, the value of Van Gieson's work may be appreciated.

The case which is made the subject of this paper offers an apt illustration of the facility with which the most bizarre and misleading appearances may be produced by unintentional injury of the cord during post-mortem examination; and but for Van Gieson's rational explanation of the real character of the apparent anomalies noted, it would in all probability have been added to the twenty-five instances of spurious "congenital malformation" already recorded.

The patient was an epileptic imbecile girl, subject to convulsions from early childhood, small, and misshapen; the cranium, face, and body were asymmetric, the right side the smaller; there was a slight lateral curvature of the vertebral column, with marked displacement of the spines of the eleventh and twelfth dorsal vertebræ. The convulsive movements usually began and were more severe upon the right (the smaller) side. The tendon-reflexes were exaggerated, the more markedly so upon the right side; a distinct ankle-clonus existed on this side. The gait was shambling and unsteady, but not characteristic. The patient was irritable, possessed a limited vocabulary and very slight intelligence. She died in her twenty-sixth year, of tuberculosis of the lungs.

The autopsy, held five hours after death, showed extensive and extreme sclerosis of the first and second temporal convolutions and of the cornu ammonis of the left hemisphere; the *right* lateral lobe of the cerebellum was smaller than the left, and its posterior portion shrunken and sclerosed. The discovery of these lesions led to a more than ordinarily careful removal of the spinal cord, this being accomplished without appreciable injury to the organ, save at the point of displacement of the eleventh and twelfth vertebræ, where some difficulty was experienced in getting through the laminæ, and a diagonal gash in the dura and enclosed cord was inflicted by the chisel. After the cord, enclosed in its membranes, was taken out, it was observed that at the dorso-lumbar junction the cord seemed remarkably small, and this fact was noted in the written report of the autopsy. This abnormally contracted portion extended from the point of injury upward for about one and one-fourth inches; the small cord could be distinctly felt through the relaxed dura; at the upper extremity of the contracted segment the cord became unduly large, and the dura seeming tensely distended by its contents; this swelling gradually diminished above, and within a distance of

one and one-half inches the cord had regained its natural size. It was conjectured that this abnormality might in some way be associated with the deformity of the spinal column and the symptoms of a spinal lesion noted during life. The tissue, seeming soft, the cord was placed in Müller's fluid for hardening without further examination or handling, a few transverse cuts being previously made through cord and dura, but leaving untouched the seat of the supposed malformation. The process of hardening was completed in alcohol, and the cord then subjected to careful inspection before dividing it into convenient bits for section-cutting.

Transverse cuts through the dura and the cord at the point of greatest apparent hypertrophy showed the seemingly normal and uninjured dorsal cord crowded to one side, and the entire space between the cord and the dura filled by a crescent-shaped mass of material, softer and paler than the cord, with a somewhat mottled surface. The cord and the outlying mass were apparently enveloped in the same unbroken arachno-pial sheath. Sections above and below this point discovered the extraneous crescent to thin away—gradually above, abruptly below, where it terminated in the small contracted portion previously mentioned. A cross cut through this contracted area disclosed the appearance of a cord shrunken to one-third its normal size, and destitute of gray matter; below, at the point where the cord resumed its normal dimensions, the wound made by the chisel, with some bruising and extrusion of the nervous tissue, was noted; over the remainder of the contracted part, as at the swelling above, the arachno-pial covering seemed uninjured. A transverse section at the junction of the swollen segment with the seemingly atrophic segment showed a considerable distortion of the gray horns of the cord and some pale splotches in the white tissue; several similar but smaller whitish patches were noted in the columns of Goll in the upper portion of the cervical enlargement. Throughout the remainder of its length the cord seemed to the naked eye to be of normal character, excepting for the disintegration observed at the point of injury in the upper lumbar region, previously referred to.

Microscopic examination of a section prepared from tissue taken from the abnormally enlarged segment resulted in the unexpected discovery that the extraneous crescent was composed of nervous tissue, gray and white, the gray arranged so as to present a rude imitation of the normal disposition of the gray matter of the spinal cord, the white showing irregular bundles of nerve-fibers interspersed between masses of apparently unorganized myelinic material; in brief, an instance of partial duplication of the spinal cord had been discovered. Some regret was felt that a cord exhibiting so interesting and unusual an anomaly should have been injured just at the seat of the malformation, and a detailed study of the organ was undertaken. The cord was cut into half-inch pieces and sections made representing practically the entire length of the cord; at the swollen and contracted parts special care was exercised, and sections in series to the number of many hundreds were made and examined.

Beginning above, the first abnormality discovered was in the upper portion of the cervical enlargement, where, in the columns of Goll, the irregular pale spots had been noted; these the microscope showed to be due to an apparently anomalous course of some of the bundles of nerve-fibers; the fibers, instead of running longitudinally and showing their cut ends only in a cross-section of the cord, pursued a more or less horizontal course, and were traceable for considerable distances across the sections; some fibers pursued a peculiar gyral or corkscrew like course; some ran in straight bundles, the fibers lying parallel; some exhibited an extremely irregular arrangement. The abnormality was entirely confined to the columns of Goll, and to the left anterior pyramidal tract (Fig. 1). From this point to the beginning of the abnormal swelling in the lower dorsal region no lesions or abnormalities meriting notice were detected. The sections then bring into view the first evidence of the outlying crescent of nerve-tissue in two separate masses of nerve-material, composed in part of bundles of medullated nerve-fibers, in part of apparently unformed myelinic material, staining deeply by the Weigert hematoxylin method. A little lower down these two masses become united, and two small patches of gray substance make their appearance. A short distance below this point the gray and white masses assume somewhat the appearance of a much-distorted anterior half of a spinal cord, which likeness becomes more pronounced when the point of greatest apparent hypertrophy is reached (Fig. 2). Here the supernumerary cord is well shown, although there is much distortion of the gray horns and many abnormalities of arrangement in the white tissue. The gray horns are larger than the gray horns of that portion of the dorsal cord around which the heterogeneous tissue has disposed itself, and the surface-area of

Fig. 1.

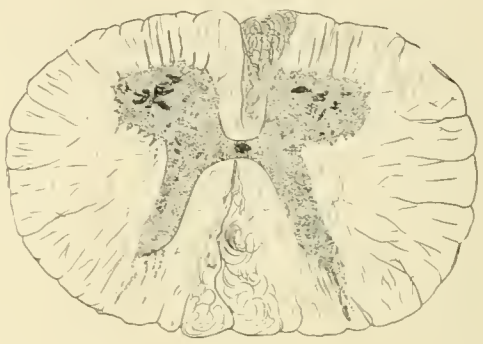

Fig. 2.

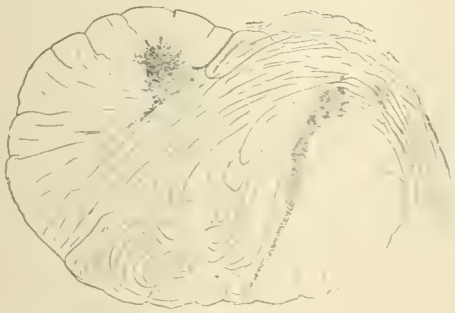
a transverse section of the accessory cord is somewhat greater than that of the dorsal cord. Below (Fig. 2) the abnormal crescent diminishes rapidly in thickness, and the cord shows the first indications of intrinsic malformation; the posterior gray horns become unduly ap-

FIG. 3.

proximated, and some distortion of the white substance, notably in the posterior columns and on each side of the anterior median fissure, appears (Fig. 3). Immediately below this point the distortion of the gray and white substances of the cord becomes extreme; large bundles of fibers run diagonally across the section, pass through the ruptured pia, and apparently become continuous with the extraneous crescent above (Fig. 4). The cord then

FIG. 4.



becomes contracted, and a transverse section shows an appearance but little resembling a spinal cord; there is simply a mass of irregularly disposed white fibers and myelinic material contained in a collapsed and shrunken arachno-pia; at the lower extremity of this shrunken part the wound inflicted by the chisel in the dura, pia, and cord is situated, and some of the cord-substance is extruded through the gash; from a point immediately below the wound to the extremity of the cord no lesion is discovered.

The features of noteworthy interest, in addition to the topographic changes illustrated in the diagrams and in the foregoing description are these: The extraneous crescent is continuous below with the mass of nerve-tissue passing out of the cord, shown in Fig. 4; and here the pia is ruptured; the extruded material and the entire mass of the outlying crescent throughout its length occupies the "sub-arachnoid space"; the arachnoid is nowhere broken, save at the point of chisel-injury, some distance below this. The heterogeneous crescent gives origin to no nerve-roots, and no bloodvessels can be traced into it.

Many hours were spent in an attempt to solve the problem of the development of this accessory cord in its peculiar situation, and of the abnormal contraction and absence of gray matter in the cord immediately below this. In looking up the literature of the subject, reference to partial doublings, somewhat resembling this case, was found in one or two of the text-books and in the writings of several German authors. The results of injury in the upper lumbar region were recognized, but it was not deemed possible that so remarkable a duplication of the cord could be produced by injury of any kind or degree. Being, however, unable to arrive at any intelligible solution of the puzzle, the whole matter was put aside until recently, when, through the courtesy of Dr. Welch, of the Johns Hopkins University, to whom a section of the cord was submitted, Van Gieson's monograph was brought to notice.

In the light of Van Gieson's researches the case is made plain. The entire abnormality is a *bruise artefact*.

The spinal cord is of especially difficult access at the dorso-lumbar junction, and it is in exactly this locality that most of the reported duplications of the cord have been situated. In the case in hand the displacement of the vertebræ made the severance of their laminæ a matter of peculiar difficulty; the chisel employed in effecting this by some mishap cut through the dura and into the pia-arachnoid and the cord itself. The spinal dura is a tough and by no means easily lacerated membrane, so that a cut through it with a chisel not particularly sharp, presupposes the application of considerable force; in this instance the cord was probably severely bruised and a powerful squeeze applied to it before the dura gave way. This violence was sufficient to detach a fragment of cord-tissue, and, rupturing the pia, forced the loosened segment upward into the sub-arachnoid space, Fig. 4 representing the point of exit. The distortions and topographic anomalies in the cord, illustrated in Fig. 3, are doubtless results of the same violence which caused the invagination. The lesser abnormalities, shown in Fig. 1, are due to an appreciated small bruise at this point (upper portion of the cervical enlargement). The invaginated crescent, of course, shows much disintegration of its structural elements and alterations in the relations of its gray and white substances; it is torn loose from its nerve-roots and nutrient vessels. The abundant formless myelinic material mentioned as taking a deep Weigert stain is derived from the crushed and broken myelin-sheaths of the white nerve-fibers. The cord, apparently shrunken to one-third its normal size, is the column of white substance remaining after the separation and upward invagination of the portion which goes to form the distorted crescent.

During the past several years probably twenty-five or more spinal cords have been removed in our autopsy-room in about the same manner as the one under consideration, and sections from them studied with greater or less care. In no one of these cases, however, has any appearance at all resembling those above sketched been discovered. Several of the cords have been injured in removal, but the results of injury have always been

easily recognizable as such; and the case immediately under consideration is the only one in which any such deceptive duplication has been unearthed.

It is a matter of some practical importance to workers in the pathology of the nervous system that the fact be recognized that, however rarely, such remarkable doublings as the one here reported do occur as a result of unintentional violence to the cord, and perchance when least expected.

CONGENITAL ABSENCE OF THE GALL-BLADDER.[1]

By AUGUSTUS A. ESHNER, M.D.,
ADJUNCT PROFESSOR OF CLINICAL MEDICINE IN THE PHILADELPHIA POLYCLINIC.

The subject from which were obtained the specimens to be presented had been under the care of my friend Dr. C. F. Pettibone, upon whose invitation I undertook the post-mortem examination, and by whose courtesy and with whose coöperation this report is made. The case occurred in a rachitic, colored child, two years old, that had never walked unsupported and had presented no symptoms suggestive of any anatomic peculiarity referable either to the biliary apparatus or to other structures. The child had just gotten its first tooth; its ribs were beaded; its chest flattened laterally; the top of its head but slightly convex and its forehead square. It had not yet been taken from its mother's breast and had presented no noteworthy derangement of the digestive apparatus. The child was the outcome of the first pregnancy of the mother, and no family history of syphilis was obtained, although the previous wife of the father had had two miscarriages. The little patient came under observation on account of a slight but rather persistent cough, with occasional dyspnea at night. The bowels were moved several times daily and the stools were pale. There was no jaundice. Upon physical examination no impairment of the pulmonary percussion-resonance was detected, but numerous fine râles were heard posteriorly and at the bases of the lungs. The heart appeared somewhat displaced downward and to the right, but the action was rhythmic and the sounds clear.

The child was lost to observation for a short time and nothing was heard of it until information came that it had died and a certificate of death was asked for. Upon post-mortem examination the epicardium was found to be injected and the pericardial cavity to contain an excess of clear fluid. The heart was large and distended with blood. Its cavities were dilated, but the valves and orifices presented no abnormality. Both lungs were involved in an extensive, widely distributed broncho-pneumonia, with, in places, some compensatory emphysema. The angulation and hyperplasia at the junction of the true ribs with their cartilages was particularly marked upon the inner surface. The kidneys presented a striking pallor of the medullary pyramids. A small supernumerary spleen was present. The bronchial and mesenteric glands were enlarged. The ileum was free from ulceration. The liver appeared of normal size and condition. It presented a whitish nodule at its anterior margin, histologic examination of sections from which shows the remains of hepatic parenchyma, in part in a state of fatty degeneration, together with hyperplasia of connective tissue, accumulations of round cells, and in places homogeneous loss of structure—changes that I take to be of syphilitic origin. The sections that I exhibit show the presence of the hepatic, portal, and biliary vessels. No gall-bladder could, however, be found, either attached to or detached from the liver, or even contained within the structure of this organ, and, as I show you, the usual fissure for the gall-bladder is wanting and there is nothing suggestive of the previous presence of this viscus. Unfortunately the relations of the hepatic artery, the portal vein, and the hepatic ducts were not attentively observed *in situ*. The usual papilla was found in the duodenum, marking the point of entrance of the choledoch and pancreatic ducts, and from this point a duct could be traced upward for a short distance, but the ducts issuing from the liver could not be isolated. The portal vein is perfectly evident and displays no abnormality. There is every reason to believe that the blood-supply of the liver was normal and that the functional activity of the organ was in no way interfered with. The case thus clearly resolves itself into one of agenesis of the gall-bladder.

That absence of the gall-bladder is not incompatible with life is demonstrated not only by cases of this kind, in which there is a congenital deficiency of that viscus, and by the cases in which it is wanting as a result of pathologic causes post-natal or as a result of surgical interference, but also by the further fact that it is normally wanting in some animals, as, for instance, the elephant, the rhinoceros, the camel, the goat, the deer, some species of fish, some birds, and some rodents.[1] Its *congenital* absence in man seems, however, to be a rare condition. In a partial survey of the literature of the subject I have been able to find but few cases of the kind. The number becomes swelled if cases be included in which the gall-bladder was absent obviously or probably as the result of obliterative processes of one kind or another. I append in chronologic sequence a brief summary of the cases that I have gathered. There are a few others to which I have not had access.

Huber[2] reports having found an absence of the gall-bladder in the dead body of a woman sixty years old. The place of the viscus seemed to be supplied by a preternaturally large hepatic duct, which opened into the duodenum in the usual situation, and the coats of which were greatly thickened, and whose lining membrane presented a villous appearance, with numerous small spots believed to be follicles. The biliary ducts were likewise enlarged.

Cholmeley[3] records the case of an infant that was noticed to be sallow at birth and soon afterward became intensely icteric. The stools were white and pasty. Death took place at the age of five weeks, being pre-

[1] Read before the Philadelphia Pathological Society, April 12, 1894.

[1] The gall-bladder may be viewed as but an elaboration of structure dependent upon some differentiation of function, representing, as it were, but a diverticulum of the union of the biliary ducts of the liver.

[2] The Philosophical Transactions of the Royal Society of London, vol. ix, from 1744 to 1749, p. 649. London, 1809.

[3] Medical Transactions of the College of Physicians of London, 1820, vol. vi, p. 50.

ceded by convulsions. Upon post-mortem examination the usual depression in the liver for the gall-bladder was found present, but the viscus itself was replaced by a narrow, impervious cord. The pancreas was enlarged and indurated. It is stated that the transmission of bile into the duodenum was prevented by pressure of the pancreas on the common duct. Cholmeley cites from Morgagni an instance in which the gall-bladder was wanting, but in which two livers were present.

Gaultier[1] has reported the case of a man, aged sixty, with jaundice, who died of tuberculosis, and in whom no trace of a gall-bladder could be found. The duodenum, however, was adherent to the liver by means of fibrous bands. In the bowel opposite the point of entrance of the choledoch duct a large biliary calculus was found. This duct passed directly into the liver without presenting any diverticulum corresponding to a cystic duct.

Baker[2] found the gall-bladder wanting in a subject that came into the dissecting-room. A puckered appearance of the liver in the usual situation of the gall-bladder suggested the destruction of this viscus by some suppurative process.

Bergmann[3] has reported the case of a woman who had long been insane, and in whom after death the left lung was found replaced by two insignificant fleshy masses, the liver enlarged, and the gall-bladder replaced by a small fibrous mass. From the liver a membranous canal passed to the duodenum.

Bergmann cites a case recorded by L'Emery[4] of absence of the gall-bladder, the bile passing from the liver to the duodenum through numerous small ducts.

Canton[5] has reported the case of a woman, sixty-five years old, dead of some "disease of the brain," and in whom the gall-bladder was wanting, although a shallow groove for its accommodation was present in the usual situation. The liver was reduced in size. The right and left hepatic ducts were of usual size and diameter, uniting at an angle below the transverse fissure of the liver to form a common choledoch duct of unusual length and caliber, and whose lining membrane presented the characters of the mucous wall of the gall-bladder.

Canton refers also to a case, reported by E. Wilson, of a fetus born at term that lived but a few hours, and presented a number of peculiarities, the most noteworthy of which was an absence of the gall-bladder. Reference is also made to two specimens in the Museum of the Royal College of Surgeons, in one of which the gall-bladder and the hepatic duct are absent, and in the other of which the gall-bladder was replaced by fibrous tissue.

Thomas[6] has reported the case of an infant five months old that had presented jaundice from the second or third day of life. The child was able to suckle, but vomited a little daily. The bowels were irregular; the stools were white or clay-colored. A week before death anasarca and ascites developed. Upon post-mortem examination not even the rudiments of gall-bladder or cystic or hepatic ducts could be found. The liver weighed fourteen ounces; microscopically its cells were found filled with yellow, granular matter, without much fat. The mesenteric glands were enlarged. Two glands in the longitudinal fissure were softened.

Trimble[1] reports the case of a woman, fifty-five years old, who for several months had presented epigastric pain, nausea, occasional vomiting, furred tongue, pyrosis, anorexia, constipation, emaciation, and ascites. After death there were found inflammatory adhesions about the pancreatic and choledoch ducts. The liver was reduced in size, and in one situation attached to the pancreas. Here it was of cartilaginous hardness, and on section was found to contain a gall-stone imbedded in the common choledoch duct. Careful examination failed to disclose the presence of even a vestige of the gall-bladder.

In 1860 Simpson,[2] before the Edinburgh Obstetrical Society, reported the case of a child four weeks old presenting a condition with features both of erysipelas and scleroderma. In the sixth week vomiting suddenly set in, and was soon followed by death. Upon post-mortem examination there were found present evidences of peritonitis. The gall-bladder could not be found, and there was no depression corresponding to its usual site. The common choledoch duct opened into the duodenum in its usual situation. The duct could be traced backward to the transverse fissure, where it broke up into the hepatic ducts.

In 1865 Sands,[3] before the New York Pathological Society, reported finding in the dissecting-room, in a tuberculous male subject about twenty years old, a liver without a gall-bladder and without a fissure for its lodgment. The liver was small, weighing one and three-fourths pounds, and its quadrate lobe was wanting.

Lynche[4] has recorded the case of an infant, eleven months old, in which icterus made its appearance a few days after birth, the stools presenting a dead-white appearance. Later on the child manifested a tendency to hemorrhage. After death the liver was found to be large, weighing one pound and two ounces. The hepatic ducts were small, but there was no trace of a gall-bladder, its place appeared to be taken by an enlarged cystic duct.

Rambault and Schachmann[5] have reported the case of a paretic dement who after death presented, in addition to the classic lesions of paretic dementia, a small liver with absence of the gall-bladder, the fossa for this viscus being replaced by a shallow fissure. There was no indication of a cystic duct. The hepatic ducts presented no abnormality. During life there had been no symptoms suggestive of the absence of the gall-bladder.

It will be seen, even on superficial analysis of the cases collated, that in most of them the absence of the gall-bladder was associated with conditions that point to obliteration of a previously existing viscus, rather than to a condition of agenesis, such as I conceive to have been present in the case now reported.

MEDICAL PROGRESS.

The Symptomatology of Syringomyelia.—SCHLESINGER (*Neurolog. Centralbl.*, 1893; *Centralbl. f. Nervenheilk. u. Psychiatrie*, March, 1894, p. 151) directs attention to several symptoms of syringomyelia to which little attention has heretofore been paid. Among these are certain paralyses of the ocular apparatus, such as are observed in the course of posterior spinal sclerosis, and are frequently but transitory. There may also be laryngeal palsies, assuming a prominent place in the manifestations of bulbar involvement, usually insidious in development and chronic in course. These laryngeal disturbances are usually motor; paresthesiæ are uncommon; diminution of the laryngeal reflex irritability is sometimes present, and sometimes the sense of pain and the thermal sense are diminished. The motor derangement consists more frequently in interference with phonation than in disturbances of respiration. Unilateral recurrent palsy is commonest; less common is unilateral posticus palsy. The pressure-sense sometimes undergoes a peculiar change, the appreciation of pressure upon the cutaneous surface being greatly impaired or entirely abolished, while no defect is observed if the pressure-sense is tested in the ordinary way.

The Function of the Muscular Coat of the Bladder in Normal Micturition.—In an experimental research, GENOUVILLE (*Archives de Physologie Normale et Pathologique*, 5e sér., t., vi, No. 2, p. 322) found that the vesical orifice of the bladder is normally opened by contraction of the unstriated muscular tunic, and that the contraction of this muscle is necessary to the expulsion of the urine. The contraction of the abdominal muscles may aid this action, but is not indispensable, and cannot replace it. Although volition seems to be directly concerned in the act of micturition, it acts rather by causing, through a psychic act, reflex contraction of the muscular coat of the bladder. Ordinarily, the contraction of the muscular coat is the result of a reflex having its point of departure in a special sensibility of the bladder to tension, the two properties of the bladder, contractility and sensibility, being intimately related, and being manifested in perfect accord in the physiologic activity of the viscus.

Glycosuria of Nasal Origin.—At the recent International Medical Congress BAYER (*Wiener medizin. Presse*, 1894, No. 15, p. 576), reported a case of occlusion of the nares, attended with various trophic disorders and with glycosuria, in which the symptoms disappeared after the removal of the nasal obstruction. It is explained that in cases of this kind the occurrence of the glycosuria is to be ascribed to the diminished oxidation and the circulatory disturbance resulting from interference with respiration and to a reflex effect upon the medulla oblongata.

THERAPEUTIC NOTES.

Applications of Guaiacol in the Treatment of Orchitis.—At a recent meeting of the Société Médicale des Hôpitaux BALZER and LACOUR (*La Méd. Moderne*, 1894, No. 28, p. 444) reported favorable results from applications of guaiacol in the treatment of orchitis. The application was soon followed by relief of pain and subsidence of the general syptoms, including fever, so that repose and sleep became possible. In the inguinal region pure guaiacol was used, but upon the scrotum an ointment containing from 2 to 5 parts of guaiacol to 30 of vaselin was applied. The applications gave rise to some burning pain, but all distress disappeared in the course of a few hours. The pain was sometimes permanently relieved after the first application, but as a rule two were required daily. As soon as the pain had ceased the applications were withheld, as they did not appear to exert any resolving influence upon the inflammatory exudate. The applications often induced a slight erythema of the scrotum, followed by desquamation and sometimes by fissures. It is suggested that the good effects are brought about principally by a reflex influence upon the terminations of the cutaneous nerves. It is admitted that cutaneous and pulmonary absorption plays a certain part, but the rapidity of the action indicates a local effect.

Potassium Bichromate in the Treatment of Various Gastric Affections.—FRASER (*Lancet*, No. 3685, p. 922) reports the successful employment of potassium bichromate in eighteen cases of various forms of dyspepsia unassociated with evidence of gastric ulcer, and in ten other cases in which distinctive symptoms of ulcer had been present at some previous time. The drug was administered in pill or in solution and on an empty stomach in doses of from one-sixth to one-twelfth of a grain twice or thrice daily, the smaller dose being, as a rule, found sufficient. The remedy showed itself capable of relieving and, often in a short time, of removing the entire group of symptoms (excepting anemia and constipation) encountered in dyspepsia, and especially pain, nausea, vomiting, and gastric tenderness. The drug also displayed anti-putrefactive properties. The effects in acute gastric ulceration with hematemesis were not favorable.

Ammonium Sulphichthyolate in the Treatment of Pulmonary Tuberculosis.—After an experience with more than one hundred cases of pulmonary tuberculosis during a period of longer than two years, COHN (*Deutsche medicin. Wochenschrift*, 1894, No. 14, p. 330) recommends the administration of ammonium sulphichthyolate, mixed with an equal part of water, in doses of from four to forty drops thrice daily. The drug is best given in a generous quantity of water before meals, and the dose is increased gradually one drop of the mixture daily. It may also, though not with the same advantage, be given in pill-form or by inhalation.

Quinin for Enuresis.—POTTS (*Therapeutic Gazette*, vol. xviii, No. 4, p. 217) has observed that in cases of chorea treated with full doses of quinin a coexisting enuresis was also corrected as long as the active administration of the drug was continued. It is suggested that the efficiency of the remedy depends in the case of enuresis, as in that of chorea, upon a stimulating influence exerted upon the inhibitory apparatus of the spinal cord. While the result is a speedy one, it is not a maintained one, and additional tonic measures are required to render the relief permanent.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

TWO WRONGS DO NOT MAKE ONE RIGHT.

THE confusion of mind with which the questions relating to revision of the Code of Ethics of the American Medical Association were approached by the estimable members of the majority of the Committee on Revision is well illustrated by a letter from a justly and highly honored member of that committee, DR. LEARTUS CONNOR, of Detroit, published in the *Journal of the American Medical Association* of May 5th.

In that communication it is apparently assumed that criticism directed against the report of the majority of the committee has been directed against the personal character and motives of the members; and in the arguments brought to sustain the work of the revisers and to defend it against critics, the personality of the critics is similarly made a subject of comment.

No good result can be thus reached. The question is one of principles, not of persons. We have never doubted the probity of the revisers or their honesty of purpose, and we shall continue to honor them as they deserve as men and as physicians, although we must reject them as guides upon questions of general medical ethics. Their character is good, but their work is abominably bad; and it is their bad work, not their good character, that we are discussing and that we urge the members of the American Medical Association to "vote down."

On the other hand, the facts that one of those who oppose the report of the majority of the committee is a professor of medicine, and that another is an authority upon genito-urinary diseases, and a third is the author of a medical book, have likewise nothing whatever to do with the questions under discussion. If these gentlemen have, in teaching or writing to the best of their ability, done anything at variance with the written Code, or with the stricter unwritten code that guides honorable physicians, let them be held to strict account for such action; but let us not be led astray from the matter really before us through the obtrusion of irrelevant issues.

To consider now, stripped of all personal allusion, the argument made for the proposed revision, there will be little difficulty in exposing its weakness.

It is said that in "no single one" of the criticisms of the proposed revision "is a single reason given to support the belief that the adoption of the committee's report would fail to benefit the profession."

This statement evinces a singular blindness. THE MEDICAL NEWS has given *three* cogent reasons out of many possible ones why the adoption of the report would fail to benefit the profession:

1. Because it is an unconditional surrender to quacks and pathists.

2. Because it is an unconditional surrender to nostrum-venders and certificate-mongers.

3. Because it is an unconditional surrender to advertisers and commercial specialists.

It is further said that the proposed revision differs from the present Code "mainly by giving greater liberty of action to the individual physician—only this and nothing more." Of course. What more is wanted? It gives liberty to do what is now prohibited. If it did not, no one would urge its adoption and no one would oppose it.

The object of a code is to impose restraints—or, rather, to state what restraints right-minded men impose upon themselves. If we object to restraint we must abolish the Code *in toto;* that would give still greater "liberty of action to the individual." But if we have a code and its concomitant restraints, that code must not give "liberty" to any action of *questionable propriety*.

THE MEDICAL NEWS would vastly prefer "No Code" to the mutilated Code of the majority of the committee. Those "who study the law that they

may do everything not punishable" might then alter their outward conduct for the worse; but those who refrain from doing evil because it is evil, and not from fear of written statutes, would continue to avoid doing the things the committee seeks to legalize.

But let us see what reason is given for the proposed abolition of restraints: "The committee believed that with the changes incident to the last forty years, especially the better general and technical education prevailing both among profession and people, it would be wise to provide for an increase of the personal liberty accorded to the individual physician."

To this we would reply by a query: How many years does it take for a wrong to "change incidentally" into a right? By the nomination of forty years, does the committee mean to imply that there is a definite rate *per annum*, say two and one-half *per cent.*, at which dishonor becomes honorable and mendacity truthful? The Decalogue was proclaimed several thousand and forty years ago. At what annual rate should the restraints which that Code places upon "individual liberty of action" be removed? Surely the committee does not need to be told that the difference between right and wrong is not a question of years! Neither is it a question of education, whether "general" or "technical." We confess we do not clearly understand the contention as to education. Are well-educated men exempted from the restraints of the present Code? Or were there no well-educated physicians in America forty years ago? Or was it the lack of education "among the people" that rendered a code necessary then that is (partially) unnecessary now? We have always been simple enough to believe that increased education brought increased and not diminished responsibilities; that one might pardon in the ignorant what he would condemn in the instructed. Perhaps, however, this, too, has incidentally changed "in the last forty years."

And now we come to the questions really at issue. "The points of objection to the revision," it is said, "are: 1, the granting of increased liberty of professional association; 2, increased liberty in profiting by mechanical inventions; 3, an increased liberty of promoting professional acquaintance." To these euphemisms for (1) consulting with pathists of all kinds, (2) patenting instruments, and (3) advertising without restraint, the writer should have added (4) "increased liberty in profiting by" the traffic in nostrums and certificates.

The Medical News has thus far said little as to patents, but it has called distinct attention to the effect of the alterations made in the section relating to patents *and nostrums*, in so far as the latter subject is concerned. In the article under review this subject is persistently and consistently ignored. Why? Is it because this is an "increase of liberty" that even the members of the committee are not prepared to defend?

Since our first writing upon the nostrum-question, in all the voluminous literature it has elicited we have yet to hear or read a single word of calm argument on the nostrum-side. Evasion of the issue or personal abuse is all that editors, contributors, or manufacturers' agents have yet produced. Here was a glorious opportunity for a frank and clear statement of the committee's reasons for endeavoring to remove the stigma from nostrum-using and nostrum-promoting. If anything decent could be said on that side, this was the time and place. We sincerely regret that the opportunity was not utilized.

To return to the arguments for "increased liberty":

1. *Professional association.* It is said that "the report does not dictate whom he [the physician] shall select . . . but affords him the liberty of making his own choice. . . . [It] would probably not alter in any respect the practical action of most physicians, but it is natural to suppose that all would feel better to be trusted more fully." Why, then, impose any restriction whatever? Why insist on "legal qualification"? Why insist on "good repute in the community"? If physicians are simply "to be trusted more fully," why the "more"? Why not trust us "fully" without restriction, "more" or less? A reputable physician will not select a disreputable consultant or law-breaking associate—so that the limitation as to "law-abiding and reputable" imposed by the committee becomes, when we talk of "trusting," simply insulting! The truth is, the committee wants to legalize consultation with homeopathists, and instead of saying so directly beats around the bush. There is only one proper way to effect this object, and that is to repeal the present prohibition against such consultation by a direct vote. Each voter will then know what he is voting on; and if the repeal be carried, the question will be relegated to the domain of individual conscience. As admitted, repeal "would probably not alter in any way the practical action of most physicians"; elevated public sentiment would be against consult-

ing with sectarians and quacks, and those who did so could not cite a platitudinous code in their defense.

2. *Patents.* "The report places the copyrighting of books and the patenting of mechanical appliances [and drugs?] used in medicine and surgery on the same basis. . . It is strange that gentlemen . . . . who have made lots of money out of the profession by securing copyrights . . . should kick against permitting the doctor who cannot write a book, but is able to invent a valuable instrument, from trying to make some money by his special talent."

In discussing the consultation question the element of money-making was not avowed; we therefore did not comment on it. Here, however, it comes undisguisedly to the front. Now, to do good work and be well paid for it is all right. We all want that. But to simply desire to "make some money out of the profession," by books or otherwise, is not a very "elevating" sentiment. We have in a previous editorial shown the difference between copyrights on books and patents on medicines and instruments, but will repeat for the committee's benefit, that *one is payment for instruction*, while *the other is tribute for permission to use a certain drug or instrument.* The copyright paid to the author of a book is exactly parallel with the fee paid a lecturer, or demonstrator, or instructor. The author teaches his reader how to do something, perhaps to make a diagnosis, or perhaps to perform an operation, or he imparts information as to the results of historic or scientific research, and he is justly entitled to payment for his labor. But, withal, he does not set up a monopoly; his opinions may be and are freely quoted, and thus made available to instruct many who never pay him a cent directly or indirectly.

On the other hand, one who patents a medicine or an instrument does set up a monopoly, and thereby exacts a tribute from each one who uses his instrument or his drug. For what is this payment made? For instruction? Not at all—but for permission to avail oneself of a certain method of treatment. It is but one step removed from nostrum-vending, and one is not surprised that a committee that defends the patenting of instruments and drugs should likewise remove the condemnation of the Code from the practice of using and recommending nostrums. But even granting, for argument's sake, that there is no difference between the copyrighting of books and the patenting of instruments and medicines, what should be the proper course of the committee and the Association? To legalize one wrong because another is committed, or to prohibit both? And what has the personal authorship of Dr. X, Dr. Y, or Dr. Z to do with a question of moral principle? A cause strong in itself does not resort to the *argumentum ad hominem.*

3. *Advertising.* "Concerning the increase of liberty given by the report to physicians in making known to *their professional brethren* their special qualifications, physicians outside of hospitals, dispensaries, and medical colleges are permitted to follow the example of those inside of these institutions. It simply puts the entire profession upon the same plane in advertising itself (*sic*)." [*Italics* are ours.]

Is this entirely ingenuous? Are cards and signs intended for the information of one's *professional brethren?* Do hospital physicians use cards and signs of the character proposed? Does any member of the committee sincerely believe that it would tend to "elevate the profession" to see such signs as, for example [if the dead giants named will forgive the association for the sake of the lesson]: DR. AGNEW, *Expert in Fractures and Amputations;* DR. WALLACE, *Obstetric Specialist;* DR. ATLEE, *The Celebrated Ovariotomist;* DR. GERHARD, *Special attention given to Physical Diagnosis*—exposed to public view? Can he imagine men of the caliber of those named resorting to such displays? Does he believe that the University of Pennsylvania, in placing Dr. Agnew's name in the public announcement of its course of instruction was "advertising" that surgeon? On the contrary, was it not making legitimate use of Dr. Agnew's reputation to advertise the University?

We agree with DR. CONNOR that there is much abuse in the matter of advertising persons, institutions, and operations. But the remedy is not the one he proposes—to legitimize advertising by everybody. Rather enforce the Code as it stands, and send to Coventry the "great hospital physician or college professor" whose "picture is printed in the great dailies," and whose "interviews and notices of big operations appear in the daily papers." THE MEDICAL NEWS has never concealed its opinions on this subject, and the editor might well object to the use of his name as an example of an evil he has gained a thousand enemies by fighting.

Once more we say: "Two Wrongs do not make a Right." The fault lies, not in the Code, but in ourselves. The Code gives no "exclusive privileges" in advertising or other shame. It is the timidity of the medical press and the medical profession in the presence of successful rascality that permits "hospital surgeons and college professors" to violate not only eternal ethical principles but the letter of the written Code. Let us try the effect of enforcing the law before we talk about repealing it, and thus legitimizing conduct that is now, at least theoretically, prohibited.

We repeat that under existing circumstances there is only one of two courses open to the American Medical Association, if it would retain its self-respect. One, and the best, is to retain the present Code unaltered; the other is to abolish the Code entirely, and trust to public opinion to maintain the proper standard of conduct. But to legalize improper conduct by the adoption of the majority report upon Revision would be as disastrous as it would be foolish.

EDITORIAL COMMENTS.

The Possibilities of Thyroid Therapy.—In view of the marvellous results obtained from the administration of some preparation of the thyroid gland in one form or another in the treatment of myxedema and allied affections, it is not at all surprising that a remedy so distinctly useful should be tentatively and experimentally employed in a large number of other conditions, including those in which there is obvious or only possible involvement of the thyroid gland, as well as those in which there is no reason whatever to suspect such involvement. Reports of successes must under these circumstances be received with judicial skepticism, particularly if not presented by one of established reputation and unassailable character. Doubt and hesitancy vanish, however, in the face of reports made by such a careful observer, conservative thinker, and competent authority as BYROM BRAMWELL, of Edinburgh, who at the last meeting of the British Medical Association reported successful results from the employment of preparations of the thyroid gland in the treatment of psoriasis. Further observations seem but to confirm the earlier conclusions, and to indicate even a still wider field of usefulness for preparations of the thyroid gland. Being aware that cases of myxedema manifested a predisposition to tuberculosis, and not infrequently died from the intercurrent disease, and reasoning that this association might be due to the absence from the juices and the tissues of the body of the secretion of the thyroid gland, DR. BRAMWELL (*British Medical Journal*, No. 1737, p. 786) was led to use of thyroid extract by internal administration in the treatment of two cases of lupus that came under his observation, and with pronounced benefit. The results in these cases suggested the possibility of the thyroid extract also being useful in other forms of tuberculosis, and as full doses are rather depressing, it would be wise, before employing the remedy in cases of pulmonary tuberculosis, to test the effect of its administration in cases of scrofulous disease of the cervical glands, bones, and joints in which the disease is not sufficiently advanced to demand surgical treatment. Finally the thought is thrown out that by improving the nutritive condition of the cutaneous structures thyroid extract may prove useful in the treatment of leprosy, and that by increasing the resisting power of the tissues it may also be of service in cases of carcinoma. From the apparently selective action of the thyroid preparations upon the skin and its adnexa we have ourselves thought that good results ought also be obtained by the internal administration or subcutaneous injection of thyroid extract in the treatment of erysipelas.

Migraine in Infancy.—Intelligent observation and accumulating experience show that infancy does not escape many of the neuroses (perhaps we may learn to say none of the neuroses) observed in mature life. The diagnosis is obviously embarrassed by the difficulties attendant upon the elicitation of symptoms. Thus, it has been conclusively demonstrated that infants and young children may be unequivocally hysterical, and there is reason to believe that they may be similarly affected with migraine. Evidence in support of the latter proposition is furnished by the report by BETZ (*Memorabilien*, March 24, 1894, p. 79) of the case of a female infant, thirteen months old, that at a time when influenza was prevalent, was seized with an attack of febrile gastro-intestinal catarrh, attended with diarrhea. In the course of this illness the infant was seized with twitching, affecting principally the hands and arms, occurring intermittently and also during sleep. It further indicated by gesture its complaint of pain in the head. Consciousness was perverted, but not lost. It was observed that the child manifested a tendency to grasp the left side of its head and to lie upon its left side, and on examination the left side of the head was found to be somewhat smaller in size than the right, while further investigation disclosed the fact that an elder sister and the mother both presented a similar asymmetry and suffered from attacks of migraine. The interesting features of the case are the age, the sex, the heredity, and the asymmetry of the face. In a diagnostic connection it is pointed out that on palpation the temperature may be found higher on the affected side than upon the opposite side, and that during the attack of pain the upper lid upon the affected side displays a tendency to droop. Therapeutically general rather than special measures are indicated. Diathetic and hereditary tendencies, as well as complicating conditions, are as far as possible to be corrected or removed. Opium may be used internally and topically with caution; ice-water compresses, topical applications of menthol, cocain, or ether may aid in the relief of pain.

New York Colony for Epileptics.—Some months ago we had the pleasure of noting (THE NEWS, Dec. 16, 1893, p. 694) the opening in Gallipolis, Ohio, of the first State Hospital for Epileptics in the United States. We have the gratification of being able to announce that the Legis-

lature of New York State has passed, and the Governor has signed, a bill establishing a colony for epileptics in that State. The colony is named after the late Oscar Craig, for some years President of the State Board of Charities. The bill provides for the purchase of a tract of 1875 acres of beautiful land in the Genesee Valley, near Mount Morris, in Livingston County. This tract is all in one piece, well watered by brooks, and consisting of fine fields, wood-land, and orchards, and already provided with picturesquely-grouped buildings to the number of thirty-five. It has been a colony of the Shakers for twenty or thirty years, and is perfectly adapted to its new use.

The law requires that all of the buildings put up should be on the village plan. A board of five managers is provided for, and by the appointment of the Governor has been constituted as follows: Dr. Frederick Peterson, of New York; Mrs. C. E. Wadsworth, of Geneseo; George M. Shull, of Mount Morris; Dr. Charles E. Jones, of Albany; and W. H. Cuddeback, of Buffalo. The managers serve without salary, and meet at the colony once or oftener monthly.

At the organization of the Board in Albany, on the 3d of May, Dr. Frederick Peterson, of New York, was elected President, and George M. Shull, of Mount Morris, Secretary.

A medical superintendent, steward, matron, pathologist, nurses, school-teachers, teachers of various industries and arts, and so on, are to be appointed as needed; but the colony will probably not be ready to receive patients before the autumn of 1895.

It is thought that the colony will ultimately number from fifteen hundred to two thousand members. As soon as possible the six hundred epileptics in the county almshouses will be taken in charge. Later private patients will be received at prices corresponding to the accommodations asked for. It is believed that the colony will become self-supporting in the course of time, and that it will grow into an industrial and agricultural village that will more than rival the similar and famous colony at Bielefeld, Germany, upon which this is, to a certain extent, modelled.

The managers may accept any bequests of persons interested in the welfare of epileptics, and it is anticipated that many charitable wealthy people will build cottages upon the splendid sites on the tract to bear their names and exist as lasting memorials to their desire to serve humanity in this wise.

The time has arrived when the State of Pennsylvania must make similar provision for her large contingent of epileptics. The Legislature can no longer fail to heed the appeals from County Medical Societies and the State Medical Society for the establishment of one or more epileptic colonies.

Dr. William P. Dodson died May 11th, at his home in Philadelphia, at the age of ninety-three years. He had spent the greater part of his professional life in the Southern United States, whither he had been compelled to remove on account of some affection of the throat.

Wm. Goodell, M.D., LL.D.—The degree of Doctor of Laws was conferred upon Dr. Wm. Goodell at the recent commencement of Jefferson Medical College.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Forty-fourth Annual Session, held at Philadelphia, May 15, 16, 17, and 18, 1894.

First Day—May 15.

Morning Session.

The Forty-fourth Annual Session of the Medical Society of the State of Pennsylvania, which was originally to have convened at Gettysburg, was opened on Tuesday morning, May 15th, in the Presbyterian Church building, Twelfth and Walnut Streets, Philadelphia. Delegates from all the county medical societies of the State were present in large numbers, and the usual spirit of fraternal interest was manifested. Shortly after the stated hour of convening, 9.30 o'clock, the President, Dr. H. G. McCormick, of Williamsport, called the meeting to order, and the meeting was inaugurated by prayer by the Rev. A. B. Philputt. His Honor, Mayor Stuart, delivered the address of welcome, in which he dwelt upon the fame and pre-eminence of Philadelphia as a center of medical learning and the propriety of its selection as the place of convention for the State Association. Dr. E. E. Montgomery, the Chairman of the Committee of Arrangements, also welcomed the visiting delegates to the hospitality of the city and medical fraternity and presented the printed program as the order of business for the session.

The report of the delegates to the session of the American Medical Association held last May in Milwaukee, Wis., was made by Dr. Wm. B. Atkinson. Chairman of the Committee. He reported a successful and pleasurable meeting, with an attendance of almost nine hundred delegates from the entire country. The report was accepted as read and placed on file.

Dr. Atkinson, as Secretary of the State organization, reported a membership of 2500. All of the county societies have shown a slow but healthy growth. The number of members added during the year is slightly in excess of that of previous years. He urged the secretaries of the various medical societies to invite all members of the profession in good standing and not already members to unite with their respective societies.

The Treasurer, Dr. G. B. Dunmire, of Philadelphia, reported a cash balance in bank of $1978.49, after deducting the expenses for the year, which amounted to $2143.75. The report was referred to the Auditing Committee.

On motion of Dr. Atkinson, all members of the Philadelphia County Medical Society not delegates to the meeting were invited to attend the sessions of the Convention and participate in the discussions.

Dr. Edward Jackson, in behalf of the Committee on Publication, reported that 2500 copies of the *Transactions* of the Association had been printed at an expense of $1070. Copies of these had been distributed among the various hospitals, colleges, and county medical societies of the State. The committee suggested that the character of the binding of the *Transactions* be improved, which could be done with but slight additional expense. It was also suggested that a page be

devoted to information concerning the American Medical Association, giving instruction as to how to become a member in that organization, etc. The report of the committee was accepted.

Dr. CHARLES W. DULLES, Chairman of the Committee on Scientific Business, stated that owing to the remoteness of the homes of the members of the committee, the work had been carried on principally by correspondence. Progress was reported, and expenses amounting to $33.73 incurred, which, it was resolved, should be placed in the hands of the Treasurer for payment.

The Legislative Committee, DR. H. G. MCCORMICK, of Williamsport, Chairman, reported the passage of the Medical Examiners' bill, and the appointment of the members of the Board.

The first examination under the new law of physicians desirous of entering upon medical practice in Pennsylvania will be held on June 11, 1894, at Pittsburg and Philadelphia.

The Committee also reported that, in accordance with the instructions given it by the Society, it memorialized the Legislature on the subject of the care of the insane. The Senate passed a bill providing for the changes which the Society desired, but the House of Representatives failed to do so. The report of the Committee was accepted, and the Committee discharged with the thanks of the Society.

DR. LIPPINCOTT, Chairman of the Committee on Contagious Ophthalmia, stated that the Committee had investigated the methods of eradicating this disease. Circulars had been sent to the ophthalmic surgeons throughout the State soliciting suggestions and assistance. The greatest danger lies in the general ignorance as to the gravity of the affection. The Committee urged additional inspection and also the importance of more rigid examination of immigrants for the existence of trachoma, which it has been ascertained is most common in New York City, chiefly because that city is the main port of immigration in this country. The report was accepted and the Committee discharged.

DR. ATKINSON read the resolutions adopted by the Philadelphia County Medical Society concerning the conduct of the *Journal of the American Medical Association* in reference to nostrums, etc. These resolutions were published in THE MEDICAL NEWS of April 28, 1894, p. 463. The discussion of the communication was postponed until Wednesday morning.

DR. G. M. GOULD read the following preamble and resolution, which were unanimously adopted:

Whereas, By all physicians it is admitted that a large proportion of the blindness of the world is due to the disease called ophthalmia neonatorum; and

Whereas, The well-known treatment of this disease by a physician, if at a sufficiently early period in its course, almost always results in preventing the blindness that would otherwise follow; and

Whereas, A committee appointed by the Ophthalmological Section of the American Medical Association at its last meeting has, after thorough consideration, drafted a blank form of a law and urged its passage by all State Legislatures, as well as advised all physicians to aid in securing the passage of such a law; and

Whereas, This blank form of a law drafted by the said Committee is as follows:

The people of the State of —— represented in Senate and Assembly, do enact as follows:

SECTION 1. Should one or both eyes of an infant become inflamed, or swollen, or reddened at any time within two weeks of its birth, it shall be the duty of the midwife or nurse having charge of such infant to report in writing within six hours to the health-officer or some legally qualified physician of the city, town, or district in which the parents of the infant reside, the fact that such inflammation, or swelling, or redness of the eyes exists.

SEC. 2. Any failure to comply with the provisions of this act shall be punished by a fine not to exceed two hundred dollars, or imprisonment not to exceed six months, or both.

SEC. 3. This act shall take effect on the —— day of ——, eighteen hundred and ninety- ——.

And whereas, Five States have already placed upon their Statute Books laws similar to or identical with the foregoing law, while in other States the same measure is under consideration; and

Whereas, The Philadelphia County Medical Society on May 9th unanimously passed a resolution indorsing the law recommended by the Committee of the Ophthalmological Section of the American Medical Association, and appointed a committee to devise means and methods of securing the enactment of such a law by the Pennsylvania State Legislature; therefore be it

Resolved, 1. That in the opinion of the Medical Society of Pennsylvania it is of the most vital importance to the welfare and happiness of the community, and to the good name of the State of Pennsylvania, which has always been foremost in matters pertaining to the health of her citizens, that the law recommended by the Committee of the Ophthalmological Section of the American Medical Association should be enacted by the Legislature of the State, and the Medical Society of Pennsylvania respectfully requests the Honorable Representatives of the State at Harrisburg to do all in their power toward placing such a law upon the Statute Books of the State of Pennsylvania.

2. That a committee of three be appointed to coöperate with the Committee of the Ophthalmological Section of the American Medical Association and the Philadelphia County Medical Society, to devise means and methods of securing the enactment of such a law.

On motion of DR. JACKSON an amendment was made and carried, that the Committee be given power to add to itself associate members.

DR. HIRAM CORSON moved that a Legislative Committee be appointed, and instructed to investigate the subject of the care and treatment of the insane, and the organization and construction of hospitals for the insane. The motion was referred to the Committee on Legislation when said committee should be appointed.

On motion of DR. ATKINSON, Dr. R. P. Granger, of New York, was extended the courtesies of the floor.

DR. J. C. GABELL, of York, offered the following resolution:

Resolved, That a committee of seven be appointed by the President of this Society to consider the feasibility of and make suggestions relative to the appointment of an inspector, whose duty it shall be to aid the State Board of Medical Examiners of Pennsylvania to more efficiently carry out the best interests of medical legislation in this Commonwealth, the committee to report under unfinished business on Wednesday. Carried.

An invitation was read from the Luzerne County Medical Society to hold the meeting in 1895 at Wilkesbarre, Pa. Referred to the Committee on Nominations. Also a resolution was offered to the effect that the Society enters its protest against the use of the name "Allopath," as applied to regular members of the profession. Carried.

DR. S. SOLIS-COHEN offered a resolution expressing it as the sense of the Pennsylvania State Medical Society that the Code of Ethics of the American Medical Association be not altered, and instructing its delegates to vote in accordance therewith. Carried unanimously. At 11.30 o'clock the meeting adjourned until 3 P.M.

AFTERNOON SESSION.

The Address in Surgery, delivered by Dr. G. D. NUTT, of Williamsport, was limited to some general remarks upon recent progress in surgery. The advances in brain-surgery and spinal surgery, including the treatment of epilepsy, the modern methods of hysterectomy, and the management of ectopic pregnancy, the exploration of the kidney, were all touched upon. Attention was called to the marked influence of aseptic surgery in reducing the mortality of major operations. The value of Wyeth's hip-joint amputation by means of skewers received especial mention. Dr. Nutt dwelt largely upon the importance of an early diagnosis in such medico-surgical diseases as appendicitis, obstruction of the bowel, etc.

"The Radical Cure of Hernia," was the title of an interesting paper read by DR. E. LAPLACE, of Philadelphia, who claimed that the term "radical" indicated of necessity a certain amount of accuracy. In considering the subject of the predisposing causes of hernia, he doubted the importance of elongation of the mesentery as a causative factor, but considered weakness of the abdominal walls as the most essential element in the etiology. The treatment of hernia includes removal of the hernia and complete retention of the bowel within the abdominal cavity; and secondly, the use of such measures as will insure strengthening of the abdominal walls. There have been advocated many methods of removing a hernia, but the writer favored the McBurney method, in which the sac is dissected and ligated, and granulation of the canal is favored by packing with iodoform-gauze. The firmest citatrices are those resulting from burns; therefore, he suggests the cauterization of a portion of the canal. Three weeks of granulation are absolutely necessary to prevent a non-recurrence of the condition. In all cases of small hernia, Bassini's operation has been followed in his hands by gratifying results. He reported 87 cases operated upon by himself in the last four years, with a mortality of *nil*; 27 scrotal cases, all large, were operated on by McBurney's method, resecting the sac, and transplanting the cord, as in Bassini's method. There were three recurrences. Sixty operations were performed according to Bassini's method, and a double operation in four patients. Silkworm-gut was used altogether. In five cases there were signs of recurrence, and these five patients were suffering from general malnutrition, and had concomitant conditions (syphilis, tuberculosis, etc.). Suppuration must be prevented by a judicious application of sutures to prevent strangulation of the tumor—not too tightly drawn—and by thorough asepsis. For three months an abdominal support must be worn. Massage of the abdominal walls was recommended to increase the nutrition of these parts. In conclusion, he regarded hernia as primarily a condition dependent upon trophic changes in the abdominal wall. If the hernia be small, the sac is not opened; if large, it is opened by McBurney's method, and the canal is cauterized with the thermocautery, and allowed to granulate. He recommended early operation for a radical cure in every case of incipient hernia.

DR. F. LE MOYNE, of Pittsburg, read a paper entitled "Modification of Pirogoff's Amputation." The modification consists in a retention of the extremities of the tibia and fibula to prevent shortening. The calcaneum is sawed through less obliquely. Good results have followed this operation. Dr. Agnew had done the same operation, also with good results.

DR. J. V. SHOEMAKER, of Philadelphia, gave some interesting clinical observations upon diseases of the skin. Six patients were shown suffering from psoriasis. The etiology varied in each case. In one case there was associated a nervous condition; in another the affection was due to rheumatism and a gouty diathesis; in another there was a disturbance of the gastro-intestinal tract. The rheumatic case, fifteen years ago, under the administration of potassium iodid, had been cured. The rheumatism has now returned, and with it the eruption. The man was taking ten grains of sublimed sulphur and one grain of cream of tartar, and the eruption was gradually fading. The treatment in each case varies with the cause. If due to gastro-intestinal lesions, dilute hydrochloric acid and liquor pepsin before meals, with sulphate of strychnin after meals, will suffice. One case had been given fried thyroid gland in the morning and evening, and the lesion of the skin was fading. Dr. Shoemaker was unable to say just how the thyroid extract acted in psoriasis.

DR. J. C. MCALLISTER, of Driftwood, read a paper on "Puerperal Eclampsia and its Treatment chiefly by the Hypodermatic Use of Veratrum Viride." He adopted the view of the etiology of the affection which ascribes it to the presence of retained excrementitious matter in the blood. The presence of albumin in the urine is not sufficient cause for prognosticating the onset of eclampsia; the albuminuria is rather the result of the eclampsia. The proper treatment of eclampsia is mainly eliminative by means of the skin, bowels, and bladder. For this purpose a variety of remedies has been advocated—venesection, chloral, chloroform, morphin. They are all of service, but in veratrum viride we have a drug which is almost free from danger, and which has a marked effect in reducing the action of the heart. By watching the pulse the efficacy of the treatment can be demonstrated. He recommended fifteen drops of the tincture as an initial dose, with whiskey or brandy as required. As a rule, the veratrum should be continued for a day or two until the convulsive tendency is over. When there is not great stupor he advised morphin hypodermatically in addition to the veratrum. In stertorous cases atropin is especially indicated. In one case he administered $\frac{1}{40}$ grain in divided doses within twenty minutes.

DR. FISHER, of Philadelphia, considered the time of the occurrence of the convulsions as an important ele-

ment in the treatment. He favored the use of hot baths rather than the use of diaphoretics internally administered.

"Chronic and Recurrent Appendicitis" was the subject of a paper read by DR. JOHN B. DEAVER, of Philadelphia, which will be published in a future number of THE MEDICAL NEWS.

DR. ORVILLE HORWITZ, of Philadelphia, contributed a paper upon "The Treatment of Stricture of the Urethra." He said that, generally, dilatation is the usual and safest method of treatment. A small-sized bougie should be tried first, in order to avoid causing abrasion or laceration of the mucous lining; the size of the instrument may be increased as the pain and bleeding diminish. The instrument should be introduced once in three days, and should be sterilized and anointed with an antiseptic ointment containing oil of eucalyptus. This is the safer method in diabetes and advanced renal disease. The death-rate of internal urethrotomy is 2 per cent., while dilatation is never followed by death. In *continuous* dilatation a small filiform bougie should be used and allowed to remain three days. Enough dilatation will then have been accomplished to proceed with some other method. This plan is of service in cases of small stricture in the membranous portion of the urethra, or in cases in which the stricture at any point is very tight. A preliminary injection of carbolized oil is a valuable procedure.

DR. DEAVER was surprised to hear that the mortality of internal urethrotomy was 2 per cent. He had operated many times, without a death. He was not an advocate of the operation in all cases, but believed it has a larger scope than that given it by Dr. Horwitz. He has had more success in external urethrotomy without, than, with the use[of a staff.

DR. JOHN H. BRINTON, of Philadelphia, in the treatment of deep stricture indorsed Dr. Horwitz's paper. He had employed rapid dilatation for twenty years, and had never met with a death. He had never met with a deep-seated idiopathic stricture through which he could not pass a filiform bougie.

DR. O. H. ALLIS, of Philadelphia, read an interesting paper on "Cramming in Medical Schools," which is to appear in a future number of THE NEWS.

The following papers were read by title: "Section of the Tendo Achillis in Certain Fractures and Dislocations of the Lower Extremity," by Dr. T. S. K. MORTON, of Philadelphia; "The Treatment of Naso-Pharyngeal Catarrh," by DR. WM. R. HOCH, of Philadelphia; "Thyroidectomy in the Treatment of Goiter," by DR. JOHN B. ROBERTS, of Philadelphia; "Rural Sanitation," by DR. T. H. WEAGLY, of Marion; and "Amputation Below the Knee," by DR. M. PRICE, of Philadelphia.

DR. D. BRADEN KYLE, of Philadelphia, contributed a paper entitled "The Effect of La Grippe on Normal and Diseased Respiratory Mucous Membranes." He said that the respiratory mucous membrane consists of a basement-membrane upon which are epithelial cells, and under which are bloodvessels, glands, and nerves. Its essential function is to secrete mucus. Any inflammatory lesion first alters the submucosa; this alteration depends upon the variety and the severity of the inflammation. He has found no germ constantly present. In those cases without preëxisting lesion of the mucosa the transudate from the vessels is more than a mere inflammatory exudate; it is a highly coagulable, albuminoid material which infiltrates the tissue. In those cases in which there were preëxisting lesions the exudate was of the same character, but its effect on tissue and function was inconstant, being controlled largely by the preexisting pathologic alteration. In all conditions the mucosa must be cleansed and rendered aseptic, after which a stimulating application may be made. Alteratives as well as tonics and stimulants must be administered internally.

SECOND DAY, MAY 16TH—MORNING SESSION.

The meeting was called to order at 9.30 o'clock, when the "Address in Medicine" was delivered by Dr. W. S. FOSTER, of Pittsburg. He spoke of the great multiplicity of proprietary mixtures, especially those containing the coal-tar preparations, which were likely to give rise to considerable confusion in the proper selection of medicines. The reaction in favor of blood-letting was noted, and also the controversy over the respective merits of chloroform and ether. The employment of tincture of digitalis in continued fevers had been followed by excellent results. He believed that the early administration of digitalis in typhoid fever, producing as it does an increase in the activity of the heart, will tend to tide the patient over the period of depression. In pneumonia, also, in conjunction with strychnin, it is of service. The use of free oxygen gas in pneumonia is a valuable advance in the treatment of that disease. He believed that preventive medicine has assumed such proportions as bid fair to place it in the foremost rank in the management of pathologic conditions.

"Christian Science in its Relation to the Medical Profession," was the title of a thoughtful paper read by Dr HILDEGARDE H. LONGSDORF, of Carlisle. She regarded this doctrine as the most pretentious and most successful outgrowth of our higher civilization. In an ingenious way she revealed the absurdities of this highly developed species of quackery.

On motion of Dr. COHEN, of Philadelphia, it was agreed to have one thousand copies of Dr. Longsdorf's paper printed by the Committee on Publication, for distribution among the laity.

DR. S. S. COHEN delivered a spirited address upon the query, "Should the *Journal of the American Medical Association* be used to Promote Quackery?" He paid an eloquent tribute to the *Pittsburg Medical Review*, which he considered as the cleanest and most outspoken medical publication in this country. He quoted the article in the Code of Ethics of the American Medical Association on patent medicines, and the duties of physicians in regard to their recognition, manufacture, and dispensation. This is an organic law of the American Medical Association, and never since its promulgation has it been repealed. It is a trust of the American Medical Association, and should as such be religiously carried out, yet the pages of the journal of this Association are filled with the advertisements of secret nostrums. In criticising the Trustees of the *Journal*, he was not criticising them personally, but only their official conduct, which he believed should ever be open to criticism. He protested that the Pennsylvania State Medical Association,

that the American Medical Association, be not made partners in such affiliations with the proprietors of quack preparations.

DR. THOMAS, of Philadelphia, stated that one of the reasons for the foundation of the *Journal of the American Medical Association* was that the profession should have a pure, ethical journalism. Now we see that *Journal* going as far or even further than other journals in helping to support itself by publishing quack advertisements. He offered resolutions embracing those adopted by the Philadelphia County Medical Association, resolutions to the same effect, but further sanctioned by the action of the State Medical Association, and to be presented to the American Medical Association at its meeting in San Francisco.

Resolved, That the Medical Society of the State of Pennsylvania hereby indorses the resolutions concerning the conduct of the *Journal of the American Medical Association* transmitted from the Philadelphia County Medical Society.

Resolved, That it is the opinion of this Society that if the finances of the American Medical Association do not permit of the publication of a journal that does not violate the Code of Ethics by the insertion of notices of secret nostrums and other objectionable advertisements, the Trustees should be instructed to cease publication.

Resolved, That these resolutions, together with the resolutions of the Philadelphia County Medical Society, be officially transmitted to each Trustee of the American Medical Association, and that the delegates to the American Medical Association elected at this meeting be instructed to present the same to the meeting of the American Medical Association at San Francisco, and to use every honorable endeavor to secure such action as shall effectually remedy the matter complained of.

DR. BISHOP suggested that if it had become necessary for the support of the *Journal* that secret nostrum advertisements find a place upon its pages, it would be well to make the suggestion at the San Francisco meeting that the publication of the *Journal* be stopped or that the Board of Trustees be reconstructed.

DR. JEFFRIES, of Delaware County, suggested that if he or any other member of any of the County Medical Societies should open themselves to such criticism as had the Board of Trustees of the *Journal of the American Medical Association*, they would have been reprimanded, suspended, or expelled from the medical organization, and he would be inclined to take similar action against the Trustees of the *Journal*.

DR. B. H. DETWILER, of Williamsport, read a paper entitled "Croup and Diphtheria," in which he advocated early depletive and revulsive treatment in all cases of membranous croup. In this way he believed that the high mortality of the disease could be diminished and intubation not be required.

DR. S. SOLIS-COHEN regarded non-diphtheric or true croup as being exceedingly rare. True croup is a sthenic inflammation, while diphtheric croup is toxic and is associated with a degree of toxemia. Hence the danger of confounding the two conditions.

DR. CHARLES HERMON THOMAS, of Philadelphia, read a paper entitled "Eye-strain from Muscular Causes and its Treatment by Tenotomy." He regarded the diplopia-tests as indispensable in arriving at any conclusion. He did not believe that a complete tenotomy is required in every case of heterophoria. A gain of from 1° to 8° may be obtained without complete severance. He quoted cases from his note-book.

DR. LIPPINCOTT, of Pittsburg, regards photophobia as the principal symptom of muscular asthenopia. He would also call attention to the association existing between epilepsy and muscular asthenopia.

Under the head of new business DR. GABLE presented the following report of the committee appointed on Tuesday:

Resolved, That the Secretary of each county society is requested to forward at once to the Secretary of the State Board of Medical Examiners a correct list of registration of doctors under the last Act, on and from the 1st day of March last, and quarterly thereafter; and in communities where there are no county societies the President of this Society shall appoint a member of this Society living in such county to procure such list, and in any case of neglect by either the officers aforesaid or the appointee to send such a list, the Secretary of the State Board of Medical Examiners of this Society shall be empowered to procure the same; and further be it

Resolved, That we recommend that $500 of the moneys of the Society, or so much thereof as may be necessary, be appropriated for the examination of the registration of physicians in this State, with the view of enforcing the Medical Examiners' Act lately passed, said money to be expended only under the direction of the State Board of Medical Examiners representing this Society, and that they shall approve all bills before being paid. Further, that the said Board of Examiners report at the annual meeting of this Society their action and expenditures under this resolution.

DR. LE MOYNE, of Allegheny, offered a resolution to the effect that at the meetings of the State Medical Association the time allotted to the reading of papers be reduced to ten minutes, and the discussion thereof to five minutes per man. As this resolution involved an alteration of the Constitution, it was laid on the table until the next annual meeting.

AFTERNOON SESSION.

At 3 o'clock the Committee on Nominations, Edward Jackson, M.D., Chairman, made its report. The officers selected for the succeeding year were as follows: President, Dr. John B. Roberts, of Philadelphia; First Vice-President, Dr. S. C. Stewart, of Clearfield County; Second Vice-President, Dr. J. A. Lippincott, of Allegheny County; Third Vice-President, Dr. J. H. Wilson, of Beaver County; Fourth Vice-President, Dr. R. Armstrong, of Clinton County; Secretary, Dr. W. B. Atkinson, of Philadelphia; Assistant Secretary, Dr. H. G. Kreutzman, of Franklin County. Chambersburg was selected as the place of the next meeting.

The address on "Mental Diseases" was delivered by DR. T. M. T. MCKENNAN, of Pittsburg. He said that the toxic origin of insanity is now generally accepted. This poison may be generated in the body of the mother or in the body of the patient himself. Auto-intoxication is the cause and not the effect of the mental condition. This may be proved by the fact that injection of the urine of a maniacal patient into the tissues of an animal will produce delirium and exaltation of the corporeal

activity, while the urine of a melancholy patient when injected produces marked bodily depression. The predisposition to psychoses should contraindicate operative procedure. The propriety of examining insane female patients cannot be doubted. The main cause of insanity in women lies in disease of the pelvic organs. The frequency of renal inadequacy in the insane has been noted, and insanity due to kidney-trouble is much more frequent than has been supposed. The close etiologic relationship between syphilis and general paralysis of the insane is now becoming quite clear. Hypnotism as a curative agent is only of value in cases of insanity of hysterical origin.

Dr. Charles W. Dulles, of Philadelphia, presented a report on "Hydrophobia," which will be published in a future number of The Medical News.

Dr. Charles K. Mills, of Philadelphia, was somewhat conservative in his views as to whether or not hydrophobia as a disease does exist. It is at any rate an extremely rare disease. He has seen a patient with sclerosis die in the Philadelphia Hospital with symptoms of hydrophobia; other nervous diseases may give rise to the symptoms of hydrophobia, and doubtless many of the so-called cases of hydrophobia are in reality cases of mistaken diagnosis.

Dr. S. MacCuen Smith, of Philadelphia, read a paper on "Simple Inflammation of the Middle Ear and their Sequelæ." In all cases the ears of the newborn child should be examined, and if no accumulations in the external auditory meatus be found, and the membrane seems to be inflamed to any extent, the middle ear should be inflated according to Politzer's method. There are two forms of acute inflammation of the middle ear: one is due to exposure to cold, wet, etc., and the other is due to the entrance of some infectious agent. Whatever the cause of the inflammation, the inflammatory exudate will undergo fatty degeneration unless removed. Inflation of the ear is the important element of treatment in most cases. Deaf-mutism must be regarded as a sequel of some preëxisting inflammatory disease.

Dr. Charles H. Burnett, of Philadelphia, had never seen an acute inflammation of the middle ear in a newborn child. The common cause of dermatitis in the external ear is swabbing out of the canal with cotton, and this in time may produce middle-ear disease. The external ear of the newborn child should be left severely alone.

Dr. B. A. Randall, of Philadelphia, suggested that in making an examination of the ear of an infant the auricle should be drawn *downward* as well as backward in order to facilitate the procedure. When injections are used in the ear, the water should be hot, of a temperature of from 110 to 118°.

Dr. Anna M. Fullerton, of Philadelphia, read a paper entitled "Studies in Obstetrics and Gynecology," based on eight years' experience in the hospital of the Woman's Medical College.

Dr. W. C. Hollopeter, of Philadelphia, contributed a paper entitled a "Brief Review of the Therapeutics of Whooping-cough." He considered whooping-cough as a very fatal, perhaps the most fatal of all diseases of infancy. This was due to the gravity of its numerous sequelæ. He considered an early recognition of the nature of the disease during the catarrhal stage as of the utmost importance. In making his diagnosis he trusts to the peculiar puffiness often observable in the mucous membrane of the eyes.

Dr. G. G. Davis, of Philadelphia, gave an interesting exhibition of some "Cases of Amputation near the Ankle," one of which had been operated upon by a country physician with perfect results; another, a boy of seventeen, had had a Chopart's amputation, and was able to go off on long tramps. Dr. Davis wished to prove the superiority of the low amputation over amputation below the knee.

The "Address in Obstetrics" was delivered by Dr. E. E. Montgomery, of Philadelphia. He touched upon a few of the more important conditions from a surgical standpoint. Symphysiotomy he regarded as capable, within certain limits, of decreasing the danger to both mother and child. The objections that had been advanced against the operation were that it was both dangerous and tedious; that there was danger of sepsis and of injury of the urethra and bladder, and that it necessitated another operation to deliver the child. While these are well founded, the other operations and obstetric conditions are of still greater gravity. In regard to puerperal sepsis, he stated that the tissues may be infected from the genital tract by an extension of the infection through the tissues, by extension through the tubes, and by extension by the bloodvessels and lymphatics. The extension by the bloodvessels is the most virulent. Curettement, douching, and thorough drainage of the cavity of the uterus by packing with iodoform-gauze constitute the treatment of this condition.

If secondary foci of the disease have developed in the uterine wall with pus-collections, extirpation of the uterus is indicated after exploratory section. It is remarkable how popular the operation of vaginal hysterectomy has become. It is used now not only for carcinoma of the cervix, but in cases of small bleeding fibroids, and in women suffering from uterine sepsis, in whom the disease is confined to the uterine walls. The speaker recommended cauterization of the stump, and the carrying of iodoform-gauze through the cervical canal into the vagina.

(To be concluded.)

NEWS ITEMS.

The Fifth District Branch of the New York State Medical Association will hold its tenth annual meeting in Brooklyn on Tuesday, May 22, 1894. The President, J. D. Rushmore, will deliver an address on "The Prevention of the Disagreeable and Dangerous Symptoms produced by Ether as a General Anesthetic." Other papers will be read as follows: "The Dietetic Treatment of Consumption," by T. J. McGillicuddy; "The Treatment of Chronic Oöphoritis by Electricity," by Edward Sanders; "Report of a Case of Chronic Peritonitis with Intestinal Fistula; Celiotomy; Enterorrhaphy; Recovery," by Frederick Holme Wiggin. General discussion of "Vaccination," opened by F. A. Jewett, S. E. Jelliffe, and H. H. Morton.

Prof. Escherich, the distinguished pediatrist, of Gratz, has been elected to the chair of the Diseases of Children, to succeed Heubner at the University of Leipsic.

ORIGINAL ARTICLES.

PARAXANTHIN AS A FACTOR IN THE ETIOLOGY OF CERTAIN OBSCURE NERVOUS CONDITIONS.

BY B. K. RACHFORD, M.D.,
CLINICIAN TO CHILDREN'S CLINIC, MEDICAL COLLEGE OF OHIO, CINCINNATI, OHIO.

THIS paper narrates the history of a patient that, at irregular intervals, had paroxysmal nervous attacks, the etiology of which was very obscure. After several months of careful study of this case I thought it possible that paraxanthin, a poisonous leukomain of the uric-acid group, by occurring in excess in the blood of this patient, might be the cause of these peculiar nervous attacks. Acting upon this idea, I procured eight liters of urine passed by the patient the day before, the day of, and some days after, a severe attack. From this urine 8 c.c. of a solution of paraxanthin was separated. One minim of this solution injected into the peritoneal cavity of a mouse produced symptoms much like those from which my patient suffered. The inference is drawn that we may have in the poisonous leukomains of the uric-acid group important and heretofore altogether overlooked factors in the production of certain nervous diseases and conditions.

That the reader may judge of the correctness of this inference, I give here a detailed history of the case and of the experiments upon which the inference is based.

Mrs. X., sixty-three years of age, is married, and the mother of six grown children. The family history is negative, except that "one sister had some nervous trouble of the heart." The patient was always a hard-working woman until a few years ago, when her grown daughters took charge of all the household affairs, and left her without occupation. She has always been rather stout, but of late years her hearty eating and inactive life have made her much stouter than before; she now weighs more than two hundred pounds, and spends most of the day in her easy chair; she has quite as capacious an appetite as she has ever had, and is now, as she has always been, especially fond of meat. From her earliest remembrance to September, 1892, she suffered from periodic attacks of "sick headache," but since this date she has not had a single characteristic sick headache; instead of sick headache she has had epileptoid attacks, which have continued to the present time at about the same interval as her previous attacks of migraine. It is the origin of these epileptoid attacks, and of the previous megrim, that will especially interest us in the study of this case.

In September, 1892, she fell in her first "spell," and was carried into the house in an unconscious condition; after about thirty minutes she regained consciousness, but did not know anything about what had happened. For twelve hours after the attack she had a severe headache, which passed away, leaving her as well as usual. The doctor who saw her in this and many of her subsequent attacks thought in the beginning that they were apoplectic. She continued to have attacks similar to this one at intervals of about three or four weeks. In all of these "spells" she became unconscious, and remained so for from twenty to forty minutes, when she would regain consciousness, to find herself suffering from a severe headache, which would pass off in from twelve to twenty-four hours, leaving her quite well again. These attacks came on without apparent exciting cause, and with absolutely no warning; she feels as well, if not better, than usual just before the attack, and they not infrequently come on at night during sleep. A number of times the patient has been seized with an attack while on her feet, and has fallen heavily to the floor. On one occasion she bruised her face and shoulder by a fall of this kind. The after-headache became less and less severe as the time passed, until at the present time "there is almost no headache following a spell." After five or six months these epileptoid attacks were less frequent, so that five or six weeks would at times intervene between the attacks, but such a long interval was usually followed by an unusually severe attack, and not infrequently by two attacks within a few hours. In the interval between the spells the patient was quite well, except that she was somewhat mentally depressed with the certain knowledge that at the end of five or six weeks she was sure to have "another spell." On September 18, 1893, three days after a very severe "spell," she came to my office for the first time. At this visit I obtained her previous history, and I prescribed phosphate of soda, in teaspoonful doses after each meal. The next day I examined her urine and found no albumin, sugar, or casts.

On January 14, 1894, the attacks had continued at intervals of from three to six weeks, but I had not been fortunate enough until this day to witness one of these attacks. On this day she had two attacks, the first one mild, the second one severe. I saw her in the second. The first attack was at 8 in the morning, and occurred as usual without warning. It lasted from twenty to thirty minutes, and she had just regained consciousness when I reached the house. At this time she was restless, somewhat confused in mind, and complained of pain in the left shoulder; the

respiration was normal, the pulse 90, strong and regular. By this time I knew enough of the case to suspect that this mild attack would be followed by another and more severe during the day. I therefore arranged matters so that I could reach the patient within a few minutes should she have another attack during the day. At 7 P.M. the second attack occurred, and I had the good fortune to be present. This attack came on while the patient was in bed. She had remained in bed all day as a precautionary measure against a second attack, and all day she had seemed as well as usual, even up to the moment of her second attack. In the beginning of the attack the attention of the family was attracted by her peculiar, noisy breathing. She became unconscious at once, and her breathing very *labored*, her lips blue, the face congested; the arms and legs were straightened and stiffened, and remained rigid for eight or ten minutes, and then became relaxed and remained so during the remainder of the attack; the congestion of the face soon passed off, and the lips became red again, but the heavy, noisy, irregular breathing continued for twenty or twenty-five minutes, and did not become quiet and regular till just before the patient regained consciousness. The pulse in the beginning of the attack was strong, regular, and about 85 or 90 per minute; it gradually increased in frequency until at the close of the attack, which lasted forty minutes, it was 120 per minute; all the time, however, it was strong and regular. After the attack the pulse gradually returned to the normal. The pupils were the same on both sides; they reacted to light and were contracted till near the close of the attack, when they became normal. There were no muscular twitchings except in her right upper eyelid, and here they occurred for a short time only during the most severe part of the paroxysm. After the heavy breathing subsided the woman lay for about ten minutes apparently in a normal sleep; she then began to move, opened her eyes, was much confused, and was not able to understand what had happened to her. She was now very restless, complained of pain in her left shoulder and wished to be moved frequently; she also complained of being sick at the stomach (this has been a common symptom in her recent attacks, but she has never vomited in any of them). About one hour later she went to sleep and slept the greater portion of the night. The next day she did not feel sick, but remained in bed, and on the second day she was up and about as usual.

This attack was "just like all of her previous spells," and as for a special purpose I have described this attack in detail, I would call particular attention to the following points, which were characteristic of all her attacks:

1. Sudden onset of attack, no warning.
2. Muscles rigid, but not convulsed.
3. Labored, gasping, irregular breathing.
4. Unconsciousness from beginning to end of the attack.
5. Heart-action rapid, but regular and strong.

In the study of this case it seemed to me that the peculiar attacks described had taken the place of the sick headaches of former years, and were therefore possibly of like origin. The case seemed to me to correspond in every particular to that class of cases which Alexander Haig[1] describes as being due to that very indefinite condition "the uric-acid diathesis." My patient was stout, inactive, a great meat-eater, had suffered from sick-headache all her life till these headaches were substituted by the explosive attacks described. Surely this was a typical "uric-acid case," and I decided to put her on the treatment recommened by Haig. I asked her to stop eating meat, to eat sparingly of eggs, and to take no wine or malt liquors. All other food, such as milk, bread, and all kinds of fruit and vegetables she might have *ad libitum*. The medical treatment consisted of a dose of Carlsbad salts each morning and 5 grains of piperazin three times a day. I placed her upon this treatment, not because I believed her symptoms due to "uricemia," but because whatever might be the cause of the symptoms, I hoped to get the same good results from treatment that Haig had reported. I also directed that all the urine should be saved and sent each morning to Mr. Otto F. Bange, a competent chemist, who very kindly took great interest in making a quantitative estimate of the urea and uric acid in this urine from day to day.

On February 25th the woman had two attacks, one mild and one very severe. I again had the good fortune to witness one of these attacks, and it was quite as severe as and in every way similar to the attack described. The treatment as outlined had been faithfully carried out, and the piperazin had been given a fair trial without apparent influence in either warding off or in modifying the severity of the attacks. The influence of the piperazin on the excretion of urea and uric acid is shown in the following table. In all of these examinations the specimen of urine examined was a part of the whole twenty-four hours' urine, except in the examinations made on the 24th, 25th, and 26th of February. The amount is calculated to 1000 c.c. of urine, which was the average amount passed by this patient in twenty-four hours.

From following table one sees that the amount of uric acid was somewhat increased during the first ten days of the treatment, and was somewhat diminished during the last days of the treatment. But the increased excretion of uric acid under this treatment did not in any way influence the frequency or severity of the attacks. I would call special attention to the amounts of urea and uric acid in the specimens of urine examined on the 25th and 26th of February, just before and just after the severe attacks of February 25th.

Urine, February 25th, 6 A.M. Just before attack, urea, 6.00; uric acid, 0.25.

[1] "Uric Acid."

Urine, February 25th, 9 A.M. Just after first attack, urea, 7.00; uric acid, 0.55.

Urine, February 25th, 5 P.M. Just before second attack, urea, 8.00; uric acid, 0.40.

Urine, February 26th, 9 P.M. Just after second attack, urea, 5.00; uric acid, 0.15.

Urine, February 26th, 8 A.M. Next morning after attack, urea 12.00; uric acid, 0.25.

Date.	Urea in 24 hours.	Uric acid in 24 hours.	Medicine.

The study of these figures is of considerable interest, as they clearly show that the excretion of urea is diminished and the excretion of uric acid increased during these attacks. The proportion of uric acid to urea is therefore greatly increased. Haig believes that the symptoms in just such cases as this may be explained upon the hypothesis that the uric acid occurs in excess in the blood and causes these symptoms by its action on the nervous centers, and that with the rapid elimination of the uric acid the blood is relieved of this excess and the symptoms subside. But Haig's hypothesis seems to me quite inadequate to explain the symptoms in the case reported, for the simple reason that *uric acid* and *its compounds are non-toxic.*

Bouchard[1] injected "experimentally into the blood thirty centigrams of uric acid for each kilogram of the animal without apparent accident." In one instance he injected sixty-four centigrams for each kilogram without injury to the animal. When death did occur, following excessive quantities of uric acid, he was convinced by his observations that death was alone due to the excess of the vehicle. Roberts[2] says that "uric acid and its compounds are deleterious simply because of their sparing solubility in the bodily media." As all experimental evidence is opposed to the idea that uric acid could produce such a group of symptoms as were presented in this case, I was impelled to search elsewhere for the cause of these attacks, and in doing so I was led to inquire into the possibility of leukomain-poisoning as a cause of the nervous paroxysms. The reasons that determined the research, in spite of the fact that the uric acid leukomains had been found in normal and many pathologic urines, in such very minute quantities as to make it highly improbable that they could enter as etiologic factors in the production of disease, were as follows:

1. In this case there was an increase in the excretion of uric acid during the attack, and Haig[1] has shown that this increased excretion of uric acid is a constant accompaniment of certain forms of sick-headache and epileptoid attacks. It therefore seemed possible that along with the increased excretion of uric acid there might be an increased excretion of uric-acid leukomains, as these bodies belong to the same chemical group and are probably formed by the same or a like metabolism.

2. It seemed altogether possible that a perverted metabolism or a defective elimination might result in these leukomains being present in the blood in abnormal quantities not at all indicated by the amount of uric acid excreted.

3. Paraxanthin, the most poisonous leukomain of the group, when injected into mice, produces symptoms much like the epileptoid attacks which this patient has. According to Salomon,[2] it produces dyspnea and rigor mortis, or stiffening of the muscles.

For the foregoing reasons I thought it worth while to inquire whether or not paraxanthin was excreted in excess in the urine during these attacks. It was decided to make the experiment as clean as possible by separating from the urine only the paraxanthin; the other xanthin compounds, some of which are poisonous, were gotten rid of.

The eight liters of urine used for the investigation were passed just before, during, and following the severe attack of the 25th of February. Boric acid was added to the urine while it stood, to prevent fermentation. This urine was delivered to Mr. Otto Bange, the chemist, with the request that he would abstract from it the paraxanthin it contained; but as this process is tedious, requiring some weeks for its completion, the patient was in the meantime looked after in the following manner: The piperazin and Carlsbad salts were discontinued, and the patient was advised to continue the same diet, ab-

staining from meat as before, and to take a teaspoonful of phosphate of sodium in a cup of hot water each morning, and ten grains of salicylate of sodium three times a day; this treatment was continued for one week. During the second week only two ten-grain doses of salicylate of sodium were given each day. During the third week only one dose per day was given, and during the fourth week no medicine was given except sodium phosphate. After this the patient again took two ten-grain doses of the salicylate per day.

On April 4th the woman had another attack, but it was not nearly so severe as those of five weeks before. Below is given a table showing the amounts of urea and uric acid excreted from day to day during the preceding three weeks:

(The amount is calculated to 1000 c.c. of urine, the average amount excreted in one day.)

Date.	Urea in 24 hrs.	Uric acid in 24 hrs.	Medicine, per day.
March 8	14.00	0.60	Acid sal., 30 grains.

April 1	6.50	0.14	Acid sal., 20 grains.
" 2	7.50	0.15	" 20 "

It will be seen from this table and the previous one that the no-meat-diet very greatly diminished the amount of urea excreted. With the exception of occasional variations the amounts of urea in the urine progressively diminished after the patient, three months previously, had been advised to approach as nearly as practicable to a vegetable diet. The amount of uric acid in the urine also during this time progressively diminished. This was no doubt in part due to the action of the medicine, and it is also a noticeable fact that the amount of uric acid excreted fell more rapidly under the salicylate of soda than under the piperazin treatment. The patient was again advised to continue the same diet, and also to continue the sodium salicylate, ten grains twice a day, with a dose of Carlsbad salts each morning.

On April 25th the patient had one light attack, which was less severe than the one three weeks before.

On April 27th, the woman had recovered quickly from the slight attack on the 25th, and was as well as usual. It was the opinion of all who have observed the patient during the past few months that she was now better than she was four months before; the attacks were comparatively mild compared to what they were then. It seemed, therefore, altogether probable that she had been improved by the treatment.

With this history of the case we can now return to the study of the etiology of these attacks, and to the inquiry whether or not this patient has an excess of paraxanthin in her urine, and, if so, could paraxanthin-poisoning account for the symptoms in her case?

Let us first inquire what is paraxanthin. Paraxanthin is one of the poisonous leukomains of the uric-acid group, and of all this group it is the most poisonous. According to Salomon, who was the first to isolate this substance, its physiologic action is as follows: In mice the reflexes are increased to a tetanus, followed by a rigor-mortis-like contraction of the muscles, and dyspnea is a constant symptom. The formula for paraxanthin is $C_7H_8N_4O_2$. It is a noticeable fact that paraxanthin, xanthin, and gerontin, the most poisonous leukomains of this group, all have two atoms of O, while uric acid ($C_5H_4N_4O_3$) has three atoms of O. Uric acid, it would seem, is therefore a more highly oxidized body than these poisonous leukomains.

Salomon also found that paraxanthin occurred in normal urine in such minute quantities that its poisonous properties were lost in dilution. From 1200 liters of normal urine he obtained only 1.2 grams—that is, one milligram of paraxanthin for every liter of urine. It would, therefore, take one-half a liter of urine to yield one-half a milligram of paraxanthin, which is the poisonous dose for mice.

From the 8 liters of urine previously spoken of, Mr. O. F. Bange isolated the paraxanthin by the method of Salkowski and Salomon.[1]

[1] The method in brief is as follows:

Method.—The phosphates are precipitated with ammonium hydrate; after twenty-four hours the urine is filtered or decanted from the precipitate, and a 3 per cent. solution of nitrate of silver is added to it, about 0.5 or 0.6 of silver being used for each 1000 c.c. of urine. It is, as a rule, necessary to add more ammonia to hasten precipitation; after precipitation the precipitate is washed six or eight times with distilled water by decantation; the silver compounds suspended in water are then decomposed with hydrogen sulphid, the current of H_2S is made to pass through the water in which the compounds are suspended for hours; the liquid is now decanted or filtered to separate it from the precipitate, and evaporated down to about 1000 c.c. if 6000 c.c. of urine have been used; the remaining uric acid is thereby separated; this liquid being filtered, ammonia is again added; after twenty-four hours it is again filtered and precipitated with silver nitrate, the silver being added as long as precipitation occurs; the supernatant liquid is removed by decantation, and the precipitate is transferred to a filter and allowed to stand for twenty-four hours in a dark place. It is then dissolved in hot nitric acid of 1.1 specific

By this method there was obtained 8 c.c. of a very concentrated solution of paraxanthin. From a drop of this solution on a glass slide characteristic paraxanthin-plates and needles crystallized out, and a drop of the solution in a solution of potassium hydrate gave the white precipitate which is characteristic of paraxanthin.

The effect of this solution on mice was next studied, mice being chosen for the experiment because they were known to be susceptible to paraxanthin poisoning, and because they were inexpensive and easily obtained.

The first experiment, on April 12, 1894, was with a full-grown house-mouse. *Time*, 5.35 P.M. Two minims of the solution were injected into the peritoneal cavity; after thirty seconds the mouse was very nervous, trembling, jerking when the sides of the can in which it was held were touched; this excitability increased almost to a tetanus, when, at the expiration of two minutes, the mouse jumped into the air and fell on its side, and after a few convulsive movements stiffened and died. The post-mortem examination showed no evidence of a needle-wound in the peritoneal cavity.

In this experiment the dose was so large that the paraxanthin proved so rapidly fatal that opportunity was not given to study the symptoms. For this reason I decided that in the next experiment I would introduce as small an amount of the solution as possible, and surely not more than one minim was used.

The second experiment was at 5.45 P.M. One minim of the same paraxanthin-solution was introduced into the peritoneal cavity of a full-grown, gray mouse. At 5.48 P.M. the mouse was very nervous, jumped spasmodically when the sides of the tin-can were touched; this reflex excitability continued until it was almost a tetanus. At 5.50 the mouse fell in convulsive movement, and almost immediately stiffened in a clonic tetanic contraction of all the muscles. This muscular tension was kept up almost uninterruptedly for three hours, when the mouse died. Toward the close of this period the muscles were relaxed, except at the onset of the attack there was no movement resembling a convulsive movement. From the beginning to the end of the attack there was dyspnea and a gasping respiration, which after a time was irregular. The heart's action was regular and apparently not affected by the poison.

By these, and many other experiments of which they are a type, it was proved that the substance separated from the urine, which responded to the chemical tests for paraxanthin, also when injected into mice produced the physiologic effects of paraxanthin.

The symptoms which are most characteristic of poisoning by this substance in the mouse are:

1. Nervousness, extreme reflex excitability—almost a tetanus.

2. Clonic, tetanic stiffening of the muscles, followed by muscular relaxation. (Convulsive movements usually absent.)

3. Dyspnea, orthopnea, asphyxia. The gasping respiration is probably the most characteristic symptom.

4. Heart unaffected.

According to Salomon one-half of a milligram will produce these symptoms in a mouse. As one minim of the 8 c.c. of concentrated solution of paraxanthin obtained from 8 liters of urine produced these symptoms, it is reasonable to conclude that this one minim contained one-half a milligram of paraxanthin, and that the 8 c.c., or 120 minims of solution contained 60 milligrams of the solution. As only one milligram of paraxanthin is found in one liter of urine, in the 8 liters of urine from this case the paraxanthin was increased as 60 to 8, or nearly eight times. From another specimen of urine, 8 liters, the paraxanthin was separated and evaporated to 8 c. c. That this solution contained paraxanthin was demonstrated by the chemical tests, and that it contained paraxanthin in very small quantities was shown by the experiment that 10 minims of the solution injected into the peritoneal cavity of a mouse did not produce the symptoms of paraxanthin-poisoning.

Upon the foregoing evidence I conclude that paraxanthin occurs in great excess in the urine passed by this patient during the epileptoid attacks already described, and that it is reasonable to believe that paraxanthin-poisoning is a potent factor in the production of these attacks.

117 Broadway.

gravity to separate the hypoxanthin. If working with 4 liters of urine, from 60 to 70 c.c. of acid will be sufficient. After two hours, filter and carefully add ammonium hydrate to neutralization, and for the third time xanthin and paraxanthin are separated, the precipitate washed, suspended in water, and again decomposed with hydrogen sulphid. It is filtered while hot, and the filtrate evaporated to 50 c.c. and a little ammonium hydrate is added, and after twenty-four hours the last traces of phosphates and oxalates will be precipitated; the filtrate is again evaporated on a sand bath, and when the liquid begins to get turbid evaporation is suspended; the next day the xanthin will be found in a mass at the bottom of the beaker; filter the liquid and evaporate to a few c.c. —from 10 to 20—and one has a concentrated solution of paraxanthin. If the solution be very concentrated, paraxanthin will crystallize out.

The Ohio State Medical Society, at its last meeting, held recently, elected the following officers for the ensuing year: President, D. N. Kinsman, M.D., Columbus; First Vice-President, C. O. Probst, M.D., Columbus; Second Vice-President, M. Stamm, M.D., Fremont; Third Vice-President, J. C. Buckner, M.D., Cincinnati; Fourth Vice-President, Robert Peter, M.D., Canal Dover; Secretary, Thomas Hubbard, M.D., Toledo; Assistant Secretary, Charles Graefe, M.D., Sandusky; Treasurer, James A. Duncan, M.D., Toledo. The next meeting is to be held at Columbus, May 15, 1895.

ACUTE APPENDICITIS.

By JOHN B. DEAVER, M.D.,
of Philadelphia.

With Remarks in Opening the Discussion.

By J. M. Da COSTA, M.D.

(Continued from p. 540.)

PROGNOSIS.

The prognosis of appendicitis depends not only upon the character of the attack and the complications which may supervene, but upon the character of the treatment instituted.

Our present knowledge gives early operation the first place in the treatment. Many cases of simple catarrhal appendicitis subside under careful and rational medical supervision; still, in the great majority, this primary attack only leaves the patient predisposed to another which is more severe and more dangerous than the original one. In my last series of cases, forty-five of which I have operated upon, forty-two had had previous attacks. In other cases which start up acutely there is over the diseased organ a gradual decrease in all the symptoms excepting tenderness, thus leaving the patient in a subacute condition. In this subacute condition the appendix may, and frequently does, go on to perforation and gangrene, without a corresponding increase in the symptoms. When the appendix has been removed a second attack is an impossibility, so that I believe that operation gives the patient the only chance for permanent recovery.

When the collection of pus is circumscribed, the general peritoneal cavity being walled off, the prognosis is generally favorable. If the general peritoneal cavity be early infected the prognosis is grave, although if operation be at once resorted to there is a possible chance of recovery; while if the infection be late or operation deferred, a fatal termination is invariably the rule. When a circumscribed appendiceal abscess ruptures and evacuates its contents into the bowel, recovery usually follows, while evacuation into the bladder is fatal in about 50 per cent. of the cases. The age of the patient is a decided factor in the prognosis, as the disease is more fatal in the very young, on account of the lessened powers of resistance.

COMPLICATIONS AND SEQUELÆ.

By far the most important and frequent complication of appendicitis is peritonitis. Inflammation or phlebitis of the right iliac vein, or thrombosis associated with edema of the corresponding lower extremity, is a complication sometimes met with in the localized suppurative variety of appendicitis, and if a fragment of the thrombus be carried along the general circulation, this may result in foci of septic pneumonia or septicemia.

If the appendix lies over the iliac bloodvessels, and undergoes ulcerative destruction, it may cause necrotic change in the walls of the bloodvessels, and result in fatal hemorrhage. Abscess of the liver, purulent collections in the pleura and pericardium, may also result from portal thrombosis or directly from the general circulation. Appendicitis may be a complication or an accompaniment of hernia. When a localized appendiceal abscess ruptures into the bowel or into the bladder, there is renewed infection from these avenues. Fecal fistula is a frequent sequel of appendicitis.

TREATMENT.

I have made no attempt to formulate a rule by which we are able to discriminate which class of cases will terminate as simple appendicitis, or go on to perforation or gangrene. There are some who claim to be able to foresee which cases of appendicitis will eventuate in recovery or assume the gangrenous type, or to recognize the onset of this dangerous complication. This is, I believe, an assumption which cannot be substantiated by experience. My experience is that the surgeon is called in so often to see cases in which the unfortunate patient, according to the attending physician's statement, has been doing well up to a few hours previously, only to find the evidences of general septic peritonitis, which invariably foretells the almost inevitable result. Is it to share the responsibility? Certainly not with the hope that operation promises recovery. Again, why should we trust to chance when we have positive means of relief in immediate operation, if the treatment to which I shall refer further on fail to accomplish the desired end? Granting that the majority of the cases of simple appendicitis will temporarily recover under careful and well-directed medical treatment, are we justified in allowing the minority to perish when we have positive means at our disposal to prevent the fatal issue?

The physician who has had the opportunity to observe many cases of appendicitis cannot but have impressed upon his mind the lesson of cause and effect—the cause being the primary attack, the effect the death from a subsequent attack.

While some may claim that they have never seen a recurrence, there are many who will bear witness to the fact that they have frequently seen subsequent attacks. My friend, Dr. J. M. Da Costa, recently related to me the history of a case in which the patient had had forty-seven previous attacks; in the forty-eighth attack he asked the surgeon who was in attendance with him to operate. The operation not only terminated favorably, but demonstrated the presence of a collection of pus within the appendix which was on the verge of rupture.

When advising operation I have been met by the statement from the attending physicians that they have seen patients recover from several recurrent attacks, and presenting this as an argument against operation. The patient just referred to, who had forty-eight attacks, certainly demonstrates to the unprejudiced mind that one more attack would most likely have resulted in rupture and septic peritonitis.

While this paper is upon the subject of "Acute Appendicitis," I may be permitted to digress to make the statement that of the thirty cases of chronic appendicitis upon which I have operated successfully this winter, the lesions present in the majority of the appendices demonstrated most clearly that an acute attack would most probably have resulted disastrously.

If operation is justifiable in the minority of cases, which without operation are fatal, is it not equally justifiable in all cases, considering that the majority which recover under well-directed medical treatment suffer subsequently from recurrent attacks, and many perish in the last attack?

In my experience operation, performed under strict aseptic precautions by a surgeon familiar with the anatomy and the technique of the abdominal cavity, and immediately following the establishment of the diagnosis, will give a mortality practically *nil*.

If the medical man had the same opportunity to observe the ravages of an appendiceal inflammation ante-mortem, as has the surgeon, particularly those who have operated many times, he would certainly be convinced of the importance of early operation; hence, I can understand the position of the conservative physician.

I will ask in advance those who will take exception to early operation, if they have ever had the opportunity to observe the treatment I advocate. Anyone who has seen a gangrenous appendix removed before perforation, and before a localized abscess or a general septic peritonitis has developed, could not fail to sanction prompt interference.

The first indication to be fulfilled in a case of simple appendicitis, or even of a supposed case, is to obtain free action of the bowels. This is best accomplished by the administration of castor-oil, followed by salines, preferably Rochelle salts, or, if the stomach is not tolerant to salines, small doses of calomel. Free evacuation of the bowels—not drastic purgation—serves the purpose of clearing the alimentary canal of all foreign and irritating substances, such as particles of undigested food, etc., and relieves the congested bloodvessels, thus modifying the degree of the subsequent inflammation. Again, this course fulfils a most important indication in having the bowels in the most favorable condition for operation in the event of its necessity. I cannot emphasize the importance of this part of the treatment too strongly, as upon it, I believe, largely depends the chance of the patient's recovery. Certainly in my experience, the bulk of patients I have seen recover without operation have been those in whom this was most thoroughly carried out, and in the cases operated upon the largest percentage of recoveries have been those in whom the bowels were not allowed to be confined. The pain in appendicitis, which is colicky in nature, is due first to the muscular contraction of the appendix and the bowels, and in the majority of instances is provoked by irritation within both; therefore, is not the emptying of the intestines of their irritating contents urgently called for? Is not the bowel, in other words, asking to be relieved? This being so, will not purgatives take the place of an anodyne, a hypodermatic of morphin, which is often and indiscreetly given? The best anodyne consists in repeated doses of salts or calomel, which do more than any preparation of opium can do, both relieving and removing the cause of the pain. Free purgation should be continued throughout the attack, sufficient to keep the contents of the bowels in a liquid state as long as the tenderness and uneasiness in the appendix exists.

Absolute rest in bed, with careful feeding, should be enforced. Turpentine in the form of hot stupes should be applied, and will relieve the distention and pain in addition to acting as counter-irritants. The use of leeches and blisters is advocated by many in preference to purgation, to accomplish the depletion of the circulation. This is not in accord with my experience. Blisters are particularly objectionable, in that they macerate the superficial layer of the integument, increase the patient's discomfort, do not accomplish the results afforded by salines or calomel judiciously administered, and, one of the strongest objections against their use, they make a septic field for operation. This latter is also true of leeches.

Opium should not be given; it usually masks the character of some of the most important symptoms. Absolute rest in bed, with careful feeding and mild purgatives, generally relieve these cases within thirty-six or forty-eight hours. In those cases in which the symptoms do not abate, and the disease seems to be progressive, the appendix should be removed. When opium has been administered and the progressive character of the case is doubtful, it is better to err upon the side of safety, and remove the appendix at once. The condition present is usually beyond the powers of Nature to remedy, while in the hands of a surgeon who pays strict attention to the aseptic details of the operation the latter entails little risk to life—less than that which is involved

in even a mild attack of appendicitis that remains stationary, with all its possibilities of lymphangitis, infection of the peritoneal cavity, retained mucopus within the appendix, and rupture of the latter into an unprotected peritoneal cavity, or ulceration and perforation from inspissated fecal matter, imprisoned by constriction within the cavity of the appendix, or from a gangrenous condition alone.

When the disease has gone on to a stage of pus-formation, and we are positive that such a condition exists, usually shown by persistent pain and tenderness which is intense on deep pressure, no time should be lost in opening the abdominal cavity, evacuating the pus, and removing the appendix at the same time. The less medication these cases receive the better, and the use of salines is especially contra-indicated. The limiting wall of the abscess-cavity is delicate, and the increased peristalsis set up by the saline may be sufficient to rupture the abscess-wall, with resultant leakage of its contents into the peritoneal cavity and subsequent peritonitis.

In all cases in which the disease is not of a mild type at the outset, as indicated by the symptoms, I believe that operation is the only treatment offering any positive means of relief, and that it should be instituted as soon as the diagnosis is established. Salines, and this is more true of opium, are especially contra-indicated in this class of cases, in which there is no certainty as to the condition of the appendix at its attachment to the cecum.

Rectal injections are contra-indicated for the same reason. I have recently seen a case in which a gangrenous appendix was forced away from its attachment to the cecum by a copius injection which was emptied into the abdominal cavity, followed in a few hours by a septic peritonitis. Prior to the injection the patient's abdomen was flat, the temperature normal, and the pulse good.

Great care should be exercised when opening these abscess-cavities or infected areas that the general peritoneal cavity be not infected. The manipulation should be very gentle, as a communication may readily be established. With a good assistant, who with gauze compresses is able to keep the field of operation well isolated from the rest of the peritoneal cavity, and also to keep the small intestines out of the way, the operation at this period of localized peritonitis, with or without sero-purulent collections, is both safe and advisable. It is almost impossible to avoid breaking away some of the adhesions, but with care the appendix can be removed without infecting the peritoneal cavity. After removal the general peritoneal cavity can be sealed off by properly packing with iodoform-gauze previously sterilized.

When the appendix has been separated from the cecum at its basal attachment by a gangrenous inflammation, if the opening in the cecum is not too large and the surrounding area not devitalized, the margins of the openings should be cut away and the opening closed by the Lembert suture. On the other hand, if the opening be large, and the adjacent area is involved in this gangrenous process, it is better to wall off this portion of the cecum, insert a glass drainage-tube into the abscess-cavity, and pack iodoform-gauze around it, thus sealing it off from the peritoneal cavity. A fecal fistula will almost always follow, but this usually closes spontaneously. I have known cases, after the abscess-cavity has simply been opened and drained, to recover with a fecal fistula, the fistulous tract communicating with the tip end of a patulous appendix. This demonstrates the importance of removing the appendix when the abscess-cavity is opened.

When the abscess-cavity is postcolic, the incision should be made through the outer layer of the ascending mesocolon, the appendix removed, and aseptic drainage established through the loin. In the postcecal appendiceal abscess, especially if the appendix be the seat of gangrene, there is great danger of infection of the liver through the venules of the portal system which are in relation with the main layer of the ascending mesocolon. When the appendix runs over the brim of the pelvis and extends into the pelvic cavity, it is always better to drain with a glass drainage-tube, placed in the most dependent portion of the pelvis. In case a secondary abscess should form and occupy the recto-vesical space in the male, it is better to drain it through the rectum, using a larger trocar and canula to penetrate it, and then insert an English catheter through the canula, while if it occupy the recto-uterine space, it should be emptied through the vagina. I think it is better to resort to this procedure than to reopen the original wound or open through the linea alba, on account of exposing the peritoneum to a second infection.

I have not been able to see the advantage of the linea alba as an avenue through which to remove the appendix, as advised by some operators.

From the fact that the appendix in its normal position lies in the right iliac fossa, the most direct route to it is through the right semilunar line or immediately to either side of it. By carrying the incision either through the rectus or the internal oblique and transversalis muscles, there is no doubt that the wound can be closed with greater security against the occurrence of a hernia, whether a series of buried sutures be used or not.

There is no question but that the Trendelenburg position offers advantages in certain cases, and that the evacuation of pus or drainage of an abscess, and the subsequent irrigation, are favored by turning the patient over on the affected side.

It has been my intention not to cite any of the numerous cases I have records of, knowing how tiresome this is to an audience, but while writing upon the treatment of this paper I was called to see a case which so clearly supports the position I hold relative to early operation, that I will beg of the Fellows the privilege of reporting it.

Friday night, April 27, 1894, Dr. Prendergast was summoned to see Mrs. O., thirty-five years of age, who on account of acute abdominal pain, accompanied by nausea, general abdominal tenderness, and constipation, was suddenly taken to her bed. The pain was so severe as, in Dr. Prendegrast's opinion, to call for a hypodermatic of morphin. Upon careful inquiry a history of one similar attack, much less severe in character and occurring four months ago, was obtained. On the following day, Saturday, the bowels having been moved by purgatives, the patient thought herself to be more comfortable. On Sunday the pain was more severe and was referred to the right iliac fossa; there was pronounced general abdominal tenderness with decided tympanites; the pulse was 100; the temperature 102°. The patient was referred to me for admission to the German Hospital. Upon being given a statement of the case over the telephone, I requested the patient to be prepared for operation. The examination of the pelvis was negative. Examination of the abdomen showed very evident general peritonitis, and excessive tenderness to pressure over the site of the appendix. Operation demonstrated a small peri-appendicular abscess; an appendix which held a southwest position, turned upward and outward upon itself, gangrenous at its distal extremity to the extent of an inch, and adherent to the floor of the right iliac fossa by its tip. The mesentery of the appendix was so infiltrated and thickened as to resemble a second appendix. The general peritoneal cavity was not shut off. The pus was evacuated, followed by irrigation and removal of the appendix. The morning after the operation the temperature was 98° and the pulse 84. The patient was passing wind and the abdominal distention was rapidly disappearing. On Tuesday morning the improvement continued. On Wednesday the pulse was 68, the temperature normal, and the bowels moved the previous night. The abdomen was flat and improvement was uninterrupted.

In opening the discussion, DR. J. M. DA COSTA said: I rise with some diffidence to speak on a subject of this kind; it is so largely surgical, and so many distinguished surgeons are present, that I am aware that I am addressing an audience of experts. But though the condition is undoubtedly in the main a surgical one, before the case gets into the hands of the surgeon the physician sees it, and to him as well as to the surgeon belongs the responsibility of declining operation or of urging operation. I shall not take up time by going into the discussion of the whole subject, but merely speak of some matters that experience has made clear to me; an experience shared in many instances with noted surgeons, but of which I may summarize the results from a general and purely medical point of view.

In the first place, there is the question of diagnosis, which, after all, belongs more to the physician, as he sees the case early, and he has to decide whether or not it is one of appendicitis. I want to say distinctly that with what Dr. Deaver has so clearly stated of the valuelessness of the thermometer in the recognition of gangrenous or purulent appendicitis, I am in accord. I could cite examples of gangrenous appendicitis, with pus around the appendix, in which the temperature was almost normal. In one instance which I saw with Dr. Morton, gangrene of the whole appendix was found, but at no time did the temperature go above 99.1°. I should also like to say that while the thermometer does not help us, the pulse does not do so much more, and that, after all, it is by the whole history, and particularly by the kind of pain, that we make up our minds as to what is the matter; I was almost going to say by the locality of the pain, but this is true only up to a certain point. In one of the most striking cases with which I was ever connected the pain was over the liver. It is sometimes epigastric; in the case that I saw with Dr. Deaver the pain was on the left side, and most puzzling it was to determine this to be an instance of appendicitis. Looking at the admirable paper of Dr. Fitz, I find that pain in the left iliac fossa occurs in only 1 per cent. of the cases. There is one seat of pain rarer, namely, pain in the hip and groin, which is so rare that it happens in only ½ of 1 per cent. The seat of pain, therefore, must not mislead us. It need not be in the right iliac fossa.

Another question in diagnosis is as to the presence of pus. If we only had a sure test indicating the presence of pus in appendicitis, it would be a most valuable addition to the whole subject; but we have not. I have already said that the thermometer does not help us. The sense of resistance and the fulness are of some value; so is severity of recurring pain. But the great tenderness that exists in cases in which pus is present is, perhaps, the most certain sign; yet it is not an absolute sign. In rectal examination with the view of detecting a swelling, I have been disappointed except when there is a considerable collection of purulent material. If I were asked what single sign is there of pus in appendicitis, I should say that the only thing, barring the marked tenderness, that comes near being a distinctive sign is the great variability of the symptoms. You will find the pulse up, then down; the respiration embarrassed at one visit, less so at another; there will be peculiar fleeting eruptions on the skin; there may be coarse capillary injection here and there. These signs, which show a septic condition, are probably the most certain, although, after all, not very certain, signs of purulent collection.

Looking to some questions of special diagnosis, typhoid fever is of a great deal of interest. One of the most remarkable instances that I ever saw was one Dr. Morton and I had together, in which there had been a previous attack of appendicitis, Dr. Morton having attended the man through it. The pain was localized in the right iliac fossa, and strongly pointed to a recurrence of the previous malady, but the temperature was 104°, and in both of our experiences this was so unusual in appendicitis that the case was allowed to go on from day to day without surgical interference, and at the end of the

sixth day lenticular spots appeared on the abdomen, the bowels became loose, and the case ran the course of typhoid fever. Here the height of temperature was so great that, notwithstanding a clear knowledge of the history, Dr. Morton most judiciously held his hand. Of course, this difficulty will not arise when we have the temperature-chart and can trace the characteristic rise of typhoid fever. But we are often not called in at the onset, and we have to judge of the case as it stands. I would state that early height of temperature, a temperature remaining above 102°, would be an important point against appendicitis and in favor of typhoid fever. On the other hand, severe and recurring pain in the right iliac fossa is against this. With regard to the spots which have been stated to exist in appendicitis, and which are supposed to indicate pus, these do not have bearing on the question of differential diagnosis. They are not the characteristic eruption. They are not rose-colored spots of definite life; they are coarser, irregular, and very fleeting.

The question of diagnosis with reference to obstruction of the bowels, as I know by experience, is sometimes very difficult; it seems almost impossible to solve the question. Every single symptom, including scanty urination, that exists in appendicitis may be present. Generally, however, the absence of fever early in the case, the markedly distended and tympanitic abdomen, the obstinate constipation, the diffuse rather than localized pain, its lesser violence, distinguish the intestinal obstruction.

I turn from these points of diagnosis to some points of treatment. It would be out of place here to go into a full discussion of the medical treatment of acute appendicitis. I will only state that in the main I agree with the doctrine that free purgation is advantageous, and that the use of opium should be very moderate and ought to be avoided, certainly early in the case, if the pain will permit us to do so. There is a remedy which, in the early stages, I have known to be of advantage—the application of ice over the region of the appendix. If time permitted, I could give the detailed history of several cases in which the symptoms of acute appendicitis disappeared under this treatment. However, I pass on to the important point where surgery and medicine touch—the question of operation. While we have to defer most largely to the judgment, to the skill, and to the acquired knowledge of the surgeon, nevertheless the physician for his part also comes to certain definite conclusions. I cannot go as far as Dr. Deaver in thinking that every case of appendicitis had better be operated on. It seems to me that if we take this view, a person with appendicitis will go to bed not with the proverbial sword of Damocles suspended over his head, but with the scalpel of the surgeon already on his abdominal wall. I believe that the majority of cases of appendicitis in the first attack recover under medical treatment. This is certainly true when no perforation has happened. I am quite willing to think that what we here speak of to-night may be antiquated in six months. The wonderful technique, the ever-growing skill of the surgeon, and the fact that things become possible to-morrow which are not possible to-day, may make us all before long come to the conclusion that the percentage of risk is much less in operating in many instances than in trusting purely to medical treatment. I am free to admit this; but, speaking from our present knowledge, I think that it is right to select only certain cases for operation. I give the results of my personal experience, much of it gained in association with surgeons. In the first place, I believe that, in addition to perforative appendicitis, it is our duty to operate early on every case of appendicitis in which there are signs of abscess, or in which there is good reason to think that pus exists, no matter how little. Let us rather occasionally be mistaken than run the risk of not operating. Therefore, if we could come to greater accuracy in the diagnosis of pus, I hold that the main point in regard to operation would be solved.

I also think that while we may and ought to have much hesitation as to the propriety of operating when appendicitis occurs for the first time, yet with every subsequent attack this hesitation should vanish. The risk becomes greater and greater. I think that when a person has had more than one attack, certainly when he has had several, especially at short intervals, it would be quite right to consider an operation as his best chance. I say this, for I have seen the results of delay. It is true the character of the attacks will have much to do with the issue. If the appendicitis be merely catarrhal, or the result of something ingested that is readily gotten rid of, a number of attacks may be borne with impunity. But the parts become altered and weakened by the repeated disorder, and, unfortunately, diagnosis has not reached the point that we can be sure of the tissue-changes that have happened and the power to withstand ulceration.

Again, when there have been signs of disturbance of a chronic kind in the lower part of the abdomen, although there has been no distinct history of appendicitis, I think that it is better to operate if a well-marked acute attack comes on. I recall a case in the Pennsylvania Hospital in which a young man, with obscure abdominal symptoms and some thickening in the right iliac fossa, was attacked with acute appendicitis. He was doing so well that I could not make up my mind to advise operation, but perforation and rapid peritonitis followed. It was afterward learned that there had been a previous appendicitis, and the autopsy showed that an early operation would most probably have saved him. I saw a similar instance in a boy eleven years of age.

There are some points that arise with reference to the time of operation in acute appendicitis which are purely matters for the surgeon. But that we ought to operate if the case goes beyond a certain day, an opinion often promulgated, I cannot agree to. I have seen cases that have gone on for a long time, for eleven days, for fourteen days, and yet perfect recovery has taken place. Therefore I do not think that the absolute law which is laid down by some, that you must operate on or soon after the third day, is a law that holds good. We must judge by the character of the case, the general symptoms, the way it is progressing, the likelihood of the presence of pus, rather than by the mere number of days.

In conclusion, I will state that I know of no question in practical medicine that is a more important, a more solemn question than this one of operation in appendicitis. On the one hand, you feel that you may be led into an operation that is unnecessary, and that in the

best hands is attended with some risk, and, on the other hand, you know that delay may be fatal. It is, indeed, a trying question, and we must solve it according to our best judgment in individual cases with close thought, putting the operation off if we safely can, but remembering the issues at stake. If we err let it be on the side of early operation rather than on that of too long delayed operation.

CLINICAL MEMORANDA.

EXTRA-UTERINE PREGNANCY SIMULATED BY A SMALL TUMOR OF THE OVARY; OPERATION; RECOVERY.

By WILLIAM H. MORRISON, M.D.,
OF PHILADELPHIA.

The possibility of diagnosticating extra-uterine pregnancy before rupture of the sac has in the past received considerable discussion, but at present the generally accepted opinion is that such a diagnosis cannot be made with any great degree of certainty. A case on which I recently operated illustrates with such force the uncertainties attending the diagnosis of ectopic gestation that it seems worthy of record.

The patient, Mrs. X., thirty years of age, the mother of four children, has been under my personal observation for a number of years. In November, 1893, that is five months ago, she had a miscarriage at two or three months, from which she recovered without incident, with the exception that a slight tendency to bleed continued. For this I curetted the uterus some two weeks later. In the repeated examinations made at this time, nothing abnormal was detected in the pelvis. Following the miscarriage, menstruation recurred every twenty-four days, until February, when the period which should have commenced February 27th did not appear until March 11th, twelve days overdue. It, however, presented nothing unusual as far as the patient observed. Two weeks later, March 27th, she was taken with sharp recurring pains in the lower part of the abdomen, somewhat more severe on the right side. After a few hours these passed away, to reappear on the following day. With the pains there was a slight discharge of blood from the vagina. It was at this time (March 28th) that I was called. The pain, while acute, did not seem to be of great severity. There was no shock, no alteration in temperature, no disturbance of pulse. There was tenderness over the whole of the lower part of the abdomen not especially localized. There was no gastric or intestinal disorder to explain the abdominal tenderness.

Vaginal examination showed the uterus to be slightly enlarged. On the right side of the pelvis nothing abnormal could be discovered, but to the left of the uterus and low down was a globular mass, apparently one and a half or two inches in diameter, which seemed to be a cyst. It was quite tender on pressure, but could be displaced upward to a certain extent. This mass while in contact with the uterus was distinct from it. A sound introduced into the uterus gave a measurement of three inches, and as it was removed brought away two or three shreds of thin membranous tissue.

A diagnosis of cystic tumor in the pelvis, probably an extra-uterine pregnancy, was made, the condition of affairs explained to the patient and her husband, and operation advised. This was acquiesced in, and on March 31st I opened the abdomen and removed a tumor which was found to be the left ovary in a state of cystic degeneration. The tube was normal. The right ovary was brought to the abdominal incision, but as it was small and presented no evidence of disease, it was allowed to remain. The after-course of the case was uneventful and the recovery complete. The enlarged ovary was ovoid in shape, and about two inches in its longest diameter. It contained three cysts. At its outer extremity was a small cavity containing about twenty minims of dark fluid blood, evidently due to a recent hemorrhage. This probably was the explanation of the sharp abdominal pains. A second small cyst at the opposite extremity was filled with clear, watery fluid, while the bulk of the tumor was made up of a cyst containing amber-colored gelatinous material.

While this case presents nothing unusual from a pathologic point of view, it does offer features of interest from a diagnostic and therapeutic standpoint. The points bearing upon diagnosis may be stated as follows:

1. A woman in whom the more common causes of suppurative tubal disease, namely, specific infection and septic contamination, could be excluded.

2. The fact that she had been submitted to examination within a few months and no pelvic tumor found. This I consider a strong point in connection with the diagnosis.

3. A delay of nearly two weeks in the appearance of the menstrual flow.

4. The occurrence of repeated, sharp, intermittent, abdominal pains, with a bloody discharge from the uterus.

5. Enlargement of the uterus and the removal of shreds of membrane from its interior.

6. The presence of a movable, globular, elastic, sensitive mass at one side of the uterus.

These facts, while rendering the diagnosis of unruptured tubal pregnancy sufficiently certain to demand prompt interference, were, as the sequel shows, not sufficient to justify an absolutely positive diagnosis.

In the treatment of ectopic gestation, aspiration of the sac, the injection of various agents into it, and the application of electricity, have been recommended and are still advised by some. In the present instance, such treatment, on account of the close relation of the tumor to the vaginal wall, would have been readily applicable, but, as the operation demonstrates, would have been useless if not injurious.

The lessons which this case teaches are: first, that an absolutely positive diagnosis of unruptured extra-uterine pregnancy is not possible, no matter how distinctive the symptoms and physical signs may appear to be; and second, that until an absolutely positive diagnosis is reached, such treatment as aspiration or injection of the sac is not to be considered.

Congress of American Physicians and Surgeons.—The President of the United States will receive the members of the Congress, their guests and visitors, and their ladies, at the Executive Mansion, on Thursday evening, May 31st, from 9 to 10 o'clock. Cards of admission may be had at the office of registration.

THREE CASES OF ATTIC SUPPURATION IN WHICH OPERATION WAS FOLLOWED BY FACIAL PARALYSIS (BELL'S PALSY.)[1]

By L. J. HAMMOND, M.D.,
of Philadelphia.

I wish to report three cases of upper tympanic or attic suppuration, in which operation was followed by facial paralysis, for the purpose of learning from those of larger experience in this very important branch of surgery, how far it is possible to avoid this complication which, owing to the anatomy of these parts, is unquestionably a condition that is likely to occur. By reviewing our anatomy of this region of the middle ear we find it marked off at about its middle by the bony ridge which forms the covering of the facial nerve, or, indeed, the nerve may pass through this region entirely devoid of any bony covering. It will, therefore, be seen that nothing but the greatest care could possibly prevent wounding this important structure, or if the bony covering be present and carious, its removal cannot be accomplished without seriously interfering with the nerve. Another problem which my limited experience has not afforded me an opportunity of solving is whether the condition would be less likely to occur if the posterior operation (of Stacke) be employed instead of the operation through the canal, the latter being the method that I have employed in each case. The patients were all treated by thorough cleansing, both by means of the cotton applicator and with the post-tympanic syringe, as far as it was possible and as long as I felt it was wise to continue it. The results obtained, in so far as the suppuration was concerned in each case, I think justify the operative procedure.

Case I.—Mr. L., thirty-two years of age, first consulted me April, 1893, when he gave a history of suppuration of the left ear for twenty-two years; suppuration from the right side had lasted but a few months, while on the left side it had been persistent during the entire period; he had been treated at intervals, though without in any way affecting the condition. The examination when I first saw him showed in the right ear a depressed cicatrix in the lower anterior portion of the membrane and some general thickening; on the left side there was a fetid discharge from the canal, which on removal showed considerable destruction of the upper wall, and the bent probe readily passed into the attic region; the hearing for whisper-sounds was on the left side, one foot, on the right, about six feet; the tuning-fork gave R. upon both sides; the patient complained of a fulness and some aching and tinnitus. The treatment, which was continued from three times to twice a week, from April until September, consisted of thorough cleansing, both by means of the cotton-carrier and hydrogen dioxid, and syringing with hot water carried well up into the cavity, and then followed by dusting the canal with borated powder. The naso-pharynx was also treated each time the ear was treated. While this treatment served to greatly lessen both the fetor and the amount of discharge, the latter at no time entirely ceased, there being at each visit some suppuration from that region. The operation consisted of removing what remained of the membrane, malleus, and incus, the head of the malleus being lost and also a large part of the body of the incus; the cavity was then thoroughly curetted and part of the upper, posterior portion of the roof of the canal was carefully chiselled away; the whole cavity was then thoroughly washed out with a hot saturated solution of boric acid, and dusted with aristol, and the canal closed with a cotton pledget. Thirty-six hours after the operation, a marked paralysis was noted of the entire left side of the face, including the eyelids and brow, which fortunately subsided in six weeks. The suppuration had entirely ceased in eight weeks. The patient has reported to me once a month, and I have been gratified to find that the good results still continue.

Case II.—Miss K. McN., twenty years old, has had suppuration on the right side for fourteen years; she has no recollection of having had suppuration on the left side, though a lower, anterior cicatrix clearly proves the contrary; the condition followed scarlet fever. When she consulted me on June 12, 1893, I found the canal partially filled with desiccated pus, removal of which brought to view an attic filled with granulation-tissue, the removal of which left the malleus-head bare. This case was treated in the routine way described until the latter part of September, when the operation was performed. The membrane, malleus, and incus were removed; the malleus was apparently not carious, while a large portion of the body of the incus was lost; the entire cavity was then thoroughly curetted and treated as in the foregoing case; paralysis here appeared on the third day after the operation and continued for about seven weeks; the discharge had entirely ceased by the end of the tenth week, and the cavity is perfectly well at the present time. The examination of the membrane within a month past shows a perfectly healthy cicatrix. The hearing, which was very deficient, was not in any way improved, though she thought the tinnitus, which was very marked, was somewhat improved.

Case III.—Mrs. Le C., thirty-four years of age, has had suppuration from the left ear for thirteen years. When I saw her first, about one and a half years ago, there was free fetid discharge, which was more profuse in this case than is usually found in cases of attic suppuration; the bent probe passed well up into the attic, and the cleansing brought down large quantities of necrotic tissue, black and very fetid; the tuning-fork gave R.; the hearing was very good, a whisper being heard at four feet; she complained of vertigo and tinnitus, the former being so great that treatment by syringing was extremely difficult to carry out. After having treated the woman for a year and more without benefiting her to any great extent—indeed, if she went longer than a week without cleansing, the discharge would become as profuse and fetid as when I first saw her; the operation was performed November 2, 1893. In addition to removal of the malleus, the head of which was almost entirely destroyed, a portion of the posterior part of the roof of the canal was chiselled away, and what remained of the membrane was excised; the incus could not be found, and was probably destroyed; paralysis was noted in this case before she had recovered from the anesthetic; it was indeed complete. The suppuration had entirely ceased by January, though for a month previous to that time it had only been sufficient in amount to harden the powder that had been blown into the canal. The paralysis in this case has been per-

[1] Read before the Section of Otology, College of Physicians, April 3 1894.

sistent, and while it is at present showing evidence of subsiding, it will, I fear, be some time before it is completely relieved; the vertigo following the operation was also a very annoying symptom, and continued for two weeks; there was, however, but slight elevation of temperature. The case is now under treatment at the University Hospital, at the hands of Dr. Potts, the electrician, who has kindly furnished me notes as to the muscular reactions, his opinion being that the nerve was not severed, but that it had been greatly irritated, probably by the pressure of a spicula of bone against it.

ELECTRICIAN'S NOTES.—The muscles did not respond to the faradic current, but did to a moderate galvanic current (about 6 to 8 milliampères). Qualitative reactions were present, the muscles responding in the peculiar slow manner characteristic of degenerated muscles and the A C C was about equal to K C C. Owing to the fact that the muscles exhibited K C C of about equal strength to that of A C C six weeks after reception of injury, we were led to assume that the nerve had not been seriously injured and to give a good prognosis. Normal reactions have returned in some of the muscles—now something over two months since treatment was begun.

In none of the cases was there any perceptible change in the hearing. There was, however, apparently some lessening of the tinnitus in Case II, and absolute relief from the vertigo in the last case. In all, the discharge was stopped, and it is reasonable to believe cured, though I am not prepared to claim this latter fact absolutely. It is my opinion that the want of proper drainage is the sole cause for the persistence in attic suppuration, as we know that drainage through the tube is usually cut off by the inflammatory adhesions within the middle-ear cavity, and thereby leaving the attic region entirely without any drainage. It would, therefore, seem to be good surgery to remove all obstructions, even though so annoying a condition as paralysis may follow.

THERAPEUTIC NOTE.

SULPHURIC-ACID PASTE IN THE TREATMENT OF EPITHELIOMA OF THE FACE.[1]

BY E. OLIVER BELT, M.D.,
OF WASHINGTON, D. C.,
LECTURER ON OPHTHALMOLOGY AND OTOLOGY, HOWARD UNIVERSITY, AND OPHTHALMIC AND AURAL SURGEON TO FREEDMAN'S HOSPITAL.

EPITHELIAL carcinomata about the eyelids, brow, nose, and cheek are not uncommon. The clinical history of an ordinary case is about as follows: Beginning usually after middle life as a small, flat, wartlike growth, the new-formation appears very innocent at first, attracting but little attention, perhaps, until some years elapse, when it begins to ulcerate; the ulceration may heal temporarily, only to begin anew later on, when it suddenly begins to spread, attacking all kinds of tissue, sometimes destroying the eyeballs, nose, and bones of the face, the patient being in a most pitiable condition until relieved by death. Fortunately most of these cases are found in very old people, who die of natural causes before the growths give much annoyance. Occasionally, however, we see them in patients between forty and sixty years of age, with whom they may become a very serious trouble, and even destroy life years before the allotted time. By proper treatment before too much tissue is involved epithelioma of the face can unquestionably be eradicated, and yet we see now and then cases that have passed beyond all help of the physician or surgeon. Inquiry into the history of these hopeless cases will usually elicit the fact that the patient has allowed the trouble to reach this stage owing *to the dread of having it cut out with the knife*, which may have been recommended by his physician, or to escape this he has had applied some "cancer cure" that he has heard of or seen advertised, which has served only to irritate, and often rapidly extend the disease. Most authorities recommend excision, and no one doubts its efficacy; but if the dread of the knife causes one to postpone treatment, it is well to try something unobjectionable to the patient and equally reliable; so we naturally turn our attention to local applications. We find many preparations recommended—among them may be named caustic potash, citrin ointment, Vienna paste, and pastes of chlorid of zinc, arsenic, and sulphuric acid, as well as the cautery. Of these some are very painful and harmful. Though the chlorid of zinc paste and the cautery seem to be the most frequently advised, my own experience leads me to call especial attention to the value of a paste made of sulphuric acid and charcoal from saffron, in about equal quantities by weight. It is by no means a new remedy, having been used years ago by Velpeau, Michel, and others; but little has been written about it, and I do not think it is used now as generally as its efficacy justifies. I first saw it used by Dr. J. J. Chisolm, while I was his assistant at the Presbyterian Eye and Ear Hospital, where it was frequently employed during the three years that I was connected with that institution, and in no case did I see an unfavorable result.

In a recent letter from Dr. Chisolm he speaks of its use as follows: "I have been using carbo-sulphuric paste for thirty-five years in epithelial troubles of the face. It is one of the very old-time applications. I was taught its value as a student. The very fact that I continue to use it is because I know nothing quite so good. If properly made with flowers of saffron, which makes the finest kind of carbon, it becomes a tenacious paste that will stick to a raw surface and become a part of the slough or dry scab, when slough and paste come off together, leaving a newly healed surface, which delights the heart of the surgeon. It is a first-rate application, which every one should know about.

If the application is limited to the diseased tissue, it is not very painful unless the new growth is extensive. A few applications usually suffice, when a dry scab is formed, which peels off somewhat like a vaccination crust, leaving only a slight scar.

A single case illustrates its value as compared with some other methods. About eighteen months ago Dr. J. came to me to have a small epithelial carcinoma removed from the side of his nose near the inner canthus of the right eye. He told me that he had recently returned from New York, where he had taken his wife to a special hospital to have a similar trouble removed from her face. She was kept in the institution at heavy ex-

[1] Read before the Medical Society of the District of Columbia, April 18, 1894.

pense for three weeks, during which time caustics and poultices were applied. She was cured, but with a great deal of discomfort, loss of time, and heavy expense. Not being pleased with the treatment, the Doctor, whose own case was pronounced worse, came to me to have the sulphuric-acid paste applied. Two applications were made in three days, and about the tenth day the growth came away entire, the Doctor not having been kept from his practice more than a half-hour. I never advise this paste when the mucous membrane is involved. In all other cases that have not progressed too far, I like it as well as the knife, and think if physicians would use it with patients who postpone treatment from the dread of cutting, there would be few cases that reach the hopeless stage.

NEW DEVICE.

A NEW FORM OF PALATE-HOOK.

BY A. H. CLEVELAND, M.D.,
OF PHILADELPHIA;
SURGEON TO THE EAR, NOSE, AND THROAT DISPENSARY OF THE PRESBYTERIAN HOSPITAL; INSTRUCTOR IN LARYNGOLOGY, PHILADELPHIA POLYCLINIC.

WHILE in most cases posterior rhinoscopic examination is possible without the aid of a palate-hook, in some instances such a device becomes an absolute necessity.

In view of this and on account of the generally unsatisfactory forms of retractor which illustrate the instrument-maker's catalogues as well as most text-books on rhinology, I desire to call attention to the instrument shown in the accompanying cut.

The main portion of the retractor consists of a piece of medium-weight steel wire about twelve inches long. This is bent back upon itself at its middle and there again sharply bent up on the flat to form a hook. At about two and a half inches from this hook the ends are again bent upward upon the flat, at an obtuse angle. From the hook to this latter bend the wires are securely fastened; from there on they are separated horizontally in a V-form. Over this outer portion slides a flattened ring having projections upon its inner side to catch in parallel notches upon the outer surface of the diverging arms. To this portion also belong the two curved arms which rest upon the upper lip, or which, if necessary, may be made to rest within the nostrils. Flattened metallic handles are fastened to the ends of the main portion.

In using the instrument the handles are approximated, and the slide drawn out until in contact with them. The hook is then introduced behind the palate, the necessary traction made to draw it forward, and the slide allowed to fall until the bars engage the lip or slight pressure may be made upon it with the ring finger.

Simply allowing the handles to spring apart fixes the catch and the instrument is in position. The angle at the vertex of the V throws the handles above the lip and thus out of the way of all manipulations.

In removal, the handles are pressed together, the instrument pushed slightly, and the hook disengaged by turning, when it may be withdrawn.

The superiority of this to all other forms of self-retaining retractors lies in the fact that both introduction and withdrawal may be accomplished with one hand. By the exercise of a little dexterity, the retractor may be used and a complete examination made with one depression of the tongue—often a great convenience when that organ is muscular and rebellious.

In my own practice I have frequently had occasion to use the hook, and it has always proved very satisfactory. In introducing this instrument I can unfortunately make no personal claim of invention. It was devised several years ago, by an American whose name I have been unable to learn, while studying in Vienna, and although in use there, is not generally known in this country.

1804 CHESTNUT STREET.

MEDICAL PROGRESS.

Akromegaly.—At a recent meeting of the Philadelphia County Medical Society, DR. S. SOLIS-COHEN presented a case of akromegaly exhibiting some structural changes not found, or at least not recorded, in all cases, and called attention to the apparently good results of treatment with desiccated thyroid gland.

The patient, some fifty-two or fifty-three years of age, came under observation about eighteen months before for relief from excruciating headache, which had for many months been so intense at times as to prevent his lying down, pressure on the scalp increasing the pain. Attention was at once attracted to the peculiarities of facial structure presented, and further examination demonstrated the characteristic curvature of the back and enlargement of the hands and feet. The patient stated that his features had materially altered within the preceding four years.

He had had to enlarge his hat-band twice, and his shoes twice within three years. The shoes were a little longer but much broader than formerly. The hands were broadened rather than lengthened; the fingers not exactly "sausage-shaped," but thick and clumsy. Distortion of the joints was to be attributed to his occupation, and probably antedated the development of the akromegalic conditions. Part of the coarseness of the skin of the hands might likewise have been due to occupation.

The enlargement and projection of the superciliary ridges, the lateral projection of the malar bones, the broadening and deepening of the chin, gave the face the characteristic lengthened, elliptic outline. The great enlargement of the nose; the thickening and projection of the lips; the heavy folds, deep furrows, and somewhat greasy texture of the skin, especially of the forehead; the stiffening and projection of the auricular cartilages, completed the picture. The lower jaw did not, however, project beyond the upper jaw. The teeth were bad. The tongue was thickened and deeply fissured. The voice was deep and had a monotonous quality, the latter only partly attributable to a "boilermaker's deafness." The laryngeal and tracheal cartilages were almost if not completely ossified. The thyroid gland could not be demonstrated. The forward thrust of head and neck,

from curvature of the cervico-dorsal spine, threw the clavicles well out from the windpipe, leaving a great hollow just above the sternum. The clavicles and scapulæ were enlarged, the ribs were broadened and apparently in contact, and the costal cartilages seem to be ossified. The narrowing of the chest and the percussion-phenomena showed an absence of emphysema; yet the breathing was scarcely at all thoracic. There was an almost inappreciable rise and fall of the clavicles, showing slight vertical motion of the thorax as a whole, and on great inspiratory and expiratory exertion an expansion of from 0.5 to 1 cm. could be determined at the nipple line. Breathing was almost exclusively abdominal.

The patient was becoming feeble; his muscles were wasting, though electric examination showed only quantitative change.

He presented vasomotor phenomena—flushing, occasional vertigo, and polyuria. The urine was deficient in solids, but did not contain sugar or albumin, nor was other abnormality detected. After treatment with thyroid-powder (5 grains in capsule every morning) the quantity of urinary water decreased and the urea-content arose, while the distressing headache was completely relieved. An intercurrent attack of violent sciatic pain disappeared after recourse to thyroid medication.

Upon the somnolence, however, no effect was obtained. The patient could still go to sleep upon the slightest provocation—indeed, without any.

Ophthalmoscopic examination disclosed no lesion of the fundus and no error in the visual field, a confirmation of the view that hemiopia and other visual errors are merely secondary phenomena, due to pituitary enlargement, and that the latter is not necessarily a feature of the pathologic complexus. The opinion was expressed that early treatment with thyroid preparations will entirely prevent overgrowth of the pituitary body, embryologic analogy seeming to indicate that it is an attempt at compensatory hypertrophy, ill-directed and baneful only by reason of the altered position of the structure.

Pickaxe Wound of the Brain.—At a recent meeting of the Surgical Section of the College of Physicians of Philadelphia, DR. JOHN B. ROBERTS presented a man who came under his observation with a small wound of the skull through which brain-substance oozed. Four weeks previously he had been struck with a pickaxe, shortly before admission to the hospital. Within an hour and a half of the injury the skull was laid open, and pieces of bone were found driven into the brain. With the mallet and chisel the edge of the fracture was cut away, and the fragments of bone removed with forceps from the brain-tissue. A finger passed nearly an inch down into the brain-structure, which was soft. The soft brain-tissue was then washed away with a stream of bichlorid solution. As there was a good deal of oozing from the pia a small piece of gauze was stuffed into the wound to make a little pressure, the scalp-wound was sewed up at the ends, but the gauze was allowed to stick out at the center. The wound united by first intention where the edges were sewn together; and by second intention where the wound had been kept open by the gauze, which was removed at the end of twenty-four hours. The wound had finally healed, and the man was well. The pulsation of the brain could be seen where the bony wall was absent.

The Mortality from Typhoid Fever.—From an analysis of the cases of typhoid fever, 144 in all, admitted to the London Temperance Hospital during a period of twenty years, and a comparative study of the results obtained in other hospitals, BENJAMIN WARD RICHARDSON (*Asclepiad*, No. 40, vol. x, p. 352) concludes that the average hospital mortality from typhoid fever is from 15 to 16 per cent. Cases received in the earliest stages and treated judiciously may exceptionally yield as low a mortality as even 2 or 3 per cent. The dangers occurring during the diseases are due to complications, and especially to those involving the alimentary canal; these dangers are much intensified by movements of the body and errors of diet. In ordinary hospital practice, including every kind of case at any stage, 9 per cent. is the most favorable average. In spite of complications, so often present when the patient is admitted, it may be possible to keep the mortality down to 9 or 10 per cent, without any use of alcohol; with baths and other suitable appliances still more encouraging results may be obtained. There is not a shadow of proof that abstinence from alcoholic treatment increases the mortality of typhoid fever.

Suprapubic Cystotomy in an Infant Two Years Old.—MINEUR (*La Policlinique*, 1894, No. 8, p. 127) has reported the case of an infant, two years old, that for two months cried upon passing water, and gave evidence of irritation referred to the penis. Examination with a sound disclosed the presence of a large calculus in the bladder. It was decided to remove the foreign body by suprapubic cystotomy. The bladder was distended with a solution of boric acid, and a water-bag was introduced into the rectum. An incision, two inches long, was made in the median line above the pubis; the bladder was supported by a suture on either side and then incised. The calculus was removed with the aid of forceps, and a rubber drainage-tube was introduced and held in place by means of a suture. The bladder was fixed to the abdominal wall and the wound closed, except at the point where the drainage-tube made its exit. On the sixth day the tube was removed, and perfect recovery soon ensued.

The Pathogenesis of the Laryngeal Complications of Typhoid Fever.—LUCATELLO (*Berliner klinische Wochenschrift*, 1894, No. 16, p. 379) has reported a case of typhoid fever in which, in addition to the classic lesions, there existed a reddish-gray hepatization of the upper lobe of the right lung and a catarrhal condition of the mucous membrane of the larynx. During life puncture of the spleen on the tenth day disclosed the presence of the typhoid-bacillus, and examination of the saliva and of laryngeal secretion on the twelfth day disclosed the presence of the same organism. It is believed that the changes induced by the presence of the organism in the larynx, sometimes resulting in ulceration, predispose to the lodgment of other microörganisms, including those with pyogenic properties, and it is through these that the secondary processes sometimes observed are brought about.

To Clean Soiled Slides and Cover-glasses ZETTNOW (*Centralblatt für Bakteriologie u. Parasitenkunde*, Bd. xv, No. 15, p. 555) recommends the employment of a solution containing 200 grams of red potassium chromate, to which are added 2 liters of hot water, and then, gradually, with constant stirring, 200 c.cm. of crude concentrated sulphuric acid. As the fluid will not penetrate beneath affixed cover-glasses, it is necessary, first, to remove these by gentle heat over a flame. To facilitate the cleaning of cover-glasses these may be heated in the fluid over a water-bath, care being taken that the fluid be well distributed, so as to act on all. The covers may then be washed in water, and afterward in a weak solution of sodic hydrate for five minutes, twice or oftener, and finally rinsed with alcohol.

THERAPEUTIC NOTES.

Congelation in Diagnosis and Treatment.—At the twenty-fourth annual meeting of the Medical Society of the State of California, DR. ALBERT ABRAMS spoke highly of the therapeutic application of freezing, by means of chlorid of methyl, or rhigolene, or some similar volatile body in the treatment of neuralgia.

In order to intensify the shock in freezing, the part to be frozen may first be rendered anemic by means of an Esmarch bandage or by parenchymatous or hypodermatic injections of water. By means of the first procedure congelation occurs sooner, is more intense, and of longer duration.

The second, which is denominated "reinforced freezing," can be employed in conjunction with the first, and is executed as follows: With a large-barrelled syringe a sufficient quantity of water is injected beneath the skin over the part to be frozen, or directly into the tissues, until an appreciable bulging is produced. If the spray is now directed on the protuberant part, a lump of ice is formed in the tissues or under the skin.

Congelation has been thus employed as a means of diagnosis for the following purposes: To distinguish between neuralgia of central and that of peripheral origin; to differentiate neuritis from neuralgia; to locate the lesion in neuralgia; to differentiate many neuralgic affections of the head, and thoracic and abdominal parietes, from visceral disease.

If a nerve, the seat of neuralgia, is frozen nearest its point of origin, the pain will disappear if the neuralgia is of peripheral origin, and persist if of central origin. In the absence of spontaneous pain, the painful points in the course of the nerve-distribution may serve as guides. Freezing is said to be a specific for all recent forms of uncomplicated neuralgia.

Pain referred to an accessible nerve, treated by freezing near its point of exit, and failing to yield to repeated applications of the spray, is not a veritable neuralgia, but a neuritis, or complicated neuralgia.

In the treatment of neuralgia, when reinforced freezing is not advisable, recourse may be had to a modified method, which is denominated "coin-freezing." The method is as follows: A coin of indifferent size is employed, and, having been previously moistened in water, is placed in close contact with the site to be acted upon; the spray is next directed on the coin. After allowing the spray to act for a certain time, which is determined by experience, it will be found impossible to remove the coin without some difficulty. The advantages claimed for this method are: That the freezing is more thorough, and that it can be accurately localized. It is less severe than reinforced freezing.

Neuralgia of the intercostal nerves may be accompanied by visceral symptoms of such prominence that the intercostal neuralgia is overlooked, and treatment is directed toward a presumable visceral disease. Such cases, while presenting a varied clinical picture, are frequently mimetic, even if only atypically so, of gastric, cardiac, renal, vesical, and esophageal affections. As a rule, however, vertebral tenderness corresponding to the exit of the nerves can be elicited, and when congelation is practised over the seat of vertebral tenderness during a paroxysm, the latter is nearly always inhibited.

It was finally pointed out that the use of congelation may be extended in surgery to the treatment of local tuberculosis, tumors, etc. Parenchymatous injections of water into tumors, coupled with freezing (reinforced freezing), may prove of inestimable value in the treatment of neoplasms. In parasitic affections of the skin good results had been obtained in some cases.

The Pathogeny and Treatment of Sciatic Neuritis.—At the recent International Medical Congress, PERSONALI (*Le Mercredi Médical*, 1894, No. 17, p. 203) expressed the view that a large number of cases of sciatic neuritis represent but a secondary process, depending upon the extension to the sciatic nerve of an inflammatory process set up by various causes in the connective tissue surrounding the coxo-femoral articulation. Support for this view is found in the pain early referred to the articulation, in the limping gait observed before the sciatic nerve is known to be involved, in the pain induced in parts adjacent to the joint by rotation of the thigh, by the extension of the pain to the entire hip, to the crest of the ilium, and to the external border of the sacrum. The treatment employed and advocated in these cases consists in the employment of the faradic current. One electrode is applied to the lumbar region; the other electrode consists of a brush made of fine, flexible copper wire, which is rapidly passed over the entire affected hip, the sciatic nerve, and the muscles of the calf; then the rapidity is diminished in order to accustom the patient to the pain of the current; and the sitting is concluded by leaving the brush in place for a minute successively upon the painful points upon the hip in the course of the nerve, and in particular over the great sciatic notch, at intervals of twenty or thirty seconds. A strong current is used, as the pain is intense; the sitting is repeated daily, and the entire treatment covers from twenty-five to forty-five sittings. The first result of the treatment consists in an aggravation of the symptoms for about a week; thereafter the pains progressively disappear.

Guaiacol in the Treatment of Erysipelas.—WHALEN (*Journal of the American Medical Association*, vol. xxii, No. 17, p. 619) reports the treatment, with satisfactory results, of several cases of erysipelas with topical applications of guaiacol in doses of from 20 to 30 minims.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 26, 1894.

NOW, THE JUDICIAL COUNCIL!

By the action of the Medical Society of the State of Pennsylvania in formally presenting to the Judicial Council of the American Medical Association a statement of the facts in the case of *The Association* vs. *The Trustees*, the subject becomes one for judicial inquiry and determination, and further discussion *pro* or *con* may well be suspended. It is proper, however, that the issue brought before the Council should be clearly understood, and our last word on the subject will be devoted to this purpose. As we read the statement of the Medical Society of the State of Pennsylvania, it charges the Trustees, not individually but as a body, with official misconduct. If a minority of that body or any individual member has by word or vote endeavored to prevent the misconduct complained of, this fact should now be made clear, so that the innocent may not suffer with the guilty. Should no statement as to individual responsibility be volunteered by either majority or minority, it is the duty of the Judicial Council to inquire into all the facts, not only in justice to individual Trustees, but in justice to itself, to the Association, and to the Medical Society of Pennsylvania, which appears as prosecuting attorney.

The indictment brought by the Pennsylvania Society has two counts:

1. That in originally admitting advertisements of secret nostrums into the columns of the *Journal*, the Trustees were guilty of a *breach of trust;* inasmuch as the organic law of the Association, virtually constituting a deed of trust under which the *Journal* is administered by said Trustees, prohibits such action.

2. That in continuing to publish such advertisements after the Association had by formal vote directed their attention to the prohibitory clause of the deed of trust, and ordered them to respect it, the Trustees added to their original violation of trust the new offence of *overt rebellion* against the constitution and laws of the Association.

The additional charges of permitting the publication of personally abusive letters, and of inserting the advertisement of a certain Sanitarium Company, are simply cumulative, and fall under the two heads of *breach of trust* and *rebellion*, already stated.

Incidentally the attention of the Judicial Council is directed to the connection of certain officials and ex-officials of the American Medical Association with the Sanitarium Company alluded to.

Failure by the Judicial Council to act with due appreciation of the gravity of the case laid before it is a disaster not to be anticipated. Those who count upon bringing about such failure forget that it would be tantamount to a confession that the Code of Ethics is meant for show rather than for use; or if for use, merely to frighten the little boys with, while the big ones climb the farmer's apple-tree, and unhindered help themselves at leisure. It would inevitably be taken as a virtual repeal of the Code, in Council, without awaiting the verdict of the Association. It is, we repeat, a disaster not to be anticipated.

Pennsylvania has been patient in waiting, temperate in statement, and moderate in demand. It does not, as it might well have done, ask the censure or expulsion of the Trustees, but submits the facts to the Judicial Council for such recommendation as in the view of the Council may best vindicate the authority of the Association. It is purification, not punishment, that is aimed at, and should the Council, in its wisdom, decide to temper justice with mercy, Pennsylvania will surely not object.

The whole proceeding, however, the humiliating necessity for the presentation to the judicial branch

of the Association of such grave charges against its most important executive branch, should make us seriously ponder. The only defence thus far made by the organ of the Trustees is that the breach of trust complained of was done for the sake of money-making. This defence assumes that the Association will adopt as its motto: "Whatever pays is right!" Had the Code of Ethics been repealed, it would have been difficult to repudiate this assumption. A more impressive object-lesson of the utter demoralization that would follow the adoption of the report of the majority of the revision committee could not well be imagined.

We trust that the delegates to San Francisco will take the matter earnestly to heart, and especially in selecting the officers and Trustees of the American Medical Association. It is not enough that these should be men of high personal character, untainted by questionable associations; they must not be men who, from indecision, timidity, or that amiable weakness miscalled "good-nature," will permit official wrong-doing to go unchecked or unchallenged.

EDITORIAL COMMENTS.

Reforms in the Care and Treatment of the Insane.—It is not often that a speaker is invited to criticise those whom he is asked to address; but this is the unique position in which Dr. Weir Mitchell found himself on the occasion of the fiftieth annual meeting of the American Medico-Psychological Association just held at Philadelphia. When first asked to speak, Dr. Mitchell wished to decline on the rather frank plea of not having anything good to say of those, as a body, who extended the invitation. Upon being assured that fair criticism would be received in a proper spirit, Dr. Mitchell hesitatingly accepted the invitation. That he was as good as his word none will doubt who had the privilege of hearing Dr. Mitchell on this occasion. Bristling with criticism was the address—criticism of the severest kind, yet well meant and perhaps, as even those most nearly concerned may admit, not entirely undeserved. The numerous defects in the management and administration of hospitals for the insane was clearly and forcibly indicated, and the requisite and suitable remedies consecutively pointed out. Reference was made to the seclusion with which the hospital alienist ordinarily surrounds himself, not coming in sufficient and frequent contact with physicians generally, thus failing to give and receive new knowledge and losing the stimulus that friendly competition and friction with one's colleagues always affords. Regret was expressed that hospital alienists had not contributed more largely to medical thought and had not furnished answers to many of the unsolved problems connected with diseases of the mind. The need, aye, the demand for skilled nurses for the care of the insane, both in hospital and out of it, was strongly emphasized, and deficiencies in equipment as regards special therapeutic measures, such as massage, electricity, hydrotherapeutics, and the like, were forcibly pointed out. Particular stress was laid upon the importance of furnishing employment for the patients, and particularly out-of-door occupation. Concerning this urgent necessity The News has frequently spoken its word. The question was raised if sufficient thought were given to the future of cases dismissed as cured, as to whether or not directions were given as to the mode of life, in order to prevent relapse or recurrence. For many of the evils it is admitted that much blame attaches to the extra-medical management. Among other things, it is too much to expect that one man shall be both administrative superintendent and medical director. The appointment of medical officers on the basis of political adherence was condemned in language none too severe, and the inadequacy of the average board of managers was only too vividly and faithfully delineated. Dr. Mitchell's ideal hospital for the insane would include a group of buildings near the city, beautifully surrounded with Nature's decorations and amply endowed; a chief medical officer, who should live and spend a part of his time outside of the hospital; an adequate resident staff, a full corps of trained nurses, and a consultant staff comprising the ablest alienists and neurologists to be had, and to be selected solely on account of their ability. If the deficiencies and evils pointed out by Dr. Mitchell were corrected, and if but a tithe of the reforms advocated were put into execution, the art and the science of medico-psychology will have received an impetus whose influence will reach far beyond the present and far beyond the circle of those to whom defect and remedy were directly pointed out.

Disgusting Wire-pullers.—The success of the methods of the lowest type of governmental and legislative politicians has served to give us some rather stupid imitators in medicine. In almost every medical society will be found a clique addicted to the ignoble arts of "pipe-laying" and office-scheming. For months prior to an election of officers these fellows are snakily at work, "fixing" matters and men with a view of forestalling or prejudicing the minds of electors, or of nominating committees, or of those who appoint such committees. According to current report the officers of the American Medical Association have already been chosen and their election assured by the wire-pullers. There is never the least doubt about the motive of the politicians—such men have but one motive. It is a motive thoroughly well recognized and understood by those who, unselfish and frank, have had dealings with these thoroughly selfish and artful tricksters. The tools made use of for their purposes are the thoughtless, the trustful, the stupid, the indifferent. The clique is usually made up of a few, cunning, oily, and sly, who never express an opinion, and who want to be leaders and manipulators, and who especially want consultation-practice; there are also others hungry for nostrums, jobbery, and profit; still others more hungry for office to satisfy vanity and ambition; a few gushers and "big-hearted," "broad-gauge" fellows with a hidden world of slimy selfishness beneath the hail-fellow-well-met masks—all "on the make" (one is compelled to use curbstone slang

to describe them)—all caring as little for scientific medicine, humanity, or our profession, as a lot of dickering Senators or Tammany politicians care for justice or for good government.

Is it not time we made an end of this execrable nonsense? The attempt to boost oneself or his "pals" into office, or to get the appointment to deliver "the address in ——," to "fix" nominating committees, to forestall the free and spontaneous action of the electors, is simply disgusting. The things that the medical politicians scheme for, by reason of the very facts of the schemers and the schemings, are precisely the things that should *not* be done.

A Desirable Amendment to State Licensing Laws.—While of course it is desirable to prevent incompetent and unqualified persons driven out of one State by medical license laws from settling in another, it is also desirable that competent and qualified physicians removing from one State to another should not be subjected to unnecessary annoyance and expense. Would it not be possible to incorporate in the various State laws an identically phrased amendment, providing that a physician legally qualified to practise in any State of the Union in which a medical license law is in effect, should be entitled to register in any other State upon presentation of a certificate of qualification from the licensing-board of his own State? In some of the recent State laws there is, we believe, a proviso that anyone who has successfully passed an examination before the Licensing Board of another State shall be entitled to practise without reëxamination, but we should be pleased to see the same privilege, or rather right, extended to competent physicians who graduated before the days of Licensing Boards, and to whom reëxamination would be a hardship, while unnecessary for the protection of the community. Such an amendment to existing laws as would secure the end desired without breaking down any of the safeguards against the irruption of quackery, established with so much difficulty, might, we think, be easily drafted by a committee of the American Medical Association, and we commend the subject to the attention of the Section on State Medicine.

REVIEWS.

Proceedings of the Philadelphia County Medical Society. Vol. xiv. Session of 1893. Lewis H. Adler, Jr., M.D., Editor. 8vo., pp. xxviii, 484. Philadelphia: Wm. J. Dornan. Printed for the Society, 1893.

This volume of *Transactions of the Philadelphia County Medical Society* is calculated to maintain the high standard of work for which this eminently representative body is known. We can only select for reference a few of the large number of subjects discussed. Perhaps the two most important discussions are those on the subject of abortion, particularly in its medico-legal aspects, and that on the steps to be taken in the prevention of tuberculosis. We are gratified to learn that a committee of five has been appointed to investigate the question of the advisability of presenting to the Legislature a bill looking toward the making of the statements of patients to their attending physicians privileged communications. The News has already expressed its conviction that the physician should, in this connection, be placed upon the same plane as the lawyer, and should be permitted in a court of law to decline to divulge information communicated by patients in the strictest of confidence. It is already well known that the County Society has adopted a resolution recommending that tuberculosis be placed upon the list of diseases to be returned to the Board of Health. The agitation has not been devoid of good, for the Philadelphia Board has, since, taken judicious action, issuing circulars of information and offering to undertake disinfection whenever requested by a physician. Registration of cases is invited, but has not been made compulsory. A paper entitled "Hypodermatic Medication in Syphilis," by Dr. Lawrence Wolff, and another entitled "The Present Position of the Hypodermatic Method in the Treatment of Syphilis," together with the discussion of both, give a good *résumé* of the opposing views upon this important subject. Attention should further be called to the admirable portable tub described by Dr. W. R. Batt, which thus makes practicable the almost universal employment of the cold bath in the treatment of the febrile process. The book also bears evidence of the operative activity of the gynecic surgeon.

The volume, as a whole, is a most creditable one, for the preparation of which not a little praise is due the editor. The mechanical details are of the usual high standard that characterizes the work of Dornan.

Transactions of the American Orthopedic Association. Vol. VI. Philadelphia: Wm. J. Dornan, 1893.

This volume contains thirty-three valuable contributions to orthopedic literature from some of the foremost orthopedists of the country. In his address, the president outlines briefly the history of the Association, illustrating therein the value or power of a thought properly directed and carried out. Scientific and practical papers on the knee by Willard, Judson, Phelps, Lovett, Taylor, and others, show thought and research in preparation. Several new knee-splints are reported which indicate originality on the part of the authors and also that methods of obtaining fixation and immobilization are being diligently sought for, though unfortunately they have not yet been discovered. The mechanical and surgical aspects of hip-joint disease are discussed by Bradford, Judson, Sherman, and others, and quite a number of hip-splints described and illustrated, indicating the need which exists of some simple form of appliance which, with certain modifications for individual cases, can be depended upon to combine extension and immobilization.

The historic papers of Judson on "Traction in Hip-disease," Griffith on "Tumor Albus," and Wilson on "Bone Operations in Equino-varus" are especially instructive contributions. Papers on other topics by Myers, Weigel, and others, and presentations of orthopedic instruments of various description also occur. The book is useful as a reference to individual opinions and judgments as expressed in the papers and the discussions following their presentation.

Philadelphia Hospital Reports. Vol. II, 1893. Edited by Charles K. Mills, M.D., and James W. Walk, M.D. 8vo, pp. x, 292. Philadelphia: J. B. Lippincott Company, 1893.

We have only words of welcome and praise for this second volume of the *Philadelphia Hospital Reports*, which contains some forty-four articles, of varying degree of interest and value, together with a catalogue of the specimens contained in the Pathological Museum. This collection of specimens constitutes really the only permanent resource of the hospital for purposes of instruction and study, as the clinical records and, to a certain degree, the pathologic records, will not afford much help to future investigators. We thus have good reason to be doubly glad to have some permanent record of the clinical and pathologic work of the hospital, a field rich beyond conception in material of both kinds, and take this occasion to express the hope that a perfected system of record-making and record-keeping may be instituted, in order to make the observations of value, not only to those now in the service, but that they shall constitute records of permanent value, to be referred to with satisfaction and profit by those who may in the future desire to consult such statistics. This volume contains a sketch, together with a good lithographic likeness, of the late D. Hayes Agnew, and also a sketch of the late Alice Fisher.

Transactions of the American Dermatological Association for 1893. Edited by George Thomas Jackson, M.D., Secretary. Pp. 82. New York, 1894.

The contents of this volume include a number of valuable and interesting papers, several of which are illustrated, discussions on Pityriasis Rosea and Pemphigus, and the Report of the Statistical Committee. There is also a list of the publications of the members during the year ending September 1, 1893. Among the papers may be mentioned that of Dr. H. Radcliffe Crocker, of London, on "Lupus Erythematosus as an Imitator of Various Forms of Dermatitis." Cases are described in which the lesions closely simulated those of erythema papulatum, erythema tuberculatum, psoriasis guttata, and lichen planus, the latter illustrated by an excellent colored drawing. In an instructive "Contribution to the Pathology of Acne Varioliformis Hebræ," Dr. John Addison Fordyce arrives at the conclusion that the affection is "an inflammation of the pilo-sebaceous system, probably microbic in origin," and that Bazin was correct in naming it acne pilaris. The histologic dissimilarity of hydradenitis and acne varioliformis, between which the clinical resemblances are very close, is explained on the supposition that in the one case the pathogenic organisms penetrate through the sweat-ducts and in the other through the hair-follicles.

Annual Report of the Health-Officer of the Port of New York for the Year 1892. 8vo, pp. 120. Albany, 1893.

Dr. Jenkins' report covers forty-seven pages, the remainder of the book consisting of seven appendices. It is mostly a narrative of the threatened invasion of cholera in the autumn of 1892, and bears evidence of the author's irritation at the criticisms of his conduct during that episode.

In Appendix E, by Dr. J. M. Byon, there is given a very interesting account of the work done by the medical staff, nurses, and assistants at Swinburne Island and the lower quarantine station. Of this the part which will most engage the attention of the profession is that bearing upon the treatment of cholera by Cantani's method of hypodermatoclysis, or the free injection beneath the skin of saline solutions. Together with enteroclysis, or rectal injections, usually of tannic acid in solution, this plan seems to have been found of essential value.

Transactions of the American Association of Obstetricians and Gynecologists. Vol. VI, for the year 1893. Philadelphia: Wm. J. Dornan, 1894

This volume scarcely calls for extended review in these columns, inasmuch as a practical *résumé* of the proceedings of the last meeting of the Association was published in The News of June 10, 1893, at page 640. It only remains to be added that the *Transactions* makes a most desirable volume, upon the editorial and mechanical preparation of which the Association is to be congratulated. At the end of the volume is a splendid likeness of the late George Jackson Fisher, of Sing Sing, N. Y., presented in connection with a memorial by Dr. William Warren Potter.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Ninety-fifth Annual Session, held at Baltimore, Md., April, 1893. Also Semi-annual Session, held at Easton, Md., November, 1892.

In addition to the usual lists of members, of officers, of committees, various reports, a record of the minutes of the two meetings of the Faculty, and sundry other matters, this brochure contains the President's Address; an interesting and valuable article by Dr. Louis McLane Tiffany, entitled "The Treatment of Facial Neuralgia by Excision of the Extra-cranial Portions of the Fifth Nerve;" as well as the Annual Address by Dr. Reginald Fitz, a timely article entitled "Intra-peritoneal Hemorrhage."

Transactions of the Medical Association of Georgia. Forty-fourth Annual Session. 1893. Atlanta, Ga.

This volume of *Transactions* contains, besides the President's Address, thirty-seven papers of varying degrees of merit. Fourteen are upon subjects included under medicine, hygiene, etc., twelve belong to obstetrics and gynecology, eight are surgical, and three are upon ophthalmic subjects.

The matters discussed give evidence of the practical interest of the meeting, but we cannot help noticing the fact that there are but few contributions on questions both in medicine and surgery that have recently engaged special attention.

Transactions of the Texas State Medical Association. Twenty-fifth Annual Session, 1893.

As is usual in a volume such as the Transactions of a local society there is much that is only of a passing interest. But this volume of *Transactions* embodies a fair proportion of valuable papers; especially would we

mention the article of Dr. Smith, on the "Generalization of Carcinoma in the Stomach," Dr. Cerna's report on the "Action and Uses of Pental," Dr. Thompson's discussion of "Whitehead's Operation for Hemorrhoids," and Dr. Hadra's "Contribution to the Pathology of the Fourchet."

Transactions of the Michigan State Medical Society for the Year 1893. Volume XVII. Detroit: Published by the Society. John Bornman & Son, Printers, 1893.

This volume, neatly printed and adorned with a portrait frontispiece, contains a number of valuable papers. That by Dr. Collins H. Johnston upon the Brand method of cold-bath treatment of typhoid fever is specially admirable in its clearness and force, and exposes the errors of many text-books and papers which do not give Brand's method, although they purport to do so.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Forty-fourth Annual Session, held at Philadelphia, May 15, 16, 17, and 18, 1894.

(Continued from p. 560.)

Third Day—May 17.

Morning Session.

The opening paper was the annual "Address in Hygiene," by Dr. J. H. Wilson, of Beaver. Preventive medicine, he said, had done more for humanity than had any other department of medical science. That cholera did not recently gain a foothold in this country and that yellow fever was stamped out when it had appeared, were both due to the labors of hygienists. He called attention to the dangerous custom in our public schools of passing books and pencils from one scholar to another, and urged that it be abolished. Diphtheria and other contagious diseases may thus be transmitted. He urged upon physicians the importance of instructing their patients in the value of personal cleanliness. In regard to pulmonary tuberculosis, he said that 165,500 persons, or 450 a day, die annually of that disease in this country. The premises vacated by a tuberculous patient should be disinfected, and the people taught that tuberculosis is not hereditary but is contagious.

Dr. Wm. P. Munn, of Denver, Colorado, spoke of the system of inspection practised in Denver houses in which contagious diseases had occurred. The records of the houses are preserved, and renters of houses may on application learn the previous history of any house in question as preserved in the Health-department. This practice insures the keeping of the houses in proper sanitary condition.

The remainder of the morning session was devoted to a study of tuberculosis in its various aspects.

Dr. A. M. Cooper, of Point Pleasant, read a paper on the "Contagious Aspect of Tuberculosis in Married People," as viewed from an experience of thirty-eight years. He adhered to the hereditary theory in regard to the etiology of the disease, and is a non-believer in the contagious theory. He quoted a series of over fifty instances of death in married persons without any immediate deleterious effect upon the surviving husband or wife.

Dr. Lawrence F. Flick, of Philadelphia, read a paper on "Prophylaxis in the Treatment of Tuberculosis," which is to appear in a future number of The Medical News.

Dr. Thomas J. Mays, of Philadelphia, read a paper on the "Strychnin Treatment of Pulmonary Consumption." He considers strychnin as one of the most important of the therapeutic measures. He places in the treatment rest as the most important factor; secondly, nutritious food; and, thirdly, strychnin. Strychnin acts upon the nervous system, stimulating it in small doses. The proper dose should be that which will produce the greatest amount of stimulation. The patient should begin with comparatively small doses, $\frac{1}{32}$ grain by the mouth, given three or four times per diem, and gradually this should be increased. In some cases $\frac{1}{10}$ or $\frac{1}{6}$ grain may be taken. A child may take $\frac{1}{32}$ grain four times daily without detriment. The drug exerts an excellent effect upon the vomiting of phthisis and also upon the nervousness and sleeplessness. The dyspnea of pulmonary tuberculosis is primarily due to weakness of the nervous supply of the lungs. Strychnin will alleviate this condition. It tones up the weak heart and is of value in correcting the anemia of the disease.

Dr. William P. Munn, of Denver, Colorado, spoke on "Colorado Climate for Consumptives," saying that certain cases of tuberculosis of the lungs may recover spontaneously without being recognized or treated. The most essential element, both of assault and resistance, is environment, and especially is climate to be considered in this respect. The children of tuberculous parents do not develop the disease if placed in a high climate such as that of Colorado. Dryness, sunshine, purity of atmosphere, rarity of atmosphere, and an equable temperature are the beneficial elements of such an altitude.

"Notes, including those of Autopsy, of a Case of Tuberculous Meningitis" were presented by Dr. Daniel Longaker, of Philadelphia, after which the meeting was open for discussion upon the subject of tuberculosis.

Dr. S. S. Cohen, of Philadelphia, believed, with Dr. Munn, that pulmonary tuberculosis should be classed among the curable diseases. Acute miliary tuberculosis and phthisis florida, on account of their rapid course and general involvement, must for the present be excluded from the curable list. Drug treatment is necessary in all cases, but the best treatment is the hygienic, by teaching the patient how to properly inflate the lungs, or by giving inhalations of compressed air, or by causing expiration into rarefied air.

Dr. J. M. Anders, of Philadelphia, said that it is probable that the tubercle-bacillus does not multiply outside of the body. It survives the severest exposure and the most active chemical reagents, however. The modern asphaltum pavement increases the dust of the street and also the danger of infection; hence street-cleaning and street-sprinkling should be enforced. Most adults have at one time or other harbored the tubercle-bacillus; but only contract the disease when in a suitable condition for so doing. The subject of immunity

and what comprises it should be well studied. He urged the importance of an early recognition of the disease. The use of tuberculin will help in this.

DR. J. C. WILSON, of Philadelphia, considered pulmonary tuberculosis as preëminently a contagious disease, as much so as is scarlet fever, and that even there is a greater contagiousness and tendency to this disease than to scarlet fever. He thinks that perhaps the early lesions of the disease which have become obsolescent may confer an immunity.

DR. J. S. COHEN, of Philadelphia, called attention to the lessened mortality of pulmonary tuberculosis. Until the last ten or twelve years the disease caused from one-fourth to one-third of all the deaths in this city; now it causes between one-sixth and one-seventh of the deaths. He would suggest the use of mares' milk instead of cows' milk, as horses never contract tuberculosis. Spirituous liquors he claims may be dispensed with, as has been proved by a year of treatment without their use in the Home for Consumptives at Chestnut Hill.

DR. WILLIAM E. HUGHES, of Philadelphia, said that while exceedingly rare, tuberculosis may occur in horses. The natural immunity of the horse is quite distinct from acquired immunity. He urged the early recognition of the acute form of tuberculosis simulating croupous or broncho-pneumonia, and that form affecting serous membranes first, as the peritoneum or pleura.

The resolution offered on May 16th by DR. I. C. GABLE, relative to the appointment of an inspector to aid the State Board of Examiners, was adopted.

The Vice-President, DR. S. S. TOWLER, offered the following communication, which received unanimous indorsement:

The Medical Society of the State of Pennsylvania respectfully presents the following facts to the Judicial Council of the American Medical Association, and asks its action thereon:

The Trustees of the *Journal of the American Medical Association*, at the meeting of the Association in 1892, at Detroit, were directed to abstain from publishing in the advertising columns of the *Journal* advertisements of secret nostrums. Such advertisements are, however, still published in the *Journal*, in defiance of the resolution.

In the *Journal* of April 7, 1894, there is advertised a Sanitarium Association which openly offers stock to those physicians who will send patients to it for treatment.

In the opinion of the Medical Society of the State of Pennsylvania, these advertisements are improper and unethical, according to the letter and spirit of the Code of Ethics of the Association. The said Medical Society of the State of Pennsylvania, therefore, asks the Judicial Council to take such action in regard to the said Trustees as is demanded to sustain the integrity of the Association and enforce the provisions of its Code of Ethics.

A resolution offered by DR. FRANK WOODBURY, of Philadelphia, was adopted, calling upon the Medical Council and State Board of Health, in their official and other publications, to refrain from the use of any sectarian designation of the Board of Examiners representing this Society, of candidates coming up for examination from the regular schools, as the sectarian designation would imply a restricted practice of medicine.

The following were appointed a Committee on Legislation: Drs. I. C. Gable, York; R. B. Watson, Clinton; H. S. Orth, Dauphin; Alex. Craig, Lancaster; and C. W. Youngman, Lycoming.

DR. S. BIRDSALL, of Susquehanna, offered resolutions, which were adopted, approving of the bill now pending in Congress for the establishment of a National Bureau of Public Health in the Department of the Interior, as tending to promote the sanitary interests and general welfare of the country, and calling upon the Pennsylvania Senators and Representatives to give the bill their earnest and active support.

AFTERNOON SESSION.

The annual "Address in Ophthalmology" was delivered by DR. GEORGE E. DE SCHWEINITZ, of Philadelphia. He mentioned, in reviewing the progress in ophthalmology, the stricturotome of Dr. C. H. Thomas, of Philadelphia, as a valuable addition to the oculist's armature. He also strongly indorsed the action of the Ophthalmologic Section of the American Medical Association as to the prophylaxis of ophthalmia neonatorum. Over 70 per cent. of cases of blindness in infants are caused by the disease, and every effort should be made to secure the passage of such a law in Pennsylvania. He spoke of the uses and abuses of mercury in eye-disease, protesting against the needless use of this drug in incurable cases.

DR. S. LEWIS ZIEGLER, of Philadelphia, read a paper on the "Treatment of Corneal Ulcer by the General Practitioner." He said that corneal ulcer was common as an expression of the strumous diathesis. Chronic constipation, errors in diet, and poor hygiene are common causes. The danger to vision is due to the central location of the ulcer. The treatment should be applied both to the nose and to the eye. Local application of compound tincture of benzoin to the nasal mucous membrane is most essential. The eye-wash consists of sodium biborate, boric acid, camphor water, and distilled water. Hot stupes for fifteen minutes, three or four times daily, may be of service. The diet should be regulated, the bowels kept open, and the relaxed condition of the skin treated by daily baths in salt water, with massage.

DR. CHARLES P. NOBLE, of Philadelphia, read a paper on "Uterine Fibroids." He dwelt on the uncertainty of the spontaneous cure of fibroid tumors. The mortality of hysterectomy has been so greatly reduced that the operation is now almost as safe as the operation for the removal of the ovaries. He especially recommended the operation with intra-abdominal, but extra-peritoneal treatment of the stump as devised by Dr. Baer, of Philadelphia. The ligation of the uterine arteries has recently been suggested as a treatment of fibroid tumors. This has been done in the hope of bringing about atrophy of the tumor. Ergot and electricity in the treatment of the tumors have failed. He believes in removing fibroid tumors as soon as discovered, to avoid the possibility of pregnancy and years of invalidism.

DR. MASSEY, of Philadelphia, contended that the mortality of hysterectomy is far greater than that of fibroid tumors left alone. He said that electricity is not used to cause disappearance of the tumor, but to produce a symptomatic cure to arrest the growth and to cause retrogression in its size.

Dr. J. M. Fisher, of Philadelphia, called attention to the danger of stirring up a latent pyosalpinx or other grave condition by the use of electricity. He had used electricity, and had found the tumor cease to grow under its use, but he had noticed that when its use was discontinued growth was resumed. In operating for hysterectomy he favors packing the vagina with gauze to lift the tumor from the pelvis.

Dr. W. E. Ashton, of Philadelphia, doubts whether electricity has any effect on the tumors except to control to a certain extent the hemorrhage. He claimed that it was impossible to tell whether or not there was a coexistent tubal disease, and as this was a common complication, electricity should be absolutely contra-indicated in any case. The extra-peritoneal method of treatment of the stump gave rise to danger of hernia, and prolonged convalescence from gangrene of the stump.

The newly-elected President, Dr. John B. Roberts, of Philadelphia, was introduced by Dr. McCormick, the retiring President. After expressing his appreciation of the honor conferred upon him, Dr. Roberts announced the following as the speakers on various topics for the next meeting, in Chambersburg: Obstetrics, Dr. W. B. Ulrich; Surgery, Dr. C. S. Stevens; Medicine, Dr. I. C. Gable; Hygiene, Dr. Hildegarde H. Longsdorf; Mental Diseases, Dr. F. X. Dercum; Otology, Dr. L. H. Taylor.

CORRESPONDENCE.

THE TREATMENT OF CONFLUENT VARIOLA.

To the Editor of The Medical News,

Sir: I desire to offer the profession through your columns a suggestion upon the treatment of confluent variola.

With a camel's-hair brush paint a large surface, preferably the back, with ichthyol (ammonium sulphoichthyolate), completely coating the surface treated. After permitting it to dry a while, or immediately if necessary, cover with absorbent cotton and permit the patient to lie down, thus pressing the material tightly against the surface, without soiling the bedding.

In a few days the ointment and cotton will peel off, leaving the surface dry. The remedy appears to destroy the microörganism. It lowers temperature, controls itching, lessens nervousness, and slows pulse and respiration when applied during the stage of secondary absorption, which is frequently so fatal. My observations were made upon a few cases in the Chicago Pesthouse.

Very truly yours,

S. W. Burson.

Chicago, Ill.

THE FIN DE SIÈCLE SURGEON.

A Rambling Lay, by One of the Laity.

Let others sing of the gentle spring, in the old familiar way,
With its robins and moons, its sighs and its spoons, its skies of blue and gray;
My muse shall refrain from this hackneyed strain—let progress my watchword be!
I 'll a tale unfold of the surgeon bold of the end of the centuree.

In olden days, when *in medias res* an egregious pain appeared,
When mysterious lumps and peculiar humps their crests in defiance reared,
The things were few that the doctor could do to subdue either growth or gripe,
But to ply with lotions and pills and potions of the good old "business" stripe.

Though bravely he fought, he could work on naught but a theoretical plan,
Nor form, as do we, an intimacy with the patient's innermost man.
In this later age we have grown so sage that few things occasion surprise,
But the doctor's pace in the modern race we view with wondering eyes.

With his knife so true, and his theories new of microbes and spores and germs,
With electric blaze, antiseptic ways, and astonishing technical terms,
He leads in the van, and his fellow-man for concealment hasn't a chance.
He is read like a book, and no innermost nook is hid from that eagle glance.

If there's cause to suspect any ill effect produced by unseemly meals,
The modern M.D. doesn't wait, not he, to ask how his patient feels,
Nor to hear him state what he thinks he ate—but without any useless fuss
He lets down a string with a bucket-like thing, and samples his contents—thus!

Into dark recesses which baffle guesses he pokes his 'scope with a grin,
Then turns on the light, and the luckless wight "all glorious is within."
When intestine strife makes a burden of life, and obstructionist lumps prevail,
Though the case be grave, to the surgeon brave there is no such word as fail.

With a wide incision and free division he charges upon the foe,
Takes what he thinks best, and puts back the rest in the place where it ought to go.
In a half-way measure he takes no pleasure, so fits out his man beside
With the latest in rings, nickel buttons, and springs, and sutures him up with pride.

In cases of fits which puzzle our wits, or in any queer brain mishap,
The troubled scenes he inspects by means of an osteoplastic flap;
Brain centers he wakes with galvanic quakes to aid his investigation—
All is clear to his sight by the modern light of cerebral localization.

He removes large hunks, or neat little chunks, as the needs of the case demand;
If the patient is dull from too small a skull, he gives it a chance to expand.
If a leg or an arm be a source of alarm, the surgeon, no whit dismayed,
Takes the matter in hand, with his skewers and band, and a sweep of his glittering blade.

But I fear that my song is becoming too long—achievements so many and great
Cannot be reviewed in a fashion so crude, and I'll just be content to state
That whatever's to blame in this mortal frame, wherever the source of ill,
He cannot be caught, he's ready for aught that challenges nerve and skill.

And if a condition defy recognition, with neatness and brilliant despatch,
He describes the same, he concocts a name, and a brand new "method" to match.
Intrepid and sage, the flower of his age, a marvel of marvels he—
Both fame and gold gets the surgeon bold at the end of the centuree!

C. ROCKWELL.

NEWS ITEMS.

Meetings of Philadelphia Medical Societies:

	Meets.	Next meeting.
College of Physicians,	1st Wednesday, Sept.—June.	June 6

Vermont State Medical Society.	October 11, 12	Montpelier, Vt.

The Prevention of Tuberculosis.—The New York Board of Health has issued a circular of information to physicians regarding the measures adopted by the Board for the prevention of tuberculosis in the City of New York.

The Department will hereafter register the name, address, sex, and age of every person suffering from tuberculosis in the city of New York, so far as such information can be obtained, and respectfully requests that hereafter all physicians forward such information on the postal cards ordinarily employed for reporting cases of contagious disease. This information will be solely for the use of the Department, and in no case will visits be made to such persons by the inspectors of the Department, nor will the Department assume any sanitary surveillance of such patients, unless the person resides in a tenement-house, boarding-house, or hotel, or unless the attending physician requests that an inspection of the premises be made; and in no case in which the person resides in a tenement-house, boarding-house, or hotel will any action be taken if the physician requests that no visits be made by inspectors, and is willing himself to deliver circulars of information, or furnish

such equivalent information as is required to prevent the communication of the disease to others.

When the Department obtains knowledge of the existence of cases of pulmonary tuberculosis in tenement-houses, boarding-houses, or hotels (unless the case has been reported by a physician and he requests that no visits be made), inspectors will visit the premises and family, will leave circulars of information, and instruct the person suffering from the disease and the family as to the measures which should be taken to guard against its spread, and, if it is considered necessary, will make such recommendations for the cleansing or renovation of the apartment as may be required to render it free from infectious matter.

In all cases in which it comes to the knowledge of the Department that premises which have been occupied by a tuberculous person have been vacated by death or removal, an inspector will visit the premises and direct the removal of infected articles, such as carpets, rugs, bedding, etc., for disinfection, and will make such written recommendations to the Board as to the cleansing and renovation of the apartment as may be required. An order embodying these recommendations will then be issued to the owner of the premises, and compliance with this order will be enforced. No other persons than those there residing at the time will be allowed to occupy such apartments until the order of the Board has been complied with. Infected articles, such as carpets, rugs, etc., will be removed by the Department, disinfected, and returned, without charge to the owner.

For the prevention and treatment of pulmonary tuberculosis it becomes of vital importance that a positive diagnosis shall be made at the earliest possible moment, and that the value of bacteriologic examinations of the sputa for this purpose may be at the service of physicians in all cases not under treatment in hospitals, the Department is prepared to make such bacteriologic examinations for diagnosis, if samples of the sputa, freshly discharged, are furnished in clean, wide-necked, stoppered bottles, accompanied by the name, age, sex, and address of the patient, duration of the disease, and the name and address of the attending physician. Bottles for collecting such sputa, with blank forms to be filled in, can be obtained at any of the drug-stores now used as stations for the distribution and collection of serum-tubes for diphtheria-cultures. After the sputum has been obtained, if the bottle, with the accompanying slip filled out, is left at any one of these stations, it will be collected by the Department, examined microscopically, and a report of the examination forwarded to the attending physician, free of charge.

The authorities of all public institutions, such as hospitals, dispensaries, asylums, prisons, homes, etc., will be required to furnish to the Department the name, sex, age, occupation, and last address of every tuberculous patient coming under observation within seven days of such time.

Circulars of information for the general public have been issued in English, German, Italian, and Hebrew.

The Philadelphia Board of Health has not deemed it wise to go so far as the New York Board. It has, however, issued a circular detailing the most important means of preventing the spread of tuberculosis, and volunteers to undertake the disinfection of rooms that have been occupied by tuberculous patients, and of beds, bedding, carpets, etc., upon notice sent to the Health Officer, at City Hall.

The American Neurological Association will hold its twentieth annual meeting at Washington, D. C., on May 29, 30, 31, and June 1, 1894. The following program is announced:

"Report of a Case of Spinal Syphilis and One of Intracranial Syphilis, with Microscopic Specimens," by Landon Carter Gray, New York. "Merycism," by William A. Hammond, Washington, D. C. "Inebriety as a Disease Analytically Studied," by R. M. Phelps, Rochester, Minn. "A Case of Myxedema treated with Sheep's Thyroid," by Samuel Ayres, Pittsburg. "Craniectomy in a Child Two Years Old," by Samuel Ayres, Pittsburg. "The Genesis of Hallucinations, Illusions, and Delusions," by H. A. Tomlinson, St. Peter. "A Case of Pontine Embolism, with Paralysis of Ocular and of Orbiculo-palpebral Movements of One Side and of the Limbs on the Other, with Remarks on Focal Lesions in the Pons," by Charles K. Mills and John Zimmer, Philadelphia. "Thyroidectomy in a Case of Graves's Disease," by J. Arthur Booth, New York. "Crossed Knee-jerks." by Guy Hinsdale and J. Madison Taylor, Philadelphia. "The Insanity of Puberty and Adolescence," by Henry R. Stedman, Boston. "Lumbar Puncture (Quincke) for the Withdrawal of Cerebro-spinal Fluid," by William Browning, Brooklyn. "Gastro-intestinal Neurasthenia, *i. e.*, Nervous Dyspepsia," by Leonard Weber, New York. "Some Problems Relating to the Cerebral Fissures," by Burt G. Wilder, Ithaca. "Exhibition of a Suicide's Brain, with Two Pistol-ball Wounds," by Burt G. Wilder, Ithaca. "Exhibition of a Neurological Percussion Hammer," by William C. Krauss, Buffalo. "Cerebral Edema," by George J. Preston, Baltimore. "The Non-operative Treatment of Metatarsalgia," by V. P. Gibney, New York. "A Case of Exophthalmic Goiter cured by Thyroidectomy," by Frederick Peterson, New York. "Cerebral Hemorrhage: Notes on its Cause and Premonitory Symptoms," by Charles L. Dana, New York. "The Cortical Localization of the Cutaneous Sensations," by Charles L. Dana, New York. "Exhibition of Sections from the Mid-brain, Pons, Medulla Oblongata, and Spinal Cord, from a Case of Chorea," by James Hendrie Lloyd, Philadelphia. "Report of a Case of Amyotrophic Lateral Sclerosis in a Child," by Charles Henry Brown, New York. "The Significance of the Exaggerated Knee-jerk and Ankle-clonus and their Relation to Diagnosis," by Graeme M. Hammond, New York. "A Case of Congenital Hydrencephalocele," by Edward B. Angell, Rochester. "A Case of Infantile Hemiplegia, Imbecility, and Epilepsy; Craniotomy; Marked Improvement," by Edward B. Angell, Rochester. "Experimental Investigations of the Physical and Chemical Action of the Galvanic Current upon the Living Organism," by George W. Jacoby and F. Schwyzer, New York. "Report of a Case of Diffuse Myelitis following Spastic and Choreic Symptoms of Three Years' Duration; with Specimens," by F. X. Dercum, Philadelphia. "Traumatism as a Cause of Locomotor Ataxia; a critical examination of the evidence, including a Report of Three Cases," by Morton Prince, Boston.

The American Climatological Association will hold its eleventh annual meeting at Washington, D.C., May 29, 30, 31, and June 1, 1894. The program includes the following papers:

"Alimentation in Pulmonary Disease," address by the President, Andrew H. Smith, New York. "The Relation which Alimentation should bear to Oxygenation in Lung Diseases," by Boardman Reed, Atlantic City. "The Methods and Value of Supervised Exercises and Diet in the Prophylaxis of Pulmonary Phthisis," by Glentworth R. Butler, Brooklyn. "The Importance of Mouth Cleanliness in the Prevention of Disease," by Clarence C. Rice, New York. "A Plea for the Earlier Recognition of Pulmonary Tuberculosis and Adoption of Proper Climatic Treatment," by H. B. Moore, Colorado Springs. "Three Years' Experience in the Sanitarium Treatment of Pulmonary Disease, near Boston," by Vincent Y. Bowditch, Boston. "Creosote, Guaiacol, and Benzoyl of Guaiacol in Phthisis," by Roland G. Curtin, Philadelphia. "Shall Anything be Done by Legal Authority to Prevent the Spread of Tuberculosis," by Frederick I. Knight, Boston. "Further Report of Cases of Phthisis treated at Colorado Springs," by S. E. Solly, Colorado Springs. "The Condition of the Heart in Diabetes and its Relation to Diabetic Coma," by Leonard Weber, New York. "Report of Cases of Chronic Heart Disease treated by the Schott Method of Baths and Gymnastics," by Robert H. Babcock, Chicago. "A New and Distinguishing Sign of Latent Aneurysm of the Aorta," by W. C. Glasgow, St. Louis. "Musical Nomenclature in Physical Diagnosis," by J. Hilyard Tyndale, New York. "Ozone in Phthisis, with Special Reference to the Pneumatic Cabinet," by Chas. E. Quimby, New York. "The Comparative Rarity of Phthisis in the Highlands of Pennsylvania and the Adjacent Counties of New York," by Guy Hinsdale, Philadelphia, "Meteorological Data of Colorado," by Samuel A. Fisk, Denver. "Sensible Temperatures," by Hon. Mark W. Harrington, Chief of Weather Bureau, Washington. "Beri-beri," by Judson Daland, Philadelphia. "Some Practical Observations on So-called Malaria," by William H. Daly, Pittsburg. "The Shock of Acute Disease," by John H. Musser, Philadelphia. "The Physical Signs of Cellular Edema of the Lung considered in their Relation to the Pathological Changes," by W. C. Glasgow, St. Louis.

The American Ophthalmological Society will hold its thirtieth annual meeting on the 30th and 31st of May, at Washington, D. C., in connection with the third triennial session of the Congress of American Physicians and Surgeons. Titles of papers to be read have been received as follows: "Two Recent Magnet Operations; one an Ideal Success, the other a Total Failure," by H. Knapp. "A Demonstration of some Photo-micrographs of the Human Retina," by William F. Norris. "The Practical Value of the Ophthalmometer," by Edward Jackson. "Family History of Irideremia and Coloboma Iridis; Cataract Operation on Two Members," by D. De Beck. 1. "A Clinical and Microscopic Study of Two Cases of Glaucoma associated with Intra-ocular Hemorrhages;" 2. "Some additional Studies on the Clinical Value of repeated Careful Correction of Manifest Refractive Error in Plastic Iritis," by C. A. Oliver. "Tumor of the Optic Nerve," by Swan M. Burnett. 1. "Degeneration in the Retinal Vessels, with Hemorrhages in the Retina and Vitreous in Gouty Patients;" 2. "Recent Experiences in the Treatment of Detachment of the Retina," by C. S. Bull. "Pseudo-erysipelas Periocularis Medicamentosa," by Edward Fridenberg. 1. "Some Typical Examples of Subnormal Accommodative Power;" 2. "The Ophthalmoscope does not always Reveal Latent Hypermetropia, with Notes of a Case;" 3. "A Case of Ophthalmitis Suppurativa following Discission of Capsular Opacity," by S. Theobald. "Removal of Steel from the Vitreous," by E. E. Holt. 1. "Colloid Disease in the Macular Region analogous in appearance to the so-called 'Drusen' in the Nerve-head;" 2. "Epithelioma of the Lid; Excision and Transplantation of the Skin without a Pedicle;" 3. "Concerning Monocular Diplopia, with Cases," by G. E. de Schweinitz. 1. "Two Cases of Sympathetic Inflammation;" 2. "A Portable Perimeter, with its Apology for Existence," by F. M. Wilson. "So-called Muscular Asthenopia," by G. W. Hale. "The Practical Value of Low-grade Cylinders," by J. A. White. "Results of Repeated Examinations of the Eyes of the Boys in the Penn Charter School of Philadelphia," by B. A. Randall. "Foreign Bodies in the Orbital Cavity," by W. B. Johnson. "Rupture of the Lymph-sheath of a Retinal Vein," by A. G. Heyl.

The Association of American Anatomists will hold its sixth annual session, May 29, 30, 31, and June 1, 1894, at Washington, D. C., in connection with the Congress of American Physicians and Surgeons, of which this Association is a constituent member.

The following papers are to be read:

"Morphology as a Factor in the Study of Disease," by Harrison Allen, Philadelphia. The discussion will be led by Thos. Dwight, Frederick H. Gerrish, Frank Baker, Burt G. Wilder. "A Plea for a Methodically-written Text-book on Anatomy," by Edmond Souchon, New Orleans. "In our Two Years' Study of Anatomy, what part of the Subject should be Covered in the First Year's Work? What Part in the Second?" by A. D. Bevan, Chicago. "Identity of Structure of Protoplasm with that of Striped Muscle," by Carl Heitzmann, New York City. "Study of the Human Cranium," by Harrison Allen. "Relation of the Olfactory to the Cerebral Portion of the Brain," by Burt G. Wilder. "On the Shortening of the Face-axis in the Evolution of the Mammalia," by Harrison Allen. "Theoretical Anatomy of the Sympathetic System," by Wm. P. Carr, Washington, D. C. "Terminology of the Nerve-cell," by Pierre A. Fish, Ithaca, N. Y. "Methods of Estimating the Height from Parts of the Skeleton," by Thos. Dwight. "A Study of the Muscular Tunic of the Large and Small Intestine of Man in the Region of the Cecum," by Robert Orton Moody, Yale University. "A Note on the occurrence of the Scapulo-clavicular Muscle," by Mr. Moody. "The Female External Genital Organs: a Criticism on Current Anatomical Description," by D. S. Lamb, Washington, D. C. "Perineum and Perineal Body," by D. K. Shute, Washington, D. C. "Notes on the Anatomy of the Orang," by B. G. Wilder.

The American Surgical Association will hold its annual meeting at Washington, D. C, May 29, 30, 31, and June 1,

1894. In addition to those already announced (NEWS, March 17, p. 300), the following papers are to be read:

"The Surgical Treatment of the so-called Surgical Kidney," by R. F. Weir, New York. "Surgery of the Ureters," by Christian Fenger, Chicago. Discussion by M. H. Richardson, H. H. Mudd, C. H. Mastin, and Ford Thompson. By invitation: "Treatment of Malignant Tumors with the Toxins of Erysipelas," by William B. Coley, New York. "Hernia," by W. T. Bull, New York. "Cases of Extra-uterine Pregnancy, with Remarks," by M. H. Richardson, Boston. "Venous Tumor of the Diploë," by L. S. Pilcher, Brooklyn. "A Case of Strangulation of Meckel's Diverticulum, caused by Volvulus of the Ileum; Operation; Death," by J. W. Elliot, Boston. By invitation: "Bone-grafting in Ununited Fractures, by a New Method," by A. M. Phelps, New York. "Mooted Points as to Fractures of the Arm, with Notice of an improved Splint," by J. McFadden Gaston, Atlanta, Ga. "The Removal of Stone in the Bladder, with the Presentation of a new Lithotrite," by W. S. Forbes, Philadelphia. "Extirpation of the Larynx," by W. H. Carmalt, New Haven, Conn. "Abscess of the Thyroid Gland," by Joseph Ransohoff, Cincinnati.

The Association of American Medical Colleges.—At the fifth annual meeting of the Association of American Medical Colleges at San Francisco on June 6, 1894, the Barnes Medical College, of St. Louis, will present a resolution that, in order to afford to the teacher and student alike, such time as is necessary to complete a proper curriculum in each department of medicine, of all regular medical students who intend graduating at the Barnes Medical College at the close of the session of 1899 and 1900, and in all subsequent classes, four years' medical study and attendance upon four regular courses of medical and clinical lectures of not less than five months each shall be required; provided, that graduates of literary colleges, who have taken a course of scientific study, graduates of schools of pharmacy, and graduates of schools of dental surgery, may be admitted to the second year's work and course of lectures without examination. The delegate of the Barnes Medical College to the meeting of the Association is instructed to vote upon all questions arising before that body, in accordance with the foregoing resolution, and to use all honorable means to secure the unanimous adoption, by all colleges, of requirements for graduation of students, of four regular courses of lectures of not less than five months each in different years.

State Board of Medical Examiners of New Jersey.—A special meeting of this Board for the examination of candidates desiring to practise medicine in this State will be held in the Capitol at Trenton, on the third Tuesday of June (the 19th), *and it will be the last meeting for the examination of candidates held under the present medical law*, as the new law enacted at the recent session of our Legislature goes into effect July 4, 1894. This new law requires all candidates to have a competent common school education, to be graduates in medicine and surgery, which they shall have studied at least four years, and upon which they shall have taken three full courses of lectures, before they can be admitted to the examination for a license, and then all will be subjected to the same examination; it also empowers the Board to accept, in lieu of an examination, the certificates of other State Examining and Licensing Boards having similar requirements.

The Meeting of the American Medical Association.—The entire work of the Association meeting in San Francisco, June 5th to 8th, inclusive, will be done in Odd Fellows' Building, corner Market and Seventh Streets.

Registration will begin in Marble Hall, Palace Hotel, on Monday, June 4th, when all who arrive early enough should register to avoid the rush on Tuesday. Working hours of the Sections will be 9 to 12 and 2 to 5, except forenoon of the first day.

The General Assembly will convene at 10 o'clock, on Tuesday.

Visitors desiring to engage rooms in advance can do so by communicating directly with the hotels, or with R. A. McLean, No. 305 Kearney Street, Chairman Committee on Hotels. Headquarters at the Palace Hotel.

Railroad tickets will be good for return till July 15th. Members will therefore have time to make numerous side excursions in the State after the meeting.

The Medical Association of Georgia adheres to the Code.—At the late meeting of the Medical Association of Georgia Dr. J. McFadden Gaston, of Atlanta, introduced the following resolution, which was unanimously adopted:

"*Whereas*, The American Medical Association at its last meeting provided for an expression in regard to the Code of Ethics from the different State Associations, to be laid before the forthcoming meeting at San Francisco, it is hereby

"*Resolved*, That the Medical Association of Georgia reasserts its adoption of, and conformity to, the Code of Ethics of the American Medical Association, as heretofore recognized by that body, and authorizes this record of its adherence to the same."

The Transactions of the Pan-American Medical Congress.—The *Proceedings of the First Pan-American Medical Congress* were compiled by the Secretary-General, Dr. Charles A. L. Reed, and transmitted to the Department of State in November, 1893. By recent joint resolution of the Senate and House of Representatives the manuscript was transmitted to Congress, and a concurrent resolution has been adopted directing the Public Printer to print the same. The manuscript is now in the office of the Public Printer, and will be put to press at once under the supervision of the Editorial Committee, of which Prof. John Guitéras, of Philadelphia, is the chairman.

The Wistar Institute of Anatomy and Biology of the University of Pennsylvania was formally opened on May 21st. The keys were presented by the Assistant Director, Dr. Milton J. Greenman, to the Provost, Dr. Pepper, who made an address appropriate to the occasion. Dr. William Osler also delivered an address. Prof. Libby, of Princeton, made some congratulatory remarks, and the Director of the Institute, Dr. Harrison Allen, made the concluding address, after which the building and its appurtenances were inspected.

Mr. Charles C. Harrison, already well known for his great interest in the University of Pennsylvania, has been elected Provost in succession to Dr. Pepper. The acceptance is only provisional, but it is hoped that Mr. Harrison can be induced to retain permanently the important trust.

Dr. Adam Politzer, the distinguished otologist of Vienna, and hitherto Extraordinary Professor of Otology in the University of Vienna, has been made an ordinary professor.

New York State Medical Reporter is the name of a new "monthly journal of medicine and surgery," edited by Dr. H. Bronson Gee, and published at Rochester, N. Y.

The Archives of Pediatrics will, with the July issue, be edited by Dr. Dillon Brown. Exchanges should be addressed: Editor, *Archives of Pediatrics*, 40 East 57th Street, New York.

Dr. Karl Stoerk has been made Ordinary Professor of Laryngology in the University of Vienna.

Dr. Malassez has succeeded Charcot in the chair of Pathological Anatomy in the University of Paris.

Dr. Joseph Gruber has been made Ordinary Professor of Otology in the University of Vienna.

Books and Pamphlets Received.

Venereal Memoranda. A Manual for Students and Practitioners. By P. A. Morrow, A.M., M.D. New York: William Wood & Co., 1894.

ORIGINAL ADDRESSES.

MORPHOLOGY AS A FACTOR IN THE STUDY OF DISEASE.[1]

BY HARRISON ALLEN, M.D.,

DIRECTOR OF THE WISTAR INSTITUTE OF ANATOMY AND BIOLOGY OF THE UNIVERSITY OF PENNSYLVANIA.

NOT long ago I heard a gentleman congratulate a distinguished professor of Greek on the ground that the subject of Greek literature was finished, that is to say, was one to which from the nature of things no important additions could be expected. Any one not a special student of the classics might be justified in making such a remark. The professor replied that he was indeed to be congratulated, but not on the ground of being devoted to a subject whose limitations were known. He then spoke of important discoveries recently made in Greek texts found in Egyptian papyri and manuscripts used in the manufacture of mummy cases. These investigations had led to entirely new conceptions of the social life of the ancient Athenians and of the characters of some of their leading authors.

In like manner the anatomist who stands on the vantage-ground of medicine is often told that by the cultivation of the last four hundred years his subject is finished—that no new thing can be said of it. Whether or not the human anatomist is to be congratulated, being thus identified, is a matter of opinion. For my part, I venture the statement that no true anatomist would be content for a moment with a science thus limited. Were he so to accept it his energies would be necessarily confined to acquiring what his predecessors had secured in an equal degree. I am sure I represent my fellow-workers when I say that the science of anatomy is awaiting important advances—not indeed by unrolling the palimpsests of tombs, or by the maceration of mummy cases, but by new readings in the infinite book of Nature.

To the physician who is busy with the practical duties of his profession anatomy is the arrangement of the structures of the adult human body by the standard of undergraduate instruction. This anatomy may be well said to be limited in the sense that Procrustes measured a giant by the length of the bed he was stretched upon; the superfluous parts were lopped off to make a fit. The text-book assumes an ideal which is properly described. The facts that exceed this ideal, or otherwise disturb it, are ignored unless they are needed by the surgeon, when they are elaborated just so far as he may dictate. "Gentlemen," said Dr. Barclay, "Vesalius and his fellows were reapers in the great field of anatomy—John Hunter and his brethren were gleaners—and we, gentlemen, are the stubble-geese!" Presentation of the facts in this wise was as well known to the old worthies as they are to us—and yet we contend that moderns can be something better than "stubble-geese." Three sciences have appeared since the days of Vesalius and of Hunter—sciences so vast as to command the time and energies of distinct bands of workers: histology, which yet awaits the discoveries of new chemicals, of apparatus of precision, and of improved means of conservation, for yet greater triumphs; embryology, which, while long claimed by the physiologist, is returning to the anatomist as his rightful inheritance; and general morphology—the most important of the three—which embraces all animated structures as parts in a scheme of philosophy.

I have employed the word morphology, for morphology is anatomy writ large; as the heading under which my remarks may be included; as one least liable to misinterpretation; and I would place within it the subject of descriptive anatomy as a conventional and unimportant part.

I confess to a feeling of impatience that the science of anatomy is still commonly taught pretty much as it was a century ago, and I cannot refrain from expressions of regret that these methods have not undergone change even in the centers which have witnessed important revolutions in other departments. The demands of the surgeon still dominate the lecture-hall. No fact that cannot be used in the clinical amphitheater is thought to possess value; the forces for the education of the medical thinker and scholar are unused; the powers of observation of the practising physician are not stimulated; the outlines of method by which the science of morphology can be extended by experiments are unthought of; while the opportunities of accumulating at the hands of the physician materials to be used in the explanation of phenomena of organic structure acting perversely, or serving as the causes of diseased action, are neglected.[1]

It is true that these and similar facts are in the possession of advanced clinical workers, but they often

[1] Read before the Congress of American Physicians and Surgeons, at its meeting, Washington, May 29, 1894.

[1] Men who have no sympathy with anatomy and physiology are apt to declare that these sciences have no connection with clinical work, and are thus absolved from considering their claims. A physician interested in the study of speech-sounds, attempting to connect this study with clinical methods, is told by leading physicians that such work is not medical but physiological. Another physician photographs the larynx in the living individual and reports his work before the laryngological section of an international medical congress, when the chair expresses his opinion that such work is not worth the doing, at least that it is not laryngological. The medical man who rises on the floor of a medical society to use the facts of the shape of the thorax as an aid in the study of the predisposition to pulmonary tuberculosis is declared by the chairman to be out of order in a discussion of the etiology of that disease. A member of a pathological society who proposes to read a paper on the anatomy of the cerebrum in connection with localization of diseased action is crowded out by a combination of the members on the ground that a pathological society is a society of clinicians and not of anatomists.

appear under heads not suggestive of their exact position in knowledge. Many important considerations are scattered through hospital reports, treatises on practice, or the transactions of pathological societies. Sometimes they are veiled under misleading titles. The actions of muscles have been held to be always corollaries of the descriptions of the muscles themselves, indeed to be logical deductions from the formulæ of their origins, insertions, and nerve-supply. Yet these facts are wrested from anatomy under the name of physiology of movements. Such a classification would bear to physiology the relations which obtain between the structure of bone and the dynamics of the skeleton, the studies of the eruption and succession of the teeth and the rates of growth of organs. Teratology is generally cultivated by obstetricians, and, if students of medicine were taught this subject it is as likely as not that it would be undertaken by the Chair of obstetrics, and thus a purely morphological series of demonstrations be not credited to the department of anatomy.

It is evident that physicians who become interested in these and allied subjects obtain their knowledge, so far as it relates to the elucidation of medical problems, after their academic education is completed. Is it not entirely proper that they should be carefully instructed in them before graduation? Is it not patent that the difference between the imperfectly educated and the accomplished physician can be determined by the use of the test of being able to interpret morphological factors in the study of disease, as well as by any other test of efficiency?

Empirical knowledge never leads to true conceptions. The basis of just lines of association must be those established by nature. In a philosophical plan there is no such thing as a series of diseases in the sense of a sequence of organic entities except when these entities have been first established. In a word, diseases are not related to each other but to their causes. Etiology is the single factor that yields conditions which can correlate. Tissue-changes furnish truer guides than function-changes. A character is a more reliable datum than a trait. A description of an organ or part is a more acceptable contribution to knowledge of classification than that of a habit. In medicine we can, in like manner, say that a sign is better than a symptom, or, what is best of all, elaborate experimentation, combined with anatomical observations on the dead, is worth all that is possible from empirical observations on the living. In clinical work demonstrations are often lacking; tests may be absent. Indeed, the physician practically acknowledges that he never proves anything, as he refers his etiology to the chemist and the bacteriologist. I take the position that he should refer to the morphologist more problems than he is inclined to do.

It is acknowledged that chemical conditions underlie texture, and it is a matter to be regretted that the morphologist gains so little by this association of truths. Not, indeed, that the knowledge of chemical changes in tissue do not enter into his problems. He is well aware of the close connection between the chemical composition of teeth and their forms, of the great influence that the beginnings of calcification of the triangular cartilage of the nasal septum exert over the shapes of the nasal septum, as well as the immense range of changes initiated in gouty and rheumatic conditions. Exact relations are shown to exist between the chemical constitution of the fluids and the shapes of some of the organs. These changes, it is true, are often unimportant to the individual, are peripheral, and apparently of no special significance. But the general shape of the gouty tooth is, so far as it goes, distinctive, as also is the fact that the lower incisor teeth are altered slightly in their relations one to another. Sir Dyce Duckworth, in his treatise on gout, states that "buck-teeth" are not uncommon, one of the lower central incisors being thrust out of rank, as was first noticed by Laycock. I have observed these characters in a large number of cases, and am confirmed as to their correctness by dental surgeons.[1] Faget[2] believes that the teeth are especially noteworthy in persons of gouty habit. They are, as a rule, well developed, with strong, hard enamel, which is rather yellow in color. They resist decay, and are firmly set in their alveoli. In time they become more or less worn down, so that the pulp-cavities begin to be visible. Pye-Smith quotes the authority of Mr. Moore for the facts that this condition may be caused by that formation of jaws which gives an edge-bite, also in cases in which the enamel is thin on the summits of the teeth.

In like manner the nails, which are so closely associated with the teeth in all morphologic characters are of value in studying the gouty diathesis.[3] The nails, according to Duckworth (*l. c.*) "are observed to be coarse and fibrous, striated and fluted, or lined vertically, in gout. This peculiarity is well marked in most persons of the arthritic diathesis, and hence is found in rheumatic persons. The nail-substance is apt to grow thick and brittle, and especially so after attacks of gout. The nails may be shed after several local attacks. The transverse depressions, described by M. Beau and Dr. Wilks, are seen in due time after gouty as after other illnesses, indicating a temporary failure and depression of nutrition of the whole body. As an entire nail takes six months to grow, the site of these furrows indicates the date of the past illness with singular exactness. Sometimes a white line marks the attack."

If among wild animals varieties were found to vary as much among themselves as do gouty and non-gouty persons, zoölogists would be justified in defining therefrom subspecies. Why should not gout be defined as well by the results of the chemical compositions of the fluids as by these compositions themselves? Indeed, biological science teaches us that morphological data are the most reliable, and it were better to define gout and rheumatism by the peripheral characters, even if we do not derive therefrom any notable practical advantage.

So long as we study diseases, as distinguished from their causes and effects, we are empirical. We hear much of the "science of medicine." Surely it is a "so-called" science when it deals only with clinical phenomena. No medical center which is dominated by a clinical element (I am anxious here to recall that by clinical work is meant literally the bedside work, or its equivalent), the study of the patient rather than the

[1] See "The Characters of the Teeth in Persons of the Arthritic Diathesis." Journal of the Odontological Society of Great Britain, 1883, p. 193.

[2] Prin. and Prac. Med., second edition, 490.

[3] Two hundred years ago Sir Thomas Browne wrote that "tempermental dignotions and conjecture of prevalent humors may be collected from spots on our nails."

causes which evolved the patient (or the possible study of the body of the patient, if he should be so unfortunate as to die), can be said to be an empirical one, and history shows it to be singularly liable to be clouded by speculative opinion. I respectfully submit that the theories of the humorists, the solidists, or any one of the many theories which have agitated the profession (the hosts of spectral forms that surge up to the line of blood in the limbo of medical philosophy), would have been impossible had the system of medicine been broadly based upon morphological data. But such a basis was not feasible until the organic sciences were themselves formulated. The great reputation of Boerhaave rests upon his recognition of chemical and anatomical data as aids to the study of medicine. The amount of anatomical reading he recommended his pupils showed a knowledge of anatomy which has probably never been approached by any of the authorities in clinical medicine since his day.

The changes in the shape and composition and use of a part of an organism constitute a variation—that is to say, an exception to a rule which has been formulated concerning their shape, composition, or use. The detection of these variations, and the propositions upon which they are based, constitute one of the chief occupations of the morphologist.

The difficulty of proving the value of minute knowledge of the muscle-fibers of the body is very great, for anatomists so rarely have an opportunity of making the necessary demonstrations. Let me illustrate a few of the very probable etiological factors in such conditions as esophageal pouch and heart-failure. Esophageal pouch is a yielding of the muscle-wall of the pharynx as it joins the esophagus in individuals who possess an insufficient number of the circular fibers of the lower pharynx or the beginning of the esophagus, which will in rare instances have developed an invagination of mucous membrane at the line of fault. This is a simple example of the manner by which a minute anatomic variation may become a factor in the etiology of disease. It is well known that the staying power of athletes relates more to minute inherited peculiarities in the heart than to any other group of conditions. Let a number of men subject themselves to the same physical test—it may be a walking-match or a swimming-match—it will be found (all things remaining equal) that the man with the best heart carries the day. May we not suppose that such a heart had an exceptionally firm closure of the foramen ovale and the ductus arteriosus? That it possessed powerful chordæ tendineæ? That the pulmonary artery was free from the slightest degree of stenosis? What is true of the heart is true of the muscles of the limbs. The differences that serve to mark the musculature of the mammalia are often minute, and not of necessity of the same functional importance as those of larger size, yet doubtless have significance in adapting the animal to special conditions of environment.

In an exact sense, the structure of an animal may be said to express the resultants of certain forces. In a sense, the work of the anatomist can be said to be that of analyzing the results of these forces—as one can determine from the shape of a cedar tree, whether it possesses a tall stem and conical masses of leaves, as is seen in a cultivated piece of protected valley, or whether it is short in stem (a mere brush), and with ragged foliage irregularly dispersed over twisted boughs, as one finds it on wind-vexed sand-dunes at the seacoast. But in a sense less exact, we cannot fix all the conditions. We know only in a general way that trees grown in localities contrasted by the degrees of violence of the wind will show correspondingly great differences in shapes. In order to accurately assign the work of the various agents, we must know everything of the temperature, degrees of humidity about the trees, the nature of the soil that nurtures them, and the habits of insects and birds that frequent them, to say nothing of the innate disposition that the trees may possess to naturally select from their organization what is best for their welfare. So it is with the causes of variations in anatomy. In a general way the variations themselves are held to be the results of a few all-pervading forces (as a rule, nutrition modified in some way from what is ordinarily met with, plus the trend of heredity), and these are inscribed in the body as dynamic energies may be recorded on a kymographion. But how inadequate such a record becomes is evident when we study any of these factors by the standard of the gross changes excited by disease. Disease in a morphological sense is the expression of forces operating inordinately or eccentrically. Yet how completely our systems fail when we attempt to explain them by the tests of nutrition or of heredity! So when the anatomist is told that his science to a great degree is one of record and not of thought, the answer may be given, properly enough, we think, that the reason lies in the inadequacy of knowledge of the causes of which structures are simply the effects. If the general clinical observer will give the anatomist more data as to the causes of congenital idiocy, the anatomist will be able better to explain the appearances he notes in the dissection of the idiot. If the ethnologist will explain the meanings of the divergences and contrasts of race, the anatomist will give a more philosophical description than is now possible of the differences between the structure of a Hottentot and that of a Northern European.

Thus we may say that in the study of anatomy it is not so much the fact but the import of the fact that is essential. Anatomical facts are like letters of the alphabet, their chief uses consisting in combination for the expression of ideas. Let us suppose that, instead of twenty-seven characters, the alphabet was made up of a thousand, would the conclusion be modified that the thousand signs were still to be regarded as aids to expression? The significance of anatomical facts lies not in their number or arrangement, but in the mind that guides the scapel and the forceps. A short time ago Drs. Chitteaden and Sterling instituted an inquiry into the shapes of the teeth and jaws in feeble-minded children. After completing their work it was deemed desirable to make an examination of the same parts in an equal number of normal children. In the attempts to find such subjects in institutions where the examinations could be conveniently conducted, it was found after proper investigation that no establishment for the reformation of children or the care of orphans would meet the requirements of the case, for such children were not normal—in reformatories, because of the possible inheritance from the criminal classes, and in the

orphanages because of the loss of at least one parent before the time of the average longevity, introduced elements of inheritance of disease (syphilis, tuberculosis, scrofula, cretinism) which invalidated any claim that might be made that the children were normal. Thus in a matter apparently as simple in essentials as the shapes of the teeth and jaws, four unknown propositions in the study of the morphology of childhood arose:

1. What are the shapes of the teeth and jaws in the normal child?

2. What are they in the feeble-minded child?

3. What are they in the children of our reformatories?

4. What are they in orphans?

Sir James Paget has lately urged the examination of varieties in different examples of the same disease after the manner of accurate botanists and zoölogists, by the observation and record of the larger external characters and indications in the human body. Among the special subjects outlined he names the following: 1st, varieties of diseases usually regarded as species, and so arranged in nosologies; 2d, the effect of mingling of diseases by hereditary transmission or otherwise.

While the method is certainly a gain over accepted clinical methods, we venture to assert that the study of etiology is not satisfactory without experimentation. Jenner tells us that John Hunter was in the habit of saying to his pupils "Do not think: try." If we are not careful we may be misled as to the meaning of this saying. We all know that Hunter was always thinking and trying. His dictum is paradoxical unless it be thus read: "Do not stop at the thought; try the thought by the test of observation or experiment."

A zoölogical station is a place where experiments are conducted in the study of the structure and relations of animals. An anatomical station must be the same if anatomy is to take its place among the progressive biological sciences. Observation has been shown to be insufficient to interpret natural processes. We can observe the effects of an experiment of nature; we can imitate such an experiment; but we cannot ignore the method by which effects are produced. Bates discovered in the Valley of the Amazon the exact conditions under which a given species of butterfly existed, so that in studying its varieties he may be said to have witnessed the creation of a new species. Every thriving organism can be said to be results of Nature's successes in her experiments, every languishing one a result of her failures.

Let me in conclusion call your attention to a subject which, while resting on biological tenets, is of professional interest. It is that the anatomical material coming under our notice is almost always that of a highly domesticated,[1] or, as one may say, over-acclimated nature, and that in order to study it with advantage we must recall what is in common between man and the animals (both in a wild and a domesticated state) about him. Not that savage man is of necessity a primitive man; he is often a degraded, a degenerate man. The ranges of anatomical structure are on that account all the more interesting. The human anatomist should hold to the hypothesis that studies in degeneration are really studies of a character so closely allied to those that are morbid that the distinction in a system of knowledge cannot be made. Our acquaintance with man as a domesticated animal, as a degenerate animal, and our ignorance of him as a wild and primitive animal, cause the morphologist to regard human structures with the same sort of interest that the botanist entertains for those plants which have been cultivated so long that he has lost knowledge of the typical form of the species. Man has doubtless undergone changes in his organization precisely like those which exist in a domesticated animal when his organization is compared to that of an ancestral form. Can the anatomy of such an animal be said to be closed? Should we not rather humbly acknowledge that we know little of a subject at once so vast and so difficult?

Dr. F. P. Henry has shown in his classic papers on anemia[1] that the red blood-corpuscles in this disease approach those of the lower animals in many if not all their characteristics, namely, in their number, their size, their shape, and the amount of hemoglobin they carry. The number of red blood-corpuscles in pernicious anemia is reduced to a degree that is normal in the coldblooded animals; the corpuscles are increased in diameter, occasionally nucleated and have a decided tendency to assume an oval outline. The change in the shape and proportion of the red blood-corpuscle in pernicious anemia is an instance of degeneracy mimicking the processes of normal evolution. The type of blood-corpuscle in pernicious anemia does not become identical with that which is normal in a coldblooded animal, but it resembles the ancestral shape because it has lost the form which is characteristic of its high position in the scale.

While degeneration is a phase of a specialization it is one portraying structures that fail to subserve the highest possible use in the economy, certainly a degree of efficiency lower than that seen in similar structures in animals in a wild state. Paleontology teaches us that the earlier types of horses possessed short crowns to the molar teeth, while recent horses have long crowns. These bear to one another a relation quite the same as that discernible in the teeth of man. The best molar type in the human subject exhibits long crowns, while the worst is one in which the crowns are short and, indeed, often scarcely protrude from the gums. The terms brachidontism and hypsodontism have been proposed to

[1] The use of the word "domesticated" in this sense needs explanation. The *Century Dictionary* gives the following phrase as a definition of "to domesticate:" "to reclaim from a state of nature." It also gives the following: "to convert to domestic use, as wild animals or plants." I have used the word in the sense first given. Man is "reclaimed from a state of nature," *i. e.*, he is not available as an absolutely feral subject. But he is not domesticated as dogs and horses are, since, as Darwin (*Descent of Man*, i, 112 expresses it, man "differs widely from any strictly domesticated animal, for his breeding has not been controlled either through methodical or unconscious selection." The effects of living in crowds, on unwholesome food, for numbers of generations, may not be those of domestication: neither are they of a kind comparable to those met with in the wild animal. The essential point I wish to make is this, that many morphological details result from self-imposed restraint, and that these details are to be treated in a manner somewhat the same as when met with in the process of changing a wild animal or plant into a domestic one

[1] Philadelphia: P. Blakiston, Son & Co., 1887, p. 116

express these conditions; and we can say that while brachidontism is a sign of an early phase of variation in the horse, it is a sign of late phase in man; that in the horse it subserves a relation to the phylogeny of the zoological group to which the horse belongs, while in man it is a sign of degeneracy due to intricate causes, prominent among which lie the profound depression of vitality arising from inherited struma, tuberculosis, syphilis, or to one or more of these conditions in combination.

In like manner the phenomena of polycuspidation in the molars relate to the evolution of the group to which a given animal belongs, and the cuspidation may be lost in the attempt to adapt the form to functions of defense. Yet if in the human molar the cusps show a disposition to recede from the quadritubercular to the tritubercular type, the result is a loss to all the previous gain. Nothing good is to be expected to accrue to the individual in which they occur. In the human dental series they are very frequently seen. We can say with certainty that the loss of a cusp in a human molar tooth is associated with decreased initial energy; and that these changes are not due, as in the case in the lower animals, to adaptation to special, and, as a rule, to higher ends.

The same remarks would apply to the proportionate size of the face as compared with that of the brain-case. The long-faced ant-eater is separated by family lines only from the short-faced sloth, and these distinctions have been brought about by the law of natural selection. But the short-faced specimens of the skull of civilized men are the results not of such a law but of the recedence from positions of high specialization secured by the operation of that law. They have tumbled from a lofty position by some profound impression on nutritive forces rather than reverted. Hence they come within the range of degenerated structures.

To what extent structures which are degenerate become on that account predisposed to disease it is difficult to say. But no difficulty exists in obtaining consent to the statement that, taken as a whole, the animal economy resists the inroads of disease in proportion as its vitalities are maintained at high levels of efficiency. It is tenable, therefore, that the different parts of the economy which resist disease are also those which are richly endowed with all the essentials of well-being. This line of thought is sustained by my own clinical studies in the diseases of the nasal chamber. Many of the exceedingly numerous variations in the shapes of the nasal chambers are examples of degenerated structures, that is to say they are degraded expressions of anatomical form due to or at least associated with a facial region which is stunted and dwarfed. If such a premise be conceded, then the next thought to my mind is logical, namely, that such structures are of necessity liable to become diseased.

We may assert without fear of contradiction that the skeleton of civilized man in like maner differs from the skeleton of uncivilized man. By civilized man in this connection I mean man as we find him to be in the great centers of population, past or present, where for acknowledged periods of unknown duration he has lived in communities having attained high grades of social organization, such as the people of modern Europe (of America so far as this continent is settled from Europe) and of ancient Peru. Doubtless Asiatic centers must be added to those enumerated. Yet of these, material for study is wanting. If I may be permitted to say in a few words what impresses me most in a series of skulls of civilized centers, it is the absence of correlation, that is to say, I find the disposition usually present in crania of wilder types of man for one part of the skull to be in harmony with another part to be largely absent. The bones themselves appear to be individualized. Let me mention some of these. The occipital bone tends to project between the lambda and the inion. The malar bone tends to elongate vertically, so that the orbit is relatively large; the ethmoid bone to extend less into the nasal chamber, so that when the middle turbinated bones are sought for in the living subject they are found to be lodged high above the plane of nostrils, and their lower borders are often oblique in position instead of horizontal. The roots of the upper molar teeth tend to be confluent, and the crowns to be elliptical in shape instead of quadrangular. Yet not infrequently a small, square orbit may be associated with an elongated jaw, or a short, set jaw with a wide, ovoid orbit.

Perhaps the best single conclusion to be drawn from the study of morphology as a factor in the study of disease is its value to humanity. The scientific study of race in connection with diseased action is almost an unbroken field. When this comparative phase of anatomy shall have been formulated we shall for the first time have a reasonable hope that the subject of human acclimatization, the geographical study of diseases, the causes and motives of migration, and thus indirectly, the history and destiny of man himself may be in shape for elucidation.

[Since the foregoing address was written my attention has been called to a paper read by M. de Giovanni on "The Morphological Examination of the Individual," an address delivered before the late International Congress at Rome. I have also received from Prof. Wilhelm Roux, of Innsbruck, a prospectus of a new publication, entitled *Archiv für Entwickelungsmechanik der Organismen*. This journal will serve as a vehicle for the expression of views much the same as those held in the foregoing address. It would seem, therefore, that the subject of morphology, especially in relation to clinical and pathological conditions, is already attracting attention.]

METHODS OF TEACHING SURGERY.[1]

BY JOHN S. BILLINGS, M.D.,
SURGEON UNITED STATES ARMY.

THIS paper has been prepared at the request of the Committee on Program, to serve as an introduction to a discussion upon the best methods of teaching surgery, and is intended to ask questions rather than to answer them. We have to consider: 1. Who are to be taught? 2. What is to be taught? 3. How it is to be taught.

Those who are to be taught include two classes: 1. The average medical student, who is presumably to become a general practitioner. 2. The men who wish to specially fit themselves for surgical work. There is a third class, namely, those who wish to learn only the least possible amount of surgery which will enable them

[1] Paper read before the American Surgical Association at Washington, Wednesday, May 30, 1894.

to get the degree of M.D., but these we need not consider to-day.

The surgical instruction to be given the average student depends on what he is required to know of anatomy and pathology before he begins his surgical studies, upon the amount of time which is allowed for surgical instruction, and upon the nature of the final examination which he must pass to obtain his degree, or license to practise.

In any case it should include the diagnosis, and best method of treatment, of the injuries and surgical diseases which the general practitioner is most often called upon to treat, including recent wounds and their complications, erysipelas, abscess, ulcers, etc.; fractures and dislocations, injuries of bloodvessels, strangulated hernia, urethral stricture, retention of urine and its consequences; obstruction of, or foreign bodies in, the air-passages; and also the selection and administration of anesthetics, the details of aseptic and antiseptic methods, and of methods of performing the most usual amputations, and ligations of bloodvessels.

Let us suppose that the instruction is to be given in a three-years' graded course; what other subjects besides those mentioned ought to be fully treated of by the surgical teacher? Under such circumstances is it worth while to go into the details of cerebral and abdominal surgery, of lithotomy and lithotrity, of excisions of organs or of the jaws and joints, of plastic and orthopedic surgery? Is it not enough to tell the average student what can be done in these directions, and refer him to special courses or to current literature for further information with regard to complicated and difficult operations requiring special instruments and apparatus? Of course, it is to be practically demonstrated that the teacher is the proper person to whom cases of this kind should be sent.

Deferring for a moment the consideration of the needs of the man who wishes to become a surgeon, we come to the question, "How are these subjects to be taught?" There are five principal methods: 1. Didactic systematic lectures. 2. Recitations. 3. Demonstrations and practical instruction by means of manikins, dummies, cadavers, and operations on animals, in the details of treatment of wounds, bandaging, dressings, and operations. 4. Theoretical clinical lectures, in which cases and operations are shown in an amphitheater. 5. Practical clinical instruction to small groups of students or ward-classes, in which, as far as possible, each student has something to do in the diagnosis or treatment or both.

The modern tendency is to reduce the time given to systematic lectures. In discussing the wisdom of this, we must bear in mind the different organization of the teaching staff in different schools, the increasing number of chairs or lectureships devoted to specialties, and the fact that the precise division of subjects among the instructors in a given school must depend to a considerable extent on local conditions, on the character, tastes, and teaching-powers of the different men who make up the faculty, on the amount and character of the facilities for laboratory and clinical teaching present, etc.

In the old-fashioned type of medical school, in which the whole instruction was given by seven or eight men, the professor of surgery taught what was called surgical pathology, or the principles of surgery, gave considerable attention to surgical anatomy, and was the clinical as well as the systematic teacher. There was at least one advantage, namely, that the teaching was consistent and harmonious; the student was not much bewildered with the conflicting views of different professors. The professor of anatomy was in training for the chair of surgery, and took very little interest in comparative anatomy or in embryology. There was no professor of pathology; and both the professor of surgery and of medicine lectured on inflammation, congestion, suppuration, etc., each from his own point of view.

At present, in a large and popular medical school, there are from twenty to thirty teachers of various grades; there is a professor of pathology, of surgery, of clinical surgery, of surgical anatomy, of orthopedic surgery, of genito-urinary surgery, etc., and the professor of gynecology takes a large share of the abdominal surgery.

Now how can the subject of surgery be subdivided among all these teachers in such a way that the whole field shall be covered, without involving useless repetitions, embarrassing contradictions, and the expenditure of an undue amount of time and labor by the student, or of the production of heart-burnings in some of the teachers? This is one of the most difficult problems in the organization of a large medical school which is to be really efficient and popular, and it is one to which no general and universal formula is applicable.

Theoretically, each professor being a thoroughly wise, unselfish, good-tempered man, desiring only the best interests of his pupils and of his school, and there being frequent consultations between them to secure harmony in their teachings, the desired result may be obtained. Practically there are usually two or three strong men in the faculty who settle what shall be done, and the rest find it expedient to submit, although they may not agree. When there are no sufficiently strong men, and all the professors are not perfectly good and unselfish, there may be trouble.

Let us consider details a little. A well-organized medical school should have a professor of pathology and pathological anatomy, under whose direction a certain amount of laboratory instruction should be given—comparatively simple for the average student, extended and elaborate for post-graduates. The greater part of his teaching for the average undergraduate student must be by lectures, with demonstrations.

Given such a teacher, with the necessary facilities, why should the professor of surgery lecture on surgical pathology or bacteriology to the average undergraduate? The only really good reason I think of is, that he should be thoroughly familiar with the subject, and at times use experimental methods in devising improvements in surgical practice, and that teaching the subject greatly helps him to obtain, classify, and retain his knowledge. But his teaching on this subject would be most valuable to a special class of advanced students, or post-graduates—who can devote themselves to it, and give the necessary time to that experimental work on animals which is absolutely essential to secure satisfactory results.

At all events, I think we can agree that the rela-

tions between the surgeon and the pathologist should be intimate and friendly, while each should be entirely independent of the other, and that the surgeon should go into details of practical application of principles in accordance with the more general teaching of the pathologist.

As regards the teaching of surgical anatomy, and of operations on the cadaver, by a teacher distinct from, and entirely independent of, the professor of anatomy on the one hand and the professor of surgery on the other, I believe that there are widely different opinions as to its expediency. Such an independent chair, or demonstratorship, is usually provided to make a place for some particular man, and its utility must depend upon who this man is.

While no general rule on this point can be laid down, might it not be best that attendance on such an independent course should be purely voluntary on the part of the class, and that it should be largely devoted to the instruction of those who wish to make a specialty of surgery? It appears to me that more use should be made of living animals than is now done in teaching the results and treatment of wounds, including details of aseptics and antiseptics, and in special courses for advanced students who should be required to perform operations under the guidance of the surgeon.

The next question is as to the part which clinical surgery should play in a course of education leading to a medical degree. The great majority of students prefer clinical teaching and demonstrations to didactic lectures, and will go where this clinical teaching is most brilliant and varied; and, so far as it goes, we must admit that this kind of teaching is generally the most useful to them, because they remember it better. How far is it possible to cover the field of diagnosis and treatment of injuries and surgical diseases by clinical teaching alone to the extent that it is desirable for the average medical student? And how far is it desirable to vary and modify the didactic teaching so as to make it supplementary to the clinical teaching?

Evidently the answers to these questions must depend in part upon the amount and variety of clinical material that is available, and hence must differ in different schools. As a rule, clinical material is not available to cover the entire field for any school, no matter how large its hospital and dispensaries—hence there must be some systematic didactic teaching. Is it best that this should be a complete independent course covering the whole field, merely using for any particular subject such cases as may happen on that day to be available, thus leaving the greater part of the clinical teaching to duplicate that which has been given in the systematic course? This is, upon the whole, the easiest way, and in favor of it is urged that it is desirable that the student should be told the same thing several times to insure his remembering it. This is the argument which used to be used in favor of the old plan of not having a graded course, but compelling the students to listen to the same course of lectures in successive years.

On the other hand, it can be seen that there would be certain advantages in deferring the systematic lectures until toward the end of the course, and then devoting them mainly to subjects which had not been illustrated in previous clinical teaching; but to make this plan a success it would be necessary that the systematic lecturer should either have given all the clinical instruction, or should be perfectly familiar with all that has been given.

A possible modification of this plan would be to let two professors divide the field of work, each taking a certain class of diseases and injuries, giving clinical instruction thereon and supplementing it with systematic teaching as suggested, and then the two men exchanging fields of work each year. An objection to this is that a considerable part of clinical teaching is given in connection with patients who select their own surgeon, and who will not make such selection with reference to any curriculum. Undoubtedly the more clinical instruction of the right kind that can be given, the better for the students and for the reputation and prosperity of the school.

But this phrase "clinical instruction of the right kind" brings up a new set of questions. How much does it profit the student to witness, from the rear benches of an amphitheater, such operations as the ligation of arteries, the extirpation of tumors, lithotomy, or nephrectomy? Undoubtedly the student is interested and learns something, and he will go where he can see—if not the operation itself, at least the heads of the persons who are busy about the patient; and it will not do to restrict his privileges much in this respect. At the same time, should not special opportunities be given to the few who are devoting themselves specially to surgery to see as much as possible of difficult and unusual operations? It appears to me that more than two hundred men cannot possibly obtain any special information from surgical clinics in an amphitheater which they could not obtain equally well in a didactic lecture, and which could not be much better given with illustrations by means of lantern slides, than by using a patient as a means of demonstrating an operation. It is quite possible to show by means of lantern slides, as Dr. Kelly has proved, to several hundred men, every detail of an operation which can be seen by the immediate assistants of the operator.

Now with regard to clinical teaching to comparatively small sections, or ward-classes, the members of which are to be brought as much as possible into contact with the patient, and even to assist in the operation of dressing. There is no doubt as to the utility and popularity of this mode of teaching, but in this connection a word may be said with regard to the relations of hospitals and dispensaries to surgical teaching.

While I believe that a hospital is not doing its fullest and best work if it is not increasing and diffusing knowledge, and that patients secure the best and most careful attention and treatment in teaching-hospitals, where the work of the staff is keenly scrutinized, yet it must be admitted that there is sometimes a danger that people will get the idea that in a teaching-hospital the interests of the patients are not as fully consulted as they should be, and will avoid that hospital as much as possible. This danger arises mainly from two things: first, the allowing students to have anything to do with the treatment, and especially with an operation. The patient wants to be operated on by the most skilled man, that is by the professor; and if he has a suspicion that after he is under the influence of an anesthetic the professor may hand the knife to a student to make perhaps his

first essay, he will avoid that place. All of us would do the same, and therefore in ward-class teaching a patient should never be deceived as to who is to perform the operation, for sooner or later the deception will be discovered and the news will spread.

The second danger to the popularity of a teaching-hospital is that patients are not infrequently made to wait until their cases can be used for clinical instruction, sometimes for hours, sometimes for days. In most cases the patient knows when he is put off for this purpose, and after one experience of the kind he will go to another hospital the next time, and advise his friends to do the same.

It is well also that the clinical surgical teacher should remember that his ability to obtain abundant clinical material depends to a very considerable extent upon the manners and on the good-will of some of his assistants, the resident physician, the nurses, etc., who are often the first to see the patient as an applicant, and who have much to do with subsequent treatment.

These assistants, residents, receiving-officers, case-takers, and nurses are not always possessed of the exquisite tact, kindly sympathy, and knowledge of human nature which it is to be presumed are invariably the characteristics of the clinical surgeon; and it is a part of his business to instruct them and perfect their manners as much as possible.

Recitations and quizzes are excellent methods of teaching for the majority of students, but are only well adapted to small classes or sections. At present they are, for the most part, conducted as a private enterprise by persons who may, or may not, be on the teaching staff. The question as to whether this mode of teaching should be made use of in the official course to a considerably greater extent than is now done is an interesting one, and is commended for discussion. It appears to me more desirable that it should be applied to the clinical teaching than to the didactic lectures, and one good result of this would be to discourage the reliance on quiz-compends, which I think invariably do more harm than good.

With regard to modes of lecturing, every man is, of course, a law unto himself; yet I will venture one or two suggestions. The teaching for a class of students should be definite, selective, and, to a considerable extent, dogmatic; and critical historical discussions should be used very sparingly.

What the student hears and sees during the first half-hour of a lecture is what he will remember best, and will have the best notes of; therefore, when there are several different ways of doing a thing, let the teacher describe first the method which he prefers, taking all the time required to fully demonstrate it and impress it on the student. After this is done the other methods may be referred to, and so much history and criticism given as time will permit. If the reasoning is given before the conclusions are stated, the student is apt to get confused, and to characterize the teacher as a "wobbler."

If the lecturer will fix in his mind the half-dozen questions or so that he would ask to test the students' knowledge of the subject upon which he is going to speak, and will then make it his main object to answer those questions clearly, definitely, and fully, he can hardly fail to give a good lecture.

In objecting to too much history in didactic or clinical lectures on surgery, I do not wish to be understood as underestimating the importance of giving historical instruction. I think that in every medical school a course of lectures on the history of medicine and surgery, combined with practical instruction in bibliographical methods, should be given; and if this is not done, then I would advise that the professor of surgery devote five or six lectures to the history and literature of his subject, which lectures will probably be most useful and interesting at the beginning of the last year of the student's course.

It was stated at the beginning of this paper that besides the average medical students, the needs of the man who wishes to specially fit himself to be a surgeon should be considered. These relate to post-graduate work mainly, for a broad foundation of medical knowledge is requisite for the man who wishes to become a surgeon. The technique of operative surgery, important as it is, is secondary in importance to skill in diagnosis and to knowledge of therapeutic methods which do not involve the use of the knife.

The man who intends to be a surgeon should not only make a special study of surgical anatomy, but should do a considerable amount of practical laboratory-work in bacteriology, pathological histology, and experimental pathology and physiology.

It is quite true that the majority of our leading surgeons could not, perhaps, by themselves make a bacteriological diagnosis, or determine fine distinctions in new-growths, and yet they do good work—having these points settled for them by younger men trained in the new methods. But the surgeon of the future should himself be trained in these methods, even though he may employ others to carry them out.

And in this connection I would remind you that bacteriology cannot be profitably studied for two or three days in a week, but that it needs at least three hours a day every day for three months for a man to learn how to begin readily to use its methods. In general, I think that all studies are best concentrated, and that the usual plan of dividing studies into an hour two days a week for this, and an hour three days a week for that, etc., is much more for the convenience of the professors than it is for the true interest of the students.

As for operative technique, much of it can be learned on animals, but much of it requires also work on the cadaver, the repetition over and over again, until, as Billroth said, a man could do it when he was asleep. The most important of all is residence in a hospital, the working as assistant to a surgeon, the seeing and handling of cases, and not merely looking at them from a distance. The number of men who are able and willing to carry out such a course of study as that indicated is limited, and the teacher of surgery cannot do very much for them except give them opportunities for seeing his methods and results; but is it not possible to give them better opportunities than can be provided for a large class of undergraduates? Should they not be required to repeatedly perform the many operations which can be advantageously performed on animals before they try these operations on man? It seems to me that in the last year of a four-years' course all students should be tested in this way; but it must be admitted that, with

the present curriculum, there is not time to spare for this purpose, especially when the graduating class is a large one.

This leads to two final questions, which, though not directly connected with "the best methods of teaching surgery," have, nevertheless, an important bearing on them. The first is: Are there not some subjects which occupy too much space in the undergraduate curriculum of our largest and best medical schools, such, for example, as inorganic chemistry and embryology? Ought not the student to be required to know so much as is required of inorganic chemistry before he begins his medical course? Is it desirable to make embryology and general morphology a part of the curriculum for all medical students, as a basis for the study of anatomy, or is it wiser to place these as elective studies in a post-graduate course, and to insist on more dissecting and a greater knowledge of practical anatomy than are now generally demanded? In this connection your attention is invited to the widely different opinions as to the best methods of anatomical teaching—as represented by Professor Macalister for the morphologists, and Mr. T. Cooke, for the old school, which have appeared in the *Lancet* and in the *British Medical Journal* during the past year.

It appears to me that the teaching of anatomy should begin with a few lectures and demonstrations on general morphology, and that the first dissections should be made on cats and dogs until a good technique has been acquired, so that the supply of human cadavers, which is always insufficient, can be fully utilized to the best advantage. I also think that it is unwise to have the final examination in anatomy one or two years before the other final examinations; the anatomy should be kept up throughout.

My last question is: Would it not be good policy for a first-class popular medical school to limit the number of pupils which it will accept to its capacity to give them proper instruction in laboratory-work, in practical anatomy, and in clinical medicine and surgery? Of course, each faculty is prepared to assert that its own school now does this, and will disapprove of fixing any limit to the number of its pupils; nevertheless, it appears to me, as an outsider, that there are at least two or three medical schools in this country which would act wisely if they would fix a limit to the number of students which they would receive either in the first or in the third year, or in both, and enforce this limit by competitive examination or by higher fees, or by both. It would bring the best men to them, and would enable them to do thoroughly good work.

An Epileptic Colony for Illinois.—At the meeting of the Illinois State Medical Society, held at Decatur, May 15–17, a resolution was introduced by Dr. J. B. Maxwell, and unanimously passed by that body, indorsing a proposition for an epileptic colony on the Bielefeld plan. The matter was referred to the Legislative Committee, and that committee (consisting of D. W. Graham, of Chicago; J. B. Maxwell, of Mt. Carmel; and B. M. Griffith, of Springfield) was instructed to bring the matter before the next Legislature, and use all honorable means to have such a colony established.

FATAL NAUSEA AND VOMITING OF PREGNANCY, WITH REPORT OF CASES.[1]

BY EDWARD P. DAVIS, A.M., M.D.,
OF PHILADELPHIA.

IN 1888, Graily Hewitt, of London, an Honorary Fellow of this Society, contributed a paper on "Severe Vomiting During Pregnancy," in which he drew attention to anteflexion and impaction of the pregnant uterus as conditions encountered in these cases and undoubtedly concerned in their causation. It is my purpose to report three cases of fatal nausea and vomiting of pregnancy, in two of which conditions described by Dr. Hewitt were present, and in one of which a pathologic condition of suggestive interest and rarity was observed. I desire also to call attention to certain clinical signs of value in the prognosis in these cases as indicating a dangerous condition of the patient. The clinical histories are briefly as follows:

CASE I.—Mrs. A., a widow, had been treated for several months by a physician who supposed her to be suffering from chronic gastritis. An expert physician who saw her in consultation had confirmed the diagnosis and approved the treatment. Her symptoms attracted the attention of a medical student boarding in the house, who suggested to the family that disease of the pelvic organs might be present, and that a vaginal examination be made. I was asked to see the patient in consultation by the physician in charge. She was emaciated, with a rapid, feeble pulse, sordes beginning upon the teeth, her eyes sunken and glassy, her breath offensive, and emaciation well marked. She was vomiting food taken, together with mucus stained with coffee-ground material.

She complained of pain in the chest beneath the sternum. Her intellect was clouded, although usually her mind was clear. Vaginal examination revealed a uterus enlarged several times the usual size; it was retroverted, the os and cervix exceedingly soft. The finger readily entered the cervical canal, but found the internal os closed. As the patient was without systematic care, she was urged to go at once to a hospital where trained nurses could attend her. Twenty-four hours after this she was removed to the Philadelphia Polyclinic; a tampon of carded wool was placed beneath the uterus, and the patient was carefully fed by rectal injections, and stimulated hypodermatically. The uterus was readily raised, and its altered position gave the patient no increased distress. Her vomiting ceased, she retained food given by the rectum, and also very small quantities of food taken by the mouth. The tampon was removed, the fundus of the uterus brought higher in the pelvis, and sustained by a packing of gauze. The patient's general con-

[1] Read before the American Gynecological Society, at its annual meeting, Washington, May 29 1894.

dition, however, grew worse, purpuric spots appeared upon the body, sordes increased, low delirium supervened, and she died apparently from exhaustion.

Permission for a post-mortem examination could not be obtained. As the pregnancy, if present, was illegitimate, nothing was said to her family regarding its existence. The size and shape of the uterus and its consistence were those of pregnancy advanced several months, and a close examination of the history of the case supported this view. The points of clinical interest in the case were the coffee-ground vomit, and profound disorganization of the blood as evidenced by extensive purpuric areas.

Case II.—This case was that of a woman, aged thirty years, who was first seen two years ago, and who complained of suffering caused by dysmenorrhea, accompanied by anteflexion and prolapse of the uterus. She experienced relief at that time by the use of carded wool tampons. She passed out of observation, and came to my notice again in October, 1893, stating that she had received treatment from another physician; that she had, she thought, suffered from abortion; that she was then pregnant about two weeks. I afterward learned from the physician who treated her that granular degeneration of the cervix had been present, with a greatly softened and patulous os uteri, with extreme anteflexion.

In addition to the usual discomfort of early pregnancy, the patient suffered from intense nausea and vomiting. She had always been of nervous temperament and lacking in self-control. She complained that, in addition to vomiting, she suffered severely from straining and retching. She was informed that her condition required very careful attention, and various remedies were given her; her diet was regulated, and peptonized milk, broths, and other suitable food were systematically given. She grew, however, steadily worse. As she was in a boarding-house, she was urged to hire a trained nurse, and to remain in bed or to change her quarters to a hospital where skilled nursing could be obtained. Her progressive increase in substernal pain and her persistent straining and retching seemed grounds for grave anxiety. She refused a vaginal examination, and did not appreciate the danger of her condition. She declined to accept my advice, and sought treatment from Dr. Elizabeth Greenbank, to whom I am indebted for notes of the case until I saw the patient in consultation before her death. Dr. Greenbank records that the patient's temperature was subnormal, her pulse remaining below 100, her condition exceedingly variable, substernal pain, occurring in the early evening, being especially severe. The patient finally allowed Dr. Greenbank to make a vaginal examination, when marked anteflexion with prolapse of the uterus were found. This examination greatly increased the patient's distress. She finally secured a house of her own, and accepted a trained nurse. Her pulse gradually increased in frequency, and at the end of the thirteenth week of pregnancy rose above 100.

At the end of the fourteenth week of pregnancy, I saw the patient in consultation with Dr. Anna Broomall; her pulse was 120, her temperature normal, her tongue slightly coated; she was but little emaciated. The uterus was anteflexed, the fundus low, the lower segment impacted in the pelvis. Under partial anesthesia, the uterus was raised and the vagina tamponed. Coffee ground vomit was present, although in slight amount; substernal distress, however, continued and was excessive. On the day following the replacing of the uterus, the patient's symptoms were aggravated. On the second day following the first consultation, the tampon was changed, and the uterus was found considerably higher in the pelvis. On the third day, another consultation with Dr. Broomall was held, and I urged that the cervix be dilated, and gave an unfavorable prognosis. Dr. Broomall urged that the stomach be washed out at the same time. Under chloroform, the internal os was found to be rigid, thickened, and tightly closed. The finger could not enter the uterus, and the bladed dilator was used until the finger could be inserted. This dilatation was increased by the use of the solid metal bougies until the index finger entered easily. The stomach was thoroughly douched with dilute saline solution. Following this dilatation, the patient's vomiting ceased, her substernal distress ceased entirely, and she spent the best night for two weeks. Her pulse was 130, her temperature 99°. In the afternoon, her temperature rose to 101°. At 6 P.M., a chill occurred, with temperature 102.6°. This was followed by syncope from which the patient slowly rallied. Pain and hemorrhage supervened, and I saw the patient at 11 P.M. She was excessively weak, but conscious, and complaining of labor-pains only. Her vomiting and substernal distress had entirely ceased. At her urgent request and that of her husband, it was decided to terminate the abortion at once. She recognized the hopelessness of her condition, but begged to be relieved of the pain of abortion and excessive weakness. She was accordingly stimulated by hypodermatic injections, and under chloroform the fetus was quickly removed, and the uterus thoroughly curetted with the blunt douche curet. It was then packed with iodoform-gauze, and carried well up into the pelvis. There was no hemorrhage during the emptying of the uterus; the patient rallied from the anesthetic, became conscious, but died in syncope shortly afterward.

The post-mortem examination was made by Dr. W. M. L. Coplin, in the presence of Dr. Broomall and myself, sixteen hours after death. The color of the body was yellow; the conjunctivæ were clear; the mucous membrane reddish. Slight subcutaneous edema was universally present. Rigor mortis was well marked, except on the abdominal walls, which were flaccid. The body was not entirely cold, although surrounded by ice. An incision was made from the tip of the sternum to the pubes. The subcutaneous fat was abundant, firm, and bright-yellow. The extra-peritoneal fat was also abundant. The omentum was fat, containing fatty masses along the colon. The fundus uteri was one inch below the umbilicus. The peritoneum and intestines were normal; no evidence of septic paresis was present. Both tubes and ovaries showed no gross evidence of disease.

The uterus was slightly edematous to pressure. The spleen was vascular, not enlarged or especially softened. Both kidneys were flabby in consistence, and the cortex stained bright-yellow. The liver was normal in shape, the gall-bladder normal, the liver-substance of normal consistence and bile-stained.

The uterus, tubes, and ovaries were removed. Longitudinal section of the entire uterus was made through the anterior wall. The uterus was distended with gauze, and was dark purplish-red in color, its sinuses filled with soft currant-jelly masses, not clotted. On the posterior wall, on a line extending between the orifices of the Fallopian tubes, a transverse line resembling scar-tissue could be seen. The internal os had been dilated, but was excessively resistant, resembling gristle. The placenta had been attached over the fundus and the orifice of the left tube; a small portion of the placenta remained adherent. No other portions of the ovum or appendages remained in the uterus. The uterus had evidently been curetted and practically emptied. No evidence of injury to the organ from dilatation or curetting could be detected. On the anterior and posterior walls of the cervix were areas of fibrous tissue, excessively firm, resembling that extending transversely across the posterior surface. In dilating the uterus these tissues had expanded more laterally than anteroposteriorly, although careful examination failed to reveal evidence of injury to them.

The stomach was long, narrow, filled one-half with fluid; areas of thrombosis were visible along its greater curvature. The stomach was ligated and removed unopened. The diaphragm was punctured, and an effort was made to remove the heart by inserting the hand into the chest. The heart was excessively friable. The valvular apertures admitted two fingers; no evidence of atheroma was present. The heart-substance was dark-red, very flabby, and tore easily. The pleuræ were smooth, non-adherent, and tough. The lungs were collapsed and contained air in portions; the substance was normal. One lung was removed and examined. The pancreas was apparently normal.

Especially noteworthy was the condition of the blood, which was fluid, dark currant-jelly in color, and without clots. No ante-mortem clot was found in the sinuses of the uterus. Also remarkable was the flabby condition of the heart, kidneys, spleen, and uterus, and the stained appearance of the parenchyma of all the viscera; this staining was with a dark currant-jelly fluid.

The patient died a cardiac death.

A close examination of the uterus revealed an exceedingly interesting condition of the cervix; this part of the womb was composed of dense connective tissue arranged in whorls; amid this tissue were found two cysts, one an inch and a quarter in diameter, the other half its size. These cysts contained thick, transparent, yellow, gelatinous substance, which on microscopic examination was found rich in small, ovoid cells without nuclei, the protoplasm in a granular condition. These were undoubtedly retention-cysts from retained secretion of mucous follicles. No bacteria were found in the cervix, although it is quite possible that parasitic growths were present. Microscopic examination of the liver showed the parenchyma in a state of granular degeneration. A very interesting phenomenon shown in microscopic sections of the kidneys is the presence of hyaline casts *in situ*, which are freely distributed throughout these organs. The illustrations appended, showing the cervix and cyst, and the

Fig. 1.

Vertical section of uterus, showing cyst in posterior wall of cervix.

walls of the cysts, are the work of Dr. David Bevan, Instructor in Microscopy in the Jefferson Medical College. The various tissues in the case were examined in the pathological laboratory of Drs. Coplin and Bevan.

Referring to the notes of the patient's condition during the last two weeks of her life, we find that albumin and hyaline casts were found in considerable quantities.

In reviewing the history and pathology of this case, I desire to call attention, first, to the conditions present in the pelvis: marked anteflexion of uterus, the neck of which was composed of dense connective tissue; the presence of retention-cysts in its cervix, the impaction of the uterus against the symphysis, and the excessive tenderness of the pelvic tissues were certainly irritant cause enough for reflex vomiting. The hematin-staining of the

patient's tissues, the fatty degeneration of the various portions of the body so extensively present, and the great softening of the heart-muscle, point to fatal anemia. This fatty degeneration was largely

Fig. 2.

Dense connective tissue in cyst-wall.

responsible for the fact that the patient seemed but little emaciated, and this appearance of nutrition was urged by one of the physicians in the case in support of a favorable prognosis.

Case III.—Mrs. X. was a primigravida, the wife of a clergyman. She was seen in consultation by me at the request of Dr. Loux, of Philadelphia, who had been called in attendance a few days previously. During the first weeks of her pregnancy she had been subjected to homeopathic medication, which consisted largely of the administration of water in teaspoonful doses, and also comforting assurances regarding the future. On examination the patient was not excessively emaciated. Her pulse varied from 100 to 120; her temperature was not above 99°; she complained of very little abdominal distress, but at night suffered from substernal pain, nausea, and vomiting. Vaginal examination revealed the uterus anteflexed and low in the pelvis, but not impacted. The physician in attendance had faithfully endeavored to feed the patient in various ways, had given sedatives, and also stimulants hypodermatically, but without avail. It was his opinion that prompt emptying of the uterus was indicated. The vomitus had been streaked with coffee-ground material for two days. After examining the patient, I agreed with Dr. Loux, that inasmuch as the uterus was not impacted, but sharply anteflexed, we would gain little by simply elevating it in the pelvis. I urged that the cervix be dilated, and that if this was not followed by immediate improvement, that the uterus be curetted and packed with gauze as soon as possible. This advice was conveyed to the husband, who was distinctly informed that his wife was in a very critical condition. He asked for delay until the following day to communicate with her relatives. Immediately after the consultation, members of his congregation persuaded him that the gloomy prognosis was entirely unjustified, and strongly urged employment of a different physician. The second physician called in consultation at once supported the view of the parishioners, and assured the husband that rest and feeding and waiting were all that were necessary, quoting the familiar obstetric teaching, that "cases of nausea and vomiting of pregnancy often improved suddenly and radically, and that the practice of abortion is rarely indicated." I did not see the patient again, but am informed by Dr. Loux that the patient went steadily from bad to worse, dying from exhaustion a short time after I saw her. In her case I based an unfavorable prognosis upon the substernal pain, coffee-ground vomit, the length of time during which she had been in an anemic condition, and her general aspect, which closely resembled, though in less degree, that of the cases already described.

In summarizing these cases, their significance to my mind lies in the fatal condition of anemia which was present. The literature of pernicious anemia in pregnant and puerperal patients affords abundant illustrations of serious impairment of the blood, sometimes accompanied by ulcer of the stomach (Leube and Fleisch, *Virchow's Archiv*, lxxxiii 1124). Atrophy of the gastric mucous membrane, often associated with hypertrophied polypoid villi, is not infrequently seen in pernicious anemia, in cases in which pain and coffee-ground vomit are familiar symptoms. The condition of the heart may be partially responsible for the substernal pain in these cases, while changes in the marrow of the bones of the thorax are thought by some to produce it (myelogenic leukemia). It is also a recognized fact that, in anemia, pain may be reflected to the central ganglia of the trunk, so that the substernal distress of which these patients complain may be properly considered as a reflex from a uterus in a pathologic condition.

In conclusion, I desire to advance the following propositions, of which the cases reported are illustrations: Nausea and vomiting of pregnancy are dangerous in proportion as they induce pernicious anemia. Such a condition of danger is to be recognized by studying these cases in the light thrown

upon them by the pathology of anemia. While it is possible that sudden and radical improvement may occur in cases in which a functional neurosis is the predominant factor, only when pernicious anemia is once established is delay dangerous, no matter at what period of pregnancy the patient is seen. While it is true that raising and sustaining an impacted uterus will relieve many milder examples of this affection, cases in which danger threatens should be met by prompt dilatation and emptying of the pregnant uterus, which are to be effected by modern surgical methods.

A SUMMARY OF THE HISTORY AND PRESENT POSITION OF THE OPERATION OF CASTRATION FOR HYPERTROPHY OF THE PROSTATE.[1]

BY J. WILLIAM WHITE, M.D.,
PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

IN the fall of 1892 I was asked to prepare an address on the surgery of the hypertrophied prostate for the coming meeting of the American Surgical Association in 1893.

In December, 1892, I requested one of my assistants, Dr. Kirby, to make a series of experiments on dogs with a view to determining whether or not castration would be followed by notable atrophy of the prostate. The thought that this was possible had been suggested to me by the comparison long ago made by Velpeau and afterward by Sir Henry Thompson between prostatic and uterine fibro-myomata.

Control-observations as to the weight of the normal prostate in dogs were begun at once. The first castration was done January 27, 1893; the others followed at intervals of a few days. The results, showing rapid atrophy, first, of the glandular and, then, of the muscular elements, were so decisive that I embodied in the paper I was writing the suggestion that castration might be a valuable therapeutic measure in many cases of hypertrophied prostate. So far as I know, the suggestion had never before been laid before the profession.

I subsequently learned of the observations of John Hunter and Owen and the confirmatory investigations of Mr. Griffiths as to the changes in and out of the rutting season in the prostate of the mole, the hedgehog, and other animals, and as to the effect of castration in various species in producing prostatic atrophy. Griffiths' observations appear to have been confined to animals already castrated for other reasons; no definite series of experiments is mentioned. He maintained, moreover, that the enlargements of the gland were not to be classed with the uterine fibro-myomata. His paper, which was written to demonstrate that the prostate is in its essential significance a sexual and not a urinary organ (a subject which has long been under discussion), contained a few illustrations, taken from various sources, of atrophy of the prostate in eunuchs. I found in addition a note by Harrison that in cases of sterility in the male the prostate had been shown to be atrophied.

No reference existed in surgical literature to any possible application of these facts to the treatment of cases of hypertrophied prostate, but they strengthened me in my decision to bring the matter up for consideration.

Theoretically, the line of argument was as follows: The prostate, while not embryologically the true homologue of the uterus, is developed from structures quite distinct from those that form the urinary passages. The structure of the prostate and that of the uterus are strikingly similar. The growth of the organ is in direct relation with the sexual life of the individual; its overgrowth occurs at a period when the sexual life is fading out, but is usually not extinct. The reproductive life ends sooner in the female than in the male, and accordingly we find fibro-myomata appearing earlier in the former than in the latter. The histology of the growths and of their varieties is remarkably alike in the two sexes. The uterine tumors do not appear after the menopause, or, if present, undergo atrophy at this time. After a certain period of life there is no increase in the tendency to enlargement of the prostate, but rather the reverse.

In the female oöphorectomy causes a disappearance of these growths and an atrophy of the uterus itself. Castration almost certainly has the same effect upon the normal prostate in our species, and I have experimentally demonstrated that it has such an effect in dogs.

The fact that we have no example of spontaneous shrinking of the hypertrophied prostate in old age may be explained by the great frequency with which the trouble causes death in such cases.

Messer's tables, founded on a dissection of 100 prostates in men over sixty years of age, disclose one interesting fact in this connection. Assuming arbitrarily that eighty may be taken as the age at which, in the great majority of men, the sexual life is absolutely and finally ended, we find that among those subjects whose prostates weighed over six drams the percentage of octogenarians or their elders was only 22.8, while among those whose prostates weighed less than six drams (many of them less than normal) the percentage was 35.3, more than half again as great. This is not only confirmatory of Desnos' observation that after a certain period of life the frequency of notable

[1] Read before the American Association of Genito-Urinary Surgeons, at its meeting, at Washington, May 29, 1894.

hypertrophy diminishes, but it suggests the possibility that in many of these cases physiologic atrophy had already begun. The subjects were not selected from among patients, but just as they happened to come within reach of the investigator.

The uncertainty as to the exact duration of sexual life in the male also weakens the force of the statement that the condition does not manifest itself until after the period of life when it should occur if it were truly homologous with the uterine growth. In addition, it may be said that there is accumulating evidence that prostatic hypertrophy begins during middle life much more frequently than was formerly supposed, and that the statistics on which we have been accustomed to rely, based on museum specimens and on the experience of surgeons to whom the patients apply only when distinct subjective symptoms have developed, are to an extent unreliable.

My view that these facts justified a trial of castration for the cure of prostatic hypertrophy was greatly strengthened by the fact that Kirby's experiments on dogs, made at my request, not only demonstrated the atrophy that took place in that species after castration, but also showed its extreme rapidity.

At the time I read the paper in Buffalo, New York, on June 1, 1893, before the American Surgical Association, my opinions rested on this foundation.

Abstracts were published during June in most of the medical journals of this country. On August 1st the paper was published in its entirety in the *Annals of Surgery*, and on September 9th a full abstract appeared in *The British Medical Journal*, that part relating to castration being unabridged.

Since June, 1893, the following communications relating to the subject have appeared:

Centralblatt für Chirurgie, No. 35, September 2, 1893. Ramm, of Christiania, reported two cases operated on earlier in the year, with marked improvement.

Ibid., No. 17, April 28, 1894. The same writer gives the dates of his operations as April 2 and April 25, 1893, and reports a practical cure in each case.

British Medical Journal, September 16, 1893. Mr. C. Mansell Moullin wrote that "the question of castration as a means for procuring involution of the enlarged prostate, raised by Professor J. W. White in his address to the American Surgical Association, deserves more than passing consideration," and stated that he had discussed it with a patient in November, 1892. He adds that "one single instance in which definite reduction in size was proved to have taken place would be of incalculable value."

Ibid., September 23, 1893, Mr. Reginald Harrison wrote, "as bearing upon the correspondence that has followed Dr. White's remarks on castration in preventing growth of the prostate," that the suggestion had been made to him by a patient some years ago, and that as a compromise he had subcutaneously divided the vasa deferentia. He knew no more of the course of the case, except that the patient was alive and well six or seven years later, and that he had "thought nothing further of it until reading Dr. White's interesting lecture."

(In the discussion that followed the reading of my paper in Buffalo, Dr. Mears asked if division of the vasa deferentia might not accomplish the same result as castration.)

Ibid., September 23, 1893. Mr. MacMunn suggested that the sexual history, past and present, of the subjects of enlarged prostate be more freely studied, as well as the conditions of the gland in different races of men and the lower animals.

Ibid., September 30th. Mr. Moullin again called attention to the importance of getting definite information as to the effect of castration upon the abnormally enlarged gland in aged persons, as he says it must now be regarded as an established fact, not only for animals but for man, that "castration in early life prevents the full development of the prostate, and in adult life causes the normally developed gland to atrophy."

Ibid., September 30th. Mr. Griffiths called attention to Ramm's cases, and added, without allusion to my paper, that "this method of treatment is no doubt likely to suggest itself to anyone who has studied the nature and function of the prostate in its relation to the sexual function." He said further that it may in some cases prove an effectual remedy, but he went on to call attention to the lack of proof that prostatic enlargement depends on sexual excitement, which had not been asserted by anyone so far as I know.

Ibid., May 12, 1894. The same writer called attention to his own letter of September 30th, and sent a translation of Ramm's latest reports of his two cases already alluded to.

Ibid., November 18, 1893. Mr. Arthur Powell described a case that he said "might be of interest in connection with Prof. White's recent address," and in which a patient with retention of urine from enlarged prostate, having undergone removal of the right testicle for a nodule, and having a small left testicle, became impotent, and obtained relief from all his urinary symptoms. Rectal examination showed "marked diminution in the size of the prostate."

THE MEDICAL NEWS, Philadelphia, December 30, 1893. Dr. Francis L. Haynes, of Los Angeles, California, announced his first operation; this was followed by two others.

In the *Buffalo Medical and Surgical Journal* March, 1894, he thus describes his cases :[1]

Following the suggestion of Prof. White, of Philadelphia, I have three times made double castrations in old men afflicted with prostatic hypertrophy.

1. Operation eighty-four days ago, in a case of two-years' standing, of moderate severity. The patient is practically cured.

2. Operation forty-seven days ago, in a desperate case, requiring catheterization every two hours, complicated by intense cystitis and by morphinism acquired as a result of frightful suffering. With the most devoted nursing this old man has improved wonderfully. Cystitis has disappeared; one third of the urine is passed spontaneously; the catheter is used about every four or five hours; morphinism has been cured; general condition good.

3. Operation fourteen days ago. Incipient case; catheterization was almost impossible because of the peculiar development of the prostate.

In a fourth case section of the vas deferens gave no definite results.

During Christmas week, 1893, I saw in consultation with Dr. F. Fremont Smith, at St. Augustine, Florida, an apparently hopeless case of hypertrophied prostate with marked sepsis, cystitis, beginning uremia, etc. I advised a trial of castration, as the condition forbade any direct attack upon the prostate. Dr. Fremont-Smith has just reported the case in a paper read before the Genito-Urinary Section of the New York Academy of Medicine. The patient fifteen weeks after operation had gained forty-five pounds, and had no symptoms of cystitis or other urinary trouble. He urinated freely and normally.

On January 31, 1894, I operated on a medical man sixty-nine years of age, who had a very large prostate, about half the size of an orange; who had passed no urine except by catheter for years, whose urine was loaded with mucus, was offensive, and at short intervals was profusely mixed with blood. At the present time, fourteen weeks later, while he has not yet urinated spontaneously, rectal examination shows a reduction in the size of the prostate to about normal dimensions. It was formerly necessary to introduce the catheter for nine and a half inches before reaching the bladder; it now goes in only eight inches when the urine begins to flow. Its introduction is easy and painless, instead of difficult and very painful. No blood has appeared in the urine for two months. The urine itself is entirely normal in appearance, odor, and in all other respects.

I have during this time suggested the operation to three other patients, all of whom have declined it on account of my frank statement that it was yet in the experimental stage and that no *promise* of benefit could be given.

The idea of castration for the relief of prostatic enlargement seems to have occurred vaguely to several persons, but certainly no one had made it public or even formulated any distinct suggestion in regard to the matter prior to my paper.

Ramm's cases, though not published until between three and four months after my paper, appear to give him the operative priority in Europe, while Haynes undoubtedly did the first operation of the kind in this country.

This, so far as I know, is the evidence existing on this subject up to this date. It would certainly seem to establish the claim of the operation to further and much more extended trial, and it shows, I think, that even on a basis of experiment and theory alone I was justified in suggesting it to the profession.

MEDICAL PROGRESS.

The Influence of Various Organic Matters upon the Bodily Temperature.—Roger (*Archives de Physiologie Normale et Pathologique*, 5e sér., t. vi, No. 2, p. 246) has experimentally determined that extracts of muscle contain thermogenic substances, although it could not be established whether these preëxisted in the tissues or were developed as a result of the manipulations employed. The total arterial blood, as a rule, induced a slight antithermic effect, although sometimes it displayed a thermogenic action, viz., when obtained from a sick animal, or from one exposed to cold; in the latter case, the effect disappeared when the animal was placed for twenty-four hours in a warm medium, or if a previous bleeding of about one-fourteenth of the total volume of blood had been practised. It was found that defibrinated blood, the serum, pleuritic exudates, and hydrocele-fluid induced elevation of temperature, sometimes preceded by a slight depression. Urine determined first a hypothermia, and secondarily a hyperthermia; the secondary effect was the more marked in proportion as the subject that furnished the urine had indulged in muscular exercise.

The Functional Activity of the Stomach after Resection of the Pylorus.—From personal observation, together with a study of the literature, Imredy (*Wiener medizin. Presse*, 1894, No. 13, p. 481) maintains that the dilated stomach may resume its normal proportions after the causative obstruction has been removed. This result takes place the more rapidly the shorter the duration of the dilatation. If in the resection a portion of the pylorus is permitted to remain this portion assumes the function of the whole, so that the stomach is as securely shut off from the intestine as it was before the operation. The motor function of the stomach also returns to the normal. Resorption and secretion take place with their previous activity, except in cases in which the resection was undertaken for carcinoma.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 2, 1894.

THE THIRD TRIENNIAL CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THIS issue of THE NEWS is given up almost exclusively to the proceedings of the Third Triennial Congress of American Physicians and Surgeons, held at Washington, D. C., from May 29th to June 1st. During the short period of its existence this body has become one of the most important (from a scientific point of view *the* most important) in this country. Made up, as it is, of national societies representing all departments of medicine and of the highest grade of membership, the work of the Congress and of its constituent elements stands for what is best in scientific medicine in this country, and this work will compare favorably with that of any other body in any part of the world. The arrangements for this Congress and for future Congresses differ somewhat from those of the first two meetings. Instead of having the general sessions entirely independent and apart from the meetings of the various constituent bodies, it has been decided to assign three afternoons and one evening in sessions of an hour and a half each to seven of the fourteen participating organizations, and each society selected prepares its own program and selects its own speakers. The selection is made alphabetically, and the general sessions of the meeting just ended were in the hands of the following societies: Anatomists, Climatologists, Dermatologists, Genito-urinary Surgeons, Gynecologists, Laryngologists, Neurologists. The remaining seven societies are in like manner to prepare programs for the Fourth Congress. As far as the reports thus far received indicate, and judging from the arrangements made and programs prepared, the work of the Congress will amply sustain the high standard which it has established.

As usual, THE NEWS has taken special pains to give the fullest and most trustworthy reports of the Congress, made by its special staff of reporters. It is besides a source of gratification that THE NEWS has been chosen as the medium of a wider communication of a number of valuable papers to the general profession, synchronously with their presentation to the Congress. Others are to follow as soon as the exigencies of our space will permit.

SOCIETY PROCEEDINGS.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Third Triennial Meeting, held at Washington, D. C., May 29, 30, and 31, and June 1, 1894.

[Specially reported for THE MEDICAL NEWS.]

FIRST DAY—MAY 29TH.

THE Congress was opened with a brief address by Dr. LANDON CARTER GRAY, of New York, Chairman of the Executive Committee. Dr. Gray then introduced the President of the Congress, DR. ALFRED L. LOOMIS, of New York, who in a few remarks thanked the Congress for the honor that it had conferred upon him by electing him to the Presidency, but as the time allotted to the session was so short, he refrained from making any extensive address.

This session was under the direction of the Association of American Anatomists, and the subject selected for consideration was "Morphology as a Factor in the Study of Disease."

The discussion was opened by DR. HARRISON ALLEN, of Philadelphia, whose paper appears in the present issue of THE NEWS. (See page 589.)

DR. THOMAS DWIGHT, of Boston, said that Dr. Allen defines morphology as anatomy writ large. The underlying idea of his paper is to plead for a longer, broader, deeper course in anatomy. The tendinous heart-strings of every anatomist will vibrate in sympathy, producing a chorus of musical murmurs. Perchance, in some, one of the factors will be the moderator band of the ruminant, which has left its normal place near the apex of the human heart to cross near the middle of the right ventricle. The expert auscultator can recognize this cord. It is good for his patient that he should know from anatomy that such a band may be present and that its sound is no sign of even functional disturbance. The ophthalmologist is none the worse that embryology

teaches him the whereabouts of the hyaloid artery, which may persist throughout life. Anomalies, therefore, as well as slighter variations are of practical importance. The surgeon needs to know of the fibrous or muscular band which may cross the axillary artery, that the brachial artery may divide high up the arm (very rarely in the lower third), and that the diverging artery, be it radial or ulnar, almost always runs superficially. A third trochanter, which seems much larger than it is when felt through the soft parts, must not be mistaken for an exostosis, nor a deltoid tubercle of the clavicle for an old fracture.

Before removing a kidney the surgeon will do well to be sure that it is not the only one. I have myself within a few months seen a case of complete absence of one kidney, the other being of about the usual size and in its proper place.

But it is not necessary to turn to anomalies to support the need of a deeper knowledge of anatomy for the practitioner. The statics and mechanics of the skeleton and the action of the muscles are becoming daily more important to the orthopedic surgeon and to the neurologist.

The anatomy of childhood is still almost in its infancy. Though not quite helpless, it has not yet made its way into text-books, but hides itself bashfully in scattered papers and monographs. A more thorough knowledge would be of great value to the practitioner in children's diseases. How interesting and how practical, in view of infant-feeding, is the story of the rate of growth of the stomach in the first months of life, and how few know it.

My views of the esteem in which anatomy is held are far less pessimistic than Dr. Allen's. It is but too true that we have many in high places absolutely ignorant themselves of anatomy, who look on its progress with a jealous aversion; but they are mostly on the wrong side of fifty and they belong to a school of thought that is doomed. On the other hand, I look with confidence to the rising lights. I see in the better class of our young practitioners a great respect for anatomy. They have a clearer vision of its sphere. One of the most gratifying incidents of my professional life is the constantly increasing number of those who come to me for information on anatomic problems or for the means of solving them.

Surely, from what I have said I shall not be suspected of indifference to the cause if I do not quite agree with Dr. Allen as to the remedy. He would have students thoroughly instructed in the highest anatomy before graduation. I reply that there is no time. As a practitioner myself of twenty-five years' standing I am appalled at the amount of knowledge of all kinds which is now necessary for the simplest practice of the profession by anyone who would not fall behind his colleagues. I heartily agree with Huxley's saying that any one who adds one tittle that is unnecessary to medical education is guilty of a very grave offence. I would leave the matter to the good judgment and tact of the professor of anatomy. While his teaching should be eminently practical in the ordinary sense of the word, I would have him incidentally point out the explanations of structures from comparative anatomy and embryology, and still more insist upon the application of morphology to disease. But I would have these things pointed out rather than pursued. I would have him show the possibilities of anatomy, which, unfortunately, are impossibilities in the regular course. Thus he will enlarge the student's horizon. It is not necessary to have followed a certain line of research to know that it gives promise of great results. The mind of a student so trained will be in a very different state from that of his comrade who has been crammed with facts from a compendium. Advanced students and graduates are those to whom the highest anatomy will be most profitable, and the more so that they can see for themselves its value, which the beginner must take on trust.

DR. FRANK BAKER, of Georgetown, D. C., said that the study of the human organism, of its structure, its functions, its diseases, of the effects that various agents have upon it, therapeutically and otherwise, must necessarily be a study of life and its manifestations; it is a biologic science. The study of morphology as a preliminary to the study of disease is a necessity. The great impulse given to the study of anatomy by Vesalius and his followers in the sixteenth century has not yet exhausted itself. The error in the Vesalian anatomy, which has prevailed up to the present time, consists in considering the body as an essentially fixed organism. From this view arises the notion that anatomy is a fixed science, but even a cursory view of the history of the science shows this assumption to be baseless. To the modern biologist the human body is by no means fixed and invariable.

The human body has been studied far more than any other organic form. There is no lack of knowledge of details, but for the ordinary student these details are not classified and arranged as the results and sequences of morphologic laws. It may even be said that inflammation itself cannot be properly understood without a knowledge of the morphologic character of the tissues involved. The whole subject of tumors has, since the investigations of Virchow, been studied from a morphologic standpoint, and it has become evident that in order to understand their causes and their history, we must know more about the laws that control cell-formation and the growth of tissues.

The human body is built up of cells, and the gross variations in form must depend upon these minute cell-activities. These variations may be of all grades. The morphologist studies them as indicating slow modifications of the form of the human body. It is well known that the body of man is slowly changing, that adaptations are going on within it, slowly fitting it more and more to its environment. In this process there are constantly left structures that have ceased to be of value, and may properly be termed vestigial. Among such may be noted the vermiform appendix, Meckel's diverticulum, the thyroglossal duct, hypospadias, and the persistence of the choroidal fissure of the eye, producing coloboma.

The erect position of the human body was gradually acquired, and in many respects the body has not yet become perfectly adapted to this posture. The shape of the pelvis has necessarily become modified that it may support the weight of the viscera, yet with all this that weight is often a cause of hernia. As a result of these changes the pelvis of civilized woman is less adapted for easy parturition than that of her savage

grandmother of the stone age. Many of the abdominal viscera show signs of maladaptation. The cecum and ascending colon are not favorably situated. The liver, instead of being supported from the spine, is slung from the diaphragm, which, to support the weight, must receive strong connections from the pericardium and the fascia that supports the heart. This arrangement must interfere with the growth and expansion of the lungs. The heart itself works at great mechanical disadvantage. The valves of the veins are not adapted to the erect posture.

As the science progresses there is no doubt that many important generalizations will be made. Some already seem almost ready for statement. Among these is to be mentioned what may be called the law of stability. It is this, that the stability of a structure varies directly according to the time it has been functionally active in the ascending series of animal life. The structures most readily attacked by disease are those at either end of the scale of activity. The originally elementary tissues, epithelium and connective tissue, are the most stable, their derivations, nerve-tissue, muscle-tissue, glandular tissue, are the least stable.

Morphology is throwing light upon a vast variety of subjects connected with the domain of medicine, not only upon the causes of disease, but upon the action of cells, the problems of therapeutics, the very springs of life that underlie heredity, development, training, and education. It is a growing science, one that is destined to a great future, promising much for the elucidation of the highest problems of medicine.

DR. BURT G. WILDER, of Ithaca, N. Y., who regretted that he had been unable to prepare a formal paper, expressed his agreement with the statement of Dr. Baker that the human body is not to be regarded as a completed structure. It is by no means completed. The physician should consider very seriously whether it is not his duty to improve the human body in the direction in which it has been moving, namely by the obliteration of that most frequent source of trouble, the appendix of the intestine. It is the unanimous consensus of opinion among surgeons that the removal of the appendix, if not gangrenous, presents no great likelihood of mortality. It is now four years since Dr. Wilder proposed that we should not only practise vaccination, but also de-appendicize the child at a period of life when time was not very valuable, and thus improve his chances of existence.

Dr. Dwight has alluded to the impossibility of putting more in the curriculum of the schools, and with this Dr. Wilder thoroughly agreed. He held that there should be more morphology taught in the preliminary school-education, and he predicted that it would not be many years before most children, prior to leaving the ordinary college, will know as much anatomy, physiology, and morphology, in the broad sense, as is now possible to be obtained by the average physician.

(Continued on page 613.)

Cholera in Russian Poland.—It is reported by cable that cholera is raging in the districts of Plock, Radom, and Petrokoff, in Russian Poland. As a precaution against the importation of cholera an order has been issued to compel all Russians entering Prussia to come *via* Illowo, where the strictest sanitary regulations are enforced.

AMERICAN SURGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at Washington, D. C., May 29, 30, and 31, and June 1, 1894.

FIRST DAY—MAY 29TH.

THE Association was called to order by the President, DR. J. EWING MEARS, of Philadelphia, who delivered the President's Address.

In this he considered matters of interest to the Fellows of the Association referring to the previous work of the Association, and the methods of best carrying on the work of the society.

The Secretary, DR. J. R. WEIST, presented for the President to the Association a gavel, which had been made from a portion of the office-chair of Professor S. D. Gross, the founder of the Association. This was accepted, with the thanks of the Association.

The first paper was one entitled "The Surgical Treatment of Empyema," by Dr. JOHN ASHHURST, JR., of Philadelphia.

The following summary was presented:

1. No operation is justifiable unless the presence of pus is certain; unless thorough treatment by medicinal agents, blisters, etc., has failed; or unless the symptoms, dyspnea, etc., are so urgent as to demand immediate relief.

2. The first operation should consist of simple aspiration, with antiseptic precautions.

3. When the fluid has partially reaccumulated, as it almost certainly will do, if purulent, incision and drainage should be practised.

4. Drainage is best effected by making two openings, one at the lowest point, and carrying a large drainage-tube through the cavity from one opening to the other.

5. Drainage should be supplemented by washing out the cavity with mild antiseptic fluids; when the lung has expanded and the discharge has nearly ceased, the tube should be shortened, the upper opening being allowed to heal, and the tube then being gradually withdrawn through the lower opening.

6. When the lung is so bound down by adhesions that it cannot expand, resection of two or more ribs should be practised (Estlander's operation, so called) in order to allow collapse of the chest-wall and to promote healing by bringing the costal and visceral layers of the pleura into contact.

7. The more extensive operations of Schede and Tillmans, while probably justifiable in exceptional cases, are not to be recommended for general employment.

DR. CHARLES B. NANCREDE, of Ann Arbor, did not see the advisability, in cases in which pus was shown to be present by aspiration, of limiting the treatment to this operation. It is held that in a few cases this will be followed by cure, but he had never seen such a case. When pus is present he preferred to immediately provide for its permanent evacuation. He called attention to the danger of the drainage-tube becoming occluded by the pressure of the ribs, and he believed that in empyema of long standing some form of excision of the ribs should be employed.

In irrigation, if the pus is not too much contaminated, sterilized water is sufficient, but if necessary an efficient antiseptic solution may be used, and if there is fear of

absorption, the chest can afterward be flushed with sterilized water.

If provision is made for the free escape of pus, he had seen no necessity for the removal of large segments of ribs.

DR. T. F. PREWITT, of St. Louis, thought that the rule that no operation is justifiable unless the presence of pus is certain needed modification. As a rule, we can determine only that fluid is present, and cannot be sure whether it is or is not pus. He thought it advisable to aspirate even when serous fluid is present. If thorough antisepsis is maintained this can do no harm. He had never seen it result in the formation of pus, and this method greatly shortens the duration of the disease. In empyema in children he had seen several recoveries follow aspiration, but never in adults. In children the pus does not seem to possess that thick, clotting character so common in adults, and which requires a free opening. In empyema in adults he invariably resects a rib, sometimes two ribs.

Attention was called to the great necessity of caution in the administration of anesthetics in this affection.

As to washing out the cavity, he always does that, using a weak solution of mercuric chlorid.

DR. DEFOREST WILLARD, of Philadelphia, said that the whole question was one of thorough drainage of an abscess-cavity. Whether or not the ribs should be excised is to be determined by the question of securing free drainage. In children the ribs are so close together that removal of a portion of a rib is usually required.

In the early treatment he favored the use of a clean aspirator, rather than to compel Nature to cause the absorption of a large quantity of fluid. Such an operation does no harm, and saves several weeks in time.

He believed that washing, as a routine measure, did more harm than good. If the pus is decomposing, freer drainage is needed. If strong antiseptic solutions are employed there is danger of renewed inflammation.

DR. JOHN E. OWENS, of Chicago, called attention to the necessity, in evacuating pus from the chest or washing out the pleural cavity, of changing the position of the patient during the process, in order that all the pus may be removed.

DR. CHRISTIAN FENGER, of Chicago, held that there are certain cases in which Schede's operation is required, viz., after milder measures, such as incision, drainage, and Estlander's operation have been fruitlessly employed. He reported a successful case, in which this operation was performed after other measures had been unsuccessfully resorted to during seven years.

DR. ROSWELL PARK, of Buffalo, thought that the treatment of empyema should be based upon the same principles as are applicable to other abscesses. In acute cases presenting streptococcus and staphylococcus forms of suppuration, it may be sufficient in a few instances to simply aspirate. A large proportion of cases of empyema, however, are essentially cold abscesses, tuberculous abscesses. In these free incision, free drainage, and excision of a rib are required. In certain cases he had resorted to scraping with the sharp spoon, and in some he had cauterized the diseased surface with a 50 per cent. solution of zinc chlorid. He reported several cases in which death would have occurred had it not been for some such radical operation.

DR. W. H. CARMALT, of New Haven, asked how far it was justifiable to go in the way of resection of ribs in these cases. He reported a recent case in which he had removed portions of five ribs, the longest piece exsected being four and a half inches. In such cases it is necessary to remove enough of the chest-wall to permit of obliteration of the cavity. He had also used the sharp spoon in order to secure a fresh surface.

DR. M. H. RICHARDSON, of Boston, said that the questions that arose in the treatment of empyema were different from those in ordinary abscess, for in the former condition we have an abscess with rigid walls. With regard to drainage, he had used double tubes provided with valves, but considered them inapplicable, and liable to cause increased trouble, for when air or pus is forced out through the tubes by coughing, a vacuum is established, and the valve is held against the chest-wall, preventing drainage. He believed that Estlander's operation is applicable only to certain forms of cavity, and that there are certain cases in which the cavity involves a large portion of the thorax, and the operation of Schede is the only one applicable after a failure of Estlander's operation.

DR. STEPHEN F. WEEKS, of Portland, Me., thought that the rule of Dr. Ashhurst, to aspirate, especially in children, was a good one. Sometimes aspiration alone will result in cure. The tuberculous cavity is to be treated differently than the cavity in which tuberculosis does not exist. Thorough drainage is sufficient in many cases. He called especial attention to drainage by packing the cavity with sterilized gauze. In twenty-four hours he removes the gauze and washes out the cavity.

DR. L. MCLANE TIFFANY, of Baltimore, maintained that the treatment of acute empyema is of more importance than that of the chronic form, as it is the more common. The most important point, as bearing upon treatment and prognosis, is the character of the pus and its bacterial cause. The reason that the empyema of children often yields to aspiration is that in many of these cases the pus is simply a pure culture of the pneumonia-coccus. In the adult we rarely have the pneumonia-coccus form of suppuration. Here we have a mixed infection. If the empyema is of the amebic form the patient dies. If empyema is due to the streptococcus, the odor is offensive and the cavity needs to be carefully washed out. If empyema is due to the staphylococcus, washing out is not required. When there is time, Dr. Tiffany prefers to withdraw some of the fluid with the hypodermatic syringe and have it submitted to bacteriologic examination.

While he uses ether in general work, in these cases he prefers the use of a few whiffs of chloroform, which appears here to have a peculiarly happy effect. Only a very small quantity is employed.

The employment of respiratory gymnastics is of much benefit in favoring expansion of the contracted lung.

DR. JAMES MCFADDEN GASTON, of Atlanta, referred to the natural tendency for the empyemic cavity to open spontaneously in the anterior part of the chest. He reported two cases in which this spontaneous opening had occurred and was followed by recovery.

DR. W. W. KEEN, of Philadelphia, read a paper entitled "Amputation of the Entire Upper Extremity (Including the Scapula and Clavicle), and of the Arm at

the Shoulder-joint; with Especial Reference to Methods of Controlling Hemorrhage; with the Report of One Case of the Former and Four of the Latter."

He considered, first, those amputations that allow of simple disarticulation at the shoulder joint itself; second, those cases in which the axilla is invaded, yet only to such an extent as to allow of its being thoroughly cleaned out, followed by amputation at the shoulder; and thirdly, those in which removal of the entire upper extremity, including the scapula and clavicle, is required.

Simple amputation at the shoulder-joint. Here the control of hemorrhage is the key to the situation. The methods for the prevention of hemorrhage are, first, those applicable to the subclavian vessels, and, secondly, those applicable to the axillary. Most text-books recommend compression of the subclavian by the thumb, or a well-padded key. Dr. Allis has modified this method by substituting a stick, eighteen inches in length, with a pad of sterilized gauze at its extremity. This obviates the danger of slipping, and can be applied without fatigue on the part of the operator. Dr. Keen has suggested compression by means of a solid pad held in position by an Esmarch bandage passing over the perineum, but on trial in the case of a child this had proved unsatisfactory. A third plan consists in ligation of the subclavian artery. This is objectionable on account of the prolongation of the operation; also on account of the necessity of resecting the clavicle in order to ligate the vein, and if the vein is not ligated there is danger of the entrance of air.

Axillary methods. 1. Those in use prior to the introduction of Esmarch's tubing. 2. Different methods of using Esmarch's tubing Under the first head we have: (*a*) compression of the inferior flap by the fingers, which seize the vessels before they are cut; (*b*) Harvey's method, by compression of the vessels by means of a padded ruler thrust into the axilla; (*c*) ligation or seizure of the vessels with hemostatic forceps before they are cut; (*d*) Gross' compressor, but practically this is never used; (*e*) Furneaux Jordan's method, by making a circular amputation at the surgical neck, securing the vessels as in a hip-joint amputation, the bloodvessels having been compressed by an Esmarch band or other method, followed by disarticulation of the upper end of the humerus.

Under the second head are: (*a*) After making the antero-external flap, a stout pin is passed through the postero-internal flap, between the vessels and the bone, and elastic tubing is wound over the ends of the pin. In this method there is danger of the vessels retracting above the constricting band; (*b*) Esmarch's method, in which an elastic tube is placed in the axilla and drawn tightly over the shoulder, where it is grasped by the hand of an assistant. This is open to the danger of slipping of the bandage after disarticulation of the bone; (*c*) Morre's method. In this method the tubing is applied as in the Esmarch method, but is held in place by a bandage passing around the chest and under the tubing in front and behind; (*d*) Wyeth's method by pins and elastic tubing. In this method the operation is performed as follows: The arm is held at a right angle to the body. The sharp-pointed cylindrical pins, eleven inches long and one-fourth of an inch in diameter, are used. The anterior pin is introduced through the middle of the anterior axillary fold at a point a little nearer the body than what may be called the center of the fold transversely. The point of emergence is of much greater importance than the point of insertion; this should be one inch within the tip of the acromion. The second pin is introduced at a corresponding point, through the posterior axillary fold, emerging an inch within the tip of the acromion. The point of emergence is of importance, for if the pin emerges near or at the tip of the acromion, the moment the head of the humerus is removed the tubing is likely to slip downward and compress the two flaps against each other, thus hiding the cavity and permitting the vessels to retract. The pins being in position, a piece of rubber tubing is wound around the axilla and shoulder on the hither side of the pins. The disarticulation having been effected, the main vessels and all visible vessels are tied and the tubing removed the spurting vessels being grasped with hemostatic forceps. Dr. Keen considers this the most satisfactory method of controlling hemorrhage, and he felt confident that anyone who adopted it would abandon all other methods in its favor, except possibly in emergency cases.

Amputation at the shoulder-joint in cases in which the axilla is invaded so high that Wyeth's pins cannot be used. In 1812, Delpech proposed to make "an oblique incision extending from the external third of the clavicle to an inch above the inferior border of the great pectoral muscle. We thus discover and can cut near to its origin on the coracoid process of the scapula, the lesser pectoral. The index finger is carried through the cellular tissue, along the serratus magnus, then the subscapular, and it is used as a hook in order to draw outward the mass of vessels and nerves. The artery is found in the anterior portion of this mass." The artery and vein are then ligated. The advantages of this method are that it gives wide access to the axilla, that we can determine with ease how far and how great is the invasion of the axilla, and, if thought advisable, the operation can be abandoned at this point; or if it is decided to proceed with the operation, the incision already made serves as the inner part of the deltoid incision. Dr. Keen has employed this method with great satisfaction in a case in which a sarcoma of great size had invaded the axilla nearly to the clavicle.

Control of hemorrhage in cases in which it is necessary to remove the arm, the scapula and the clavicle. The methods that have been employed in these cases have been (1) simple compression of the subclavian artery; (2) compression of the artery after resection of the clavicle; (3) ligation of the subclavian prior to beginning the amputation; (4) resection of the middle half of the clavicle and ligation of the subclavian; (5) Wyeth first tied the artery, then formed his flaps, and, when the arm, clavicle, and scapula were connected with the trunk by only the veins and nerves, secured the veins and cut the nerves; (6) the artery and vein have both been tied after resection of the middle portion of the clavicle. The last seems to be by far the preferable method. Its advantages are that it prevents hemorrhage from division of the axillary and its branches, it diminishes the amount of blood lost during the operation, it prevents the entrance of air into the veins, it permits of a large opening of the space between the upper extremity and

the chest, and it enables us to divide the posterior attachments of the upper extremity, where the arterial circulation is still going on, at the end of the operation.

As a rule, recovery from this operation follows in from two to three weeks. The mortality in the more recent operations has been extremely low, one in fourteen. Again, by this method we can often amputate wide of the disease, by reason of the relative smallness of the flaps required. In view of these facts it was urged that in all cases of malignant disease of the upper extremity of the humerus, or even of the lower extremity when it is already diffused, we should not content ourselves with mere amputation at the shoulder-joint, but should at the same time extirpate the scapula and the clavicle.

Dr. Keen reported the case of a woman, aged twenty years, in which the arm, scapula, and clavicle were removed for myeloid sarcoma. The patient recovered, and was perfectly well six months after the operation.

Dr. Roswell Park, of Buffalo, said that he had in two cases successfully removed the entire upper extremity, in one for railroad injury, and in the other for extensive epitheliomatous ulcer. In the first case the clavicle was already broken, and the subclavian vessels were secured at the point of fracture. In the second case the clavicle was divided and the vessels tied.

Dr. Charles B. Porter, of Boston, in illustration of the rapidity with which malignant disease may advance, reported the case of a patient with sarcoma of the radius, whose arm was amputated above the elbow. The disease soon recurred, an amputation at the shoulder-joint was performed, and again the disease recurred, but so high up that no operation could be undertaken. The whole history of the case extended over only one year after the first operation. A case was also reported in which the arm had been torn off in a railroad accident and the scapula and outer portion of the clavicle had been subsequently removed by an osteoplastic resection, and the wound was closed with skin-grafts. Three months later a hard plate of bone had formed very similar in shape to the scapula.

Dr. John Ashhurst, Jr., of Philadelphia, said that he had once used the Wyeth pins satisfactorily in an amputation at the shoulder-joint. Another device to which he had resorted in several cases was to make the incision in the lower flap from without inward and secure the vessels in the wound.

ASSOCIATION OF AMERICAN PHYSICIANS.

Ninth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

First Day—May 29th.

Dr. Reginald H. Fitz, of Boston, delivered the President's Address, taking for his subject the "Rise and Fall of the Licensed Physician in Massachusetts, 1781–1860." He pointed out that the first legislation concerning the regulation of medical practice in Massachusetts was enacted at Boston on May 3, 1649, than which there was none more stringent until the years immediately preceding the war of the Revolution.

In 1760 the city of New York had found it necessary to regulate the practice of medicine within its limits on account of the abundance of quacks preying upon the community. Five years later the Medical School of the University of Pennsylvania was established, and in the following year the New Jersey Medical Society was founded. In still another year the Medical School of Columbia College began its career; and in 1771 the colony of New Jersey passed its act regulating the practice of medicine, to be followed in 1774 by the abortive attempt in Connecticut.

The Massachusetts Medical Society was organized in 1781 with the express purpose of making a just discrimination between duly educated and properly qualified practitioners and those who ignorantly and wickedly administer medicine. For many years its Fellows acted most judiciously in endeavoring to include within their number every educated and moral practitioner in the State. They accomplished this largely by the force of example, association, and united encouragement. The State made them the sole source of licenses to practise. The progress of Thomsonianism left their responsibilities essentially intact. The advent of homeopathy found them weak where they should have been strong, short-sighted where they should have been far-seeing. The leaders were obliged to follow, and the reproval of the Censors prevailed against the wisdom of the Councillors.

Homeopathic diplomas and homeopathic certificates are now accepted by the Society. Homeopathic physicians have been found fitted to practise by the great public, which decides this question for all. Ten years of increasing intolerance destroyed seventy years of enthusiastic effort, devoted labor, tactful management, and wise council in the public interest. The State revoked the control of medical practice, and the people have been the sufferers. The history of Massachusetts in this respect is the history of the country. She was one of the last of the States to lay down the control, and she will be one of the last to resume it.

Dr. Beverley Robinson, of New York, read a paper on the "Treatment of Certain Symptoms of Croupous Pneumonia, particularly in Adults." He laid special stress upon the management of two symptoms of the first stage of the disease, namely, pyrexia and pulmonary congestion. He does not use the modern antipyretics, except in special cases. Phenacetin he regards as the best of these, for the reason that in addition to its antipyretic action it also induces sleep. The spirit of mindererus, potassium citrate, and magnesium sulphate he uses largely. Quinin, in doses of from 2 to 4 grains every three hours, is antipyretic. Cold sponging and cool baths are not especially efficacious; if the temperature of the patient is over 104°, and the pulse is rapid and delirium is present, a tub-bath may be advantageously employed. He has seen bad results, however, following immersion in a tub-bath; sponging, with friction, is preferable. The advantage of the bed-bath is the avoidance of shock and exposure, and the ease with which it can be given. The bath should last from fifteen to thirty minutes, and is to be repeated whenever the temperature is over 103°; prompt relief follows, the temperature falling to 100°

Aconite and aconitin act by diminishing the heart's action through its motor ganglia. The heart is slowed in a very alarming manner, and may be arrested in

diastole; gr. $\frac{1}{150}$ of aconitin may produce serious results; hence he does not believe in its use. The administration of small and repeated doses of antimony oxysulphuret, gr. $\frac{1}{32}$ every hour or two hours, is much superior to the use of aconite. It renders the sputum more fluid, and therefore easier of expectoration, and in this way diminishes the dyspnea. It is also well borne by the aged and by children. It may be used in both the first and second stages of the disease. Nitroglycerin, by the mouth, or better, hypodermatically, in doses of gr. $\frac{1}{50}$ or $\frac{1}{25}$, is an excellent remedy in this disease. It strengthens the weak pulse, removes the cyanosis, and relieves the dyspnea. Inhalations of oxygen in pneumonia usually give relief, but in some instances the dyspnea is increased by its use. Especially in cases of general edema have unfavorable results been noted. In failure of the right heart inhalations are, according to some authorities, of marked service, though the subject is still open for discussion. The abundant use of cold spring-water, Apollinaris, and other table-waters is of service in promoting diuresis and diaphoresis, and in this way reducing the abnormal temperature of the body. Alcohol is beneficial in many cases, not only on account of its nutritive value, but also because it aids the respiratory function. It also gives nerve-force, controlling the adynamia and nervousness. There are only two contra-indications to its employment, namely, when the patient is plethoric, and when there is hepatic engorgement and gastric catarrh. In these cases, small and repeated doses of calomel will act in the most beneficial manner. Digitalis or digitalin in small doses may be given to control an irregular heart; otherwise either is not to be used, on account of inducing vascular contraction. Strychnin by the mouth or hypodermatically, from gr. $\frac{1}{30}$ to $\frac{1}{15}$, is a very useful drug; at times, however, it may produce nervous irritability. Nitroglycerin acts by bleeding from the veins into the arteries, in this way taking the place of the old method of bleeding, which was often followed by excellent temporary results. In cases of threatened heart-clot, venesection, followed injections of salt-solution, may yield excellent results. Black coffee is of service when other remedies cannot be borne by the stomach, and may tide the patient over. Caffein does not replace the use of coffee for the reason that it is merely an alkaloid, and does not possess the nutritive value of the coffee.

DR. PEABODY, of New York, remarked that pain, with insomnia and cough, is an urgent symptom of croupous pneumonia, that could be controlled by the use of small doses of morphin hypodermatically, as gr. $\frac{1}{6}$, repeated once or twice during the night. He objects to the too frequent use of water in reducing the temperature. He has very rarely found heart-clot as a pathologic feature in this disease, and believes that many of the so-called cases of ante-mortem clot are in fact but post-mortem clots.

DR. J. C. WILSON, of Philadelphia, believed that, owing to the varied clinical manifestations of pneumonia, the treatment must be largely expectant and symptomatic. Cold baths have not been satisfactory in his hands. Local applications of cold to the chest have been advantageous in many cases. In sthenic cases, with delirium and other nervous manifestations, cold affusions of from one-half to one gallon of cold water, poured over the head and shoulders, will often act as the turning-point in the disease. Venesection proves beneficial in many cases of pneumonia by attenuating the toxemia and removing from the blood a quantity of effete material. He indorses the use of small amounts of opium, as, *e. g.*, gr. ij or iij of Dover's powder, from every two to four hours.

In concluding the discussion DR. ROBINSON remarked that the purpose of his paper had been to oppose the treatment of the disease by the use of the so-called "Trinity" pill or its modifications, and also to direct attention to the fact that drugs are often used without a full knowledge of their constitution or why they are used.

DR. SAMUEL A. FISK, of Denver, Colorado, presented a paper entitled "A Treatment of Typhoid Fever." He stated that the mortality of typhoid fever in Denver was much smaller than in other large cities. His treatment, he claimed, was attended with a shorter duration of the disease, and with marked amelioration in the symptoms, as proved by the comparative chart which he offered for examination. He believed that the average case of typhoid fever in Denver was milder than the average case in the East. During his treatment the patient had no tympanites, no dry tongue, no marked delirium, and but slight nervous manifestations. The treatment consists in absolute rest. If the patient is seen early in the disease one dose of calomel, gr. v, is given at night, followed in the morning by a saline. The diet is restricted to milk, of which a tumblerful is given every three hours. If the patient cannot take simple milk the fluid is peptonized, or buttermilk is given. He administers a turpentine mixture composed as follows: Oil of turpentine, f℥ij; castor-oil, f℥ij; bismuth subnitrate, ℥iv; and mucilage of acacia, a sufficient quantity. With this he maintains a moist tongue and stimulates the bowels. For the restlessness he gives a Dover's powder, gr. v, or McMunn's elixir of opium, ♏x. Water or ice is given freely. Antipyretics, including quinin, are absolutely interdicted. Whiskey is always given. Strophanthus is preferred as a heart-stimulant. Brand's cold baths are never used, and tepid sponging is not often employed.

DR. C. F. FOLSOM, of Boston, thought that the number of cases reported by Dr. Fisk was too small to generalize from. He believed that the cases included in the series were mild ones, and doubted whether the medicine had much influence upon the result.

DR. WILLIAM OSLER also thought that the treatment had had no influence upon the disease, and that the patients, evidently suffering from but a slight attack of the disease, needed no medicine, but would have recovered on the cold water treatment and good nursing.

DR. C. F. FOLSOM, of Boston, reported "Six Cases of Traumatic Headache," all relieved by the operation of trephining, the dura, however, not being opened. The patients were all affected with grave neuralgic pains centering in a lesion of the scalp, and associated with alterations in disposition, and in some instances with epileptic seizures.

DR. FREDERICK P. HENRY, of Philadelphia, made a "Clinical Report of Two Typical Cases of Raynaud's Disease." In one, hemoglobinuria was present; and in the second, scleroderma. He believes that neither endar-

teritis obliterans nor peripheral neuritis should be regarded as an etiologic factor in the production of the disease. The theory of arteriospasm is most probably correct, and especially does he believe this, as the disease is most common in women and girls, in whom vascular spasm is most common. The hemoglobinuria is due probably to the excretion by the kidneys of hemoglobin that has exuded in the asphyxiated parts. Hemoglobinemia often exists without the coëxistence of hemoglobinuria. The relationship between Raynaud's disease and chilblains has recently been studied, and the query has been raised whether the two are not different stages of a single necropathic dyscrasia.

Dr. Harold C. Ernst, of Boston, read a paper entitled "Dr. S. C. Martin's Researches on the Bacteria of Vaccinia." He stated that the late Dr. Martin had, by the use of a simple solution of fuchsin as a staining-reagent, discovered in the serum of cowpox a coccus and a bacterium. These two forms he demonstrated to be but different stages in the development of the same germ. Two inoculations made by Dr. Williams, of Roxbury, showed that from the pure culture in blood-serum, typical vaccinal effects were obtained in one case, and the successes with culture-inoculations in calves were numerous.

Dr. W. H. Welch, of Baltimore, spoke of the negative results obtained by others, and the extreme importance of the results. The work needs confirmation by others; the bacteriologic procedure is simple.

Dr. Ernst, in closing, said that the closest investigation had failed to discover any fallacy in the methods of Dr. Martin.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Eighth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

First Day—May 29th.

The President, Dr. George Chismore, of San Francisco, read a paper on a "Modification of Bigelow's Operation for Stone in the Bladder, Designed to Meet Cases in which the Prostate is Enlarged." He called attention to the difference in the conditions present in the cases complicated by prostatic enlargement, to the intolerance of such patients to prolonged operative procedures and to trauma of the bladder.

In view of these facts, Dr. Chismore advocated, 1. Local anesthesia in preference to general anesthesia; 2. Short sittings; 3. Removal of any remaining fragments after the patient has fully recovered from the effects of the previous operation, and as soon as such fragments can be detected with the vesical sound. His procedure is as follows: The bladder is emptied, and from one to two ounces of a 4 per cent. solution of cocain hydrochlorate are injected. The lithotrite should be introduced as carefully as possible, and if spasm is present a short pause should be made rather than force the instrument in the face of this obstruction. As soon as the stone is found it should be crushed as rapidly as possible, but no prolonged search should be made for remaining fragments, as this adds very considerably to the gravity of the operation. Any evacuator may be employed, but Dr. Chismore employs a very simple one devised by himself.

Usually there are no after-symptoms, and the patient feels relieved at once. Occasionally there is some swelling of the deep urethra. If any fragments are left, the old symptoms gradually return. The operation of crushing these fragments may be done without anesthesia. Dr. Chismore still employs Bigelow's instrument in cases of hard calculi, as his instrument does not possess the strength requisite for crushing such stones. He maintained that in all cases of vesical calculus, complicated by enlargement of the prostate, the operation described offers every prospect of success; and that any stone which could be removed by perineal lithotomy may be crushed with less suffering and with greater success by this method.

Dr. J. William White called attention to the gravity attending the use of a general anesthetic in many of these cases, the effect of which was to cause congestion or actual inflammation of the already crippled kidneys. When the integrity of the kidney is open to question, he thought the method described would occupy an important place.

Dr. Francis Watson, of Boston, was inclined to consider the method a retrogression. The higher mortality of lithotrity over litholapaxy is due to the retention of the crushed fragments, and he was unable to see how the same injurious effect could fail to follow Dr. Chismore's method if some fragments were removed. He was, however, most favorably impressed with the statistics given, and theoretic objections must be withdrawn when such a good showing can be made. Dr. Watson advocated in the class of cases alluded to in the paper the method so strongly indorsed by Reginald Harrison, of performing perineal cystotomy and crushing and evacuating by this route.

Dr. William K. Otis, of New York, favored suprapubic lithotomy in cases of stone in the bladder, in the presence of considerable enlargement of the prostate gland, as this operation gives an opportunity to inspect the bladder and provides for drainage. In many cases, however, he thought Dr. Chismore's method would be very suitable.

Dr. John P. Bryson was struck by the statement made by Dr. Chismore, that he was able to dilate the prostatic urethra, adding that whenever he had attempted this so much irritation followed that he has given it up entirely. He employs the cystoscope with advantage in gaining definite information of the exact intra-vesical conditions present. He thought that local anesthesia is coming more and more into use, and in many instances is exceedingly satisfactory. He agreed with Dr. White that general anesthetics are in many cases dangerous. He thought, with Dr. Watson, that most of the fatal cases are due to traumatism of the prostatic urethra. Dr. Bryson was not inclined to regard remaining fragments with apprehension in these cases, inasmuch as the pouched condition of the *bas fond*, the presence of residual urine and the tolerance already established, make the bladder much more tolerant than under the usual conditions.

Dr. James Bell concurred with Dr. Otis in preferring the supra-pubic operation for stone in prostatic cases. He was struck by the large amount of cocain employed

by Dr. Chismore, and asked if toxic effects had ever been noted.

DR. EDWARD MARTIN called attention to the recently established fact that chloroform is equally as irritating to the kidneys as ether, and that its use, therefore, in patients supposed to have diseased kidneys cannot be considered free from grave danger.

In concluding the discussion, DR. CHISMORE stated that he had employed cocain-anesthesia in all operations for stone in the bladder since June, 1889. In a few cases he has noted a little pallor, restlessness, or nervousness, and a mild degree of intoxication, but never any symptoms that caused anxiety. In some cases he has used as much as eight fluidounces, but usually less than half of this quantity is employed. He prefers to operate in a small bladder, and therefore injects only an ounce or an ounce and a half. Attention was called to the fact that in the class of cases under discussion the bladder is very tolerant, and that an uncrushed fragment would cause less disturbance than insistance on removing the last particle by a prolonged search. He is gradually employing smaller and smaller instruments. A condition not usually recognized was described as catheter-stricture. This is usually a stricture of large caliber occurring somewhere in the middle of the pendulous urethra in those who are obliged to use the catheter habitually. The presence of this anterior stricture is likely to cause a spasm of the deep urethra on passing the lithotrite.

DR. J. WILLIAM WHITE followed with a paper on "A Summary of the History and Present Position of the Operation of Castration for Hypertrophy of the Prostate," which will be found in full in another part of this issue of THE NEWS (see p. 601).

In the discussion that followed, DR. L. BOLTON BANGS congratulated Dr. White upon the suggestion advanced, and considered the subject a most important one. Considering the relative frequency of enlarged prostate, and the uncertainty and unsatisfactoriness of the means for its relief, any treatment that promises relief from the great distress so often present must be recognized by every one as a great stride forward.

DR. BRYSON, alluding to the reference by Dr. White of the possibility of section of the vasa deferentia accomplishing the same result as castration, inclined to a negative view. He referred to the fact that after double epididymitis, although the vasa deferentia were practically cut off, no change was to be noted in the condition of the prostate. An interesting case was reported in this connection of a man, aged sixty-one years, who, eleven years previously, had consulted him for enlargement of the prostate, with six ounces of residual urine, and complicated with acute cystitis due to instrumentation. The cystitis improved, but six months later the man returned with tuberculosis of the right testicle. This was removed. One year later he again appeared with a similar condition of the left testicle. With a view of sparing the patient a portion of the diseased gland, he made an attempt to curet away the diseased portion after a cutaneous incision, but the organ was so disorganized that it all came away. At the end of a year there was a distinct diminution in the frequency of urination, the improvement being most marked at night. There was at this time evidence of tuberculous disease of the prostate and seminal vesicles. Fifteen months later the man declared himself free from all urinary trouble.

DR. BELFIELD reported the case of a young man, aged twenty-three years, who had both testicles removed for tuberculosis, and in whom the prostate gland had shrunk to a mere nodule.

DR. WATSON reported two instances of abscess of one testicle, in which the prostate underwent marked diminution in size on the side corresponding to the affected testicle, and slight decrease on the opposite side.

DR. MARTIN stated that he had had the opportunity of examining the patient upon whom Dr. White had operated, both before the operation and within a few days. Before operation the gland was as large as half an orange. At the recent examination it was found to have shrunk to the normal size.

In closing, DR. WHITE said, among other statements of interest, that before operation the patient whose case he had reported was obliged to pass the catheter nine and one-half inches before urine began to flow; while three weeks after operation the urine was drawn on passing the catheter eight inches. It is stated as a fact by horsemen, that if the cord is left long at the time of castrating a stallion the animal has much more life (spirit) than if the cord is cut short. This may have an important bearing upon the operation under discussion, and would teach that success is more likely to follow the operation if the cords are cut short.

The next paper was one by DR. SAMUEL ALEXANDER, of New York City, entitled "A Suggestion as to the Best Method of Removing Fibro-adenomatous Growths from the Prostate." The operation which Dr. Alexander has found so satisfactory in two cases is that recommended by Dr. Belfield, consisting in a supra-pubic and a perineal cystotomy. It was found by pressing the base of the bladder toward the perineum with the fingers in the supra-pubic wound, that it was easy to enucleate the nodular prostatic outgrowths. His experience would lead him to employ the method in any subsequent case in which operative measures were indicated.

The discussion was participated in by DRS. WATSON, BELFIELD, WHITE, BRYSON, BELL, BANGS, and CHISMORE. Drs. Belfield and Chismore stated that they had given up the use of Petersen's bag; the first because he had seen serious symptoms follow its introduction, and the latter because he had found it entirely useless. Dr. Bryson considers the rectal bag of distinct value. He prefers to introduce it and distend it with eight fluidounces of water before injecting the bladder. In injecting the bladder he uses a hand-bulb, as he is thus enabled to appreciate approximately the amount of intra-vesical pressure. He called attention to the very free hemorrhage sometimes encountered, and stated that its source was from the mucous membrane and submucous tissue.

DR. FRANCIS S. WATSON, of Boston, followed with a "Report of Some Cases of Rupture of the Urethra." Five cases were alluded to. The first was that of a seaman who had sustained a traumatic rupture of the pendulous urethra, a blow crushing the penis against the symphysis pubis. On account of the swelling the urethra was occluded and the urine, separating the skin from the deeper structures, worked its way backward to the abdominal wall, where it collected, making an artifi-

cial bladder. Rupture finally occurred externally. The treatment consisted in draining the infiltrated tissue, in performing perineal section, and finally in opening the urethra at the point of rupture and suturing first the urethra, then the corpus spongiosum and lastly the skin. Recovery was complete.

In the four other cases the rupture occurred during coitus. In one of these there was violent hemorrhage, in another, none whatever. In one case, owing to extensive infiltration, the entire skin of the penis and scrotum sloughed. The exposed surfaces were covered by skin-grafts in the manner recommended by Thiersch, with a most satisfactory result.

DR. GARDNER W. ALLEN, of Boston, presented a brief paper entitled "Remarks Upon the Treatment of Cystitis." Of internal remedies he expressed a preference for the saline diuretics. Locally, boric-acid solution is probably the most useful. Very gratifying results frequently follow the use of silver nitrate and potassium permanganate. If one fails, the other will frequently succeed. He rarely employs the silver solution stronger than 1 per cent. The permanganate solution should not be stronger than from 1 : 5000 to 1 : 4000 at first, but the strength may gradually be increased to 1 : 2000. In a very severe case, in which it was thought necessary to perform perineal cystotomy for drainage, injections of iodoform-emulsion produced the most marked improvement. The injections were made three times weekly in the beginning of the treatment, and later twice a week.

DR. MARTIN, stated that he has found tri-kresol a better antiseptic and less irritating than the substances usually employed in inflammations of the deep urethra and bladder.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(Continued from p. 606.)

SECOND DAY—MAY 30TH.

THE first portion of the session was under the charge of the American Climatological Association, and the subject chosen for consideration was "Sewer Gas."

DR. ALEXANDER C. ABBOTT, of Philadelphia, opened the discussion by a paper entitled "Chemical, Physical, and Bacteriological Studies of Air over Decomposing Surfaces, with Especial Reference to their Application to the Air of Sewers."

He said that a study of the literature of the subject leaves the impression that many of the opinions advanced are not based on exact methods of investigation. We are now tolerably well acquainted with the nature of the air of sewers, and we know that, as ordinarily found, it does not differ conspicuously from the air that we are accustomed to breathe. Studies in bacteriology demonstrate the comparative poverty of sewer-gas in bacteria. The general impression is that the air of sewers is under an active pressure and tends to force its way into the houses, but numerous experiments with pressure-gauges show that this is not the case. The studies upon the chemic, bacteriologic, and physical side of the subject, together with observations on the health of those constantly exposed to the emanations of sewage, are not of a nature to warrant the opinion that sewer-air is the dangerous factor that some believe it to be. There does not seem to be a single conclusive demonstration that the air of sewers stands in causal relation to the diseases for which it has been held accountable.

Among the problems that Dr. Abbott has endeavored to solve experimentally in the laboratory is whether or not it is possible to demonstrate on animals that the gases arising from sewage or from other decomposing substances have any direct effect upon the health of the animal or its ability to resist infection. The method of experimentation was given in detail. The teaching that, because materials containing organisms capable of producing disease are constantly gaining access to the sewers, the air of these sewers must of necessity also contain such organisms is simply an opinion, not supported by observations that justify its acceptation as a fact. The more conservative of those who believe in a causal relation between the air of sewers and pathologic conditions are coming to the opinion that this air is not directly concerned in the production of disease, but that its continuous respiration in some way interferes with the normal vital resistance of the tissues, and thus renders them more susceptible to infections to which they may be exposed.

Dr. Abbott detailed his experiments on animals and concluded that if experiments upon animals are of any value in demonstrating the positive or negative effects of air saturated with the gaseous products of decomposition, it does not seem reasonable to suppose that the air of a sewer or cess-pool, in the enormous dilution in which it exists at the time that it reaches an individual in a house to which it has access, can be of much importance, either in the direct production of the diseased conditions or in influencing the vital powers of resistance of the individual who inhales it.

DR. A. JACOBI, of New York, read a paper on "The Effect of Sewer-gas in the Production of Disease," embracing the following conclusions: The atmosphere contains specific germs, both living and dead, which are frequently found in places that were infected with specific disease. In sewers fewer such germs have been found than in the air of houses and school-rooms. Moist surfaces, such as the contents of sewers and cess-pools and the walls of sewers, while emitting odors, do not give off specific germs, even in a moderate current of air. Splashing of the sewer-contents may separate some germs, and then the air of sewers may become temporarily infected, but the germs will sink to the bottom again. Choking the sewers, the introduction of hot factory-refuse, leaky house-drains, and the absence of traps may cause sewer-air to ascend or be forced back into houses; but this complication of circumstances must certainly be rare.

Whatever arises from the sewer under these circumstances is offensive and irritating. A number of ailments, such, perhaps, as sore-throat may originate from this cause, but no specific disease will be generated by it, except under the rarest of conditions, for specific germs are destroyed by the process of putrefaction in the sewers and the worse the odor the less is the danger, particularly from diphtheria. The causes of this disease are varied and the search for the origin in an individual case is often unsuccessful. Irritation of the throat and naso-pharynx is a frequent source of local catarrh. This

creates a resting-place for the germs of diphtheria, which are ubiquitous during an epidemic, and thus an opportunity for diphtheria is furnished. Of the specific germs, those of typhoid fever and dysentery appear to be the least subject to destruction by cess-pools and sewers. These diseases appear to be sometimes referable to direct exhalation from privies and cess-pools. Fewer cases, if any, are attributable to sewer-air. A simple outlet from the sewer would be dangerous to the general health because of the density of the odors (not germs) arising therefrom. Therefore, very thorough and multiple ventilation is required. The impossibility or great improbability of specific diseases arising from sewers opening into our houses, but protected by good drains and efficient traps, must, however, not lull citizens and authorities into indolence or carelessness; for the general health will suffer from the chemic exhalations and the vitality of cell-life, and the power of resistance will be undermined.

Dr. Beverly Robinson, of New York, read a paper entitled "Sewer-gas as a Cause of Throat-disease, or the Effect of Bad Drainage on the Throat." Defective sewage may produce a sore-throat of a benign character, which affords a soil suitable for inoculation by the germ of diphtheria when present in the air. It is an admitted fact that the throat swarms with bacteria at all times, and possibly the bacillus of Löffler is occasionally among these; but these organisms are incapable of doing much harm if the individual is in good health. Through the depressing influence brought about by bad drainage, etc., they are capable of multiplying and increasing in virulence and finally causing infectious sore-throat. It is therefore clear how important it is to keep up an excellent condition of general health to avoid contracting disease of the throat. Proper disinfecting washes and gargles are also of value. While the connection between effluvia from sewers and drains and the condition of the throat cannot always be determined, yet in many cases it is clearly demonstrated. That many cases of tonsillitis are immediately caused by the air of sewers and fecal emanations scarcely admits of doubt. In some instances the cases of sore-throat have been confined to particular parts of houses, and when the bad sewage has been remedied they have ceased to recur. When cases of diphtheria, tonsillitis, or erythematous sore-throat occur in houses in which the plumbing is found to be defective, care should be taken not to ascribe these diseases necessarily to this cause. While throat-affections often occur where the drainage is bad, they may occur where the sewage is in perfect condition, or where there is no sewage at all.

The second part of the session was under the direction of the American Dermatological Association.

The subject for discussion was Leprosy.

The opening article was on "The Distribution of Leprosy in North America," by Dr. James Nevins Hyde, of Chicago. Reference was first made to the different ways in which leprosy could gain entrance into the United States. The northern part of the country has suffered far less than the southern, and even in the latter portion the disease is more common in the southern than in the northern districts. The United States is exposed to the entrance of leprosy from the four principal points of the compass—north, south, east, and west. That the total result up to the present time is insignificant has been due not to wisely directed vigilance, but rather to the general excellence of the habits, of the resources, and of the environment of the people.

At the present time the distribution of leprosy in the United States cannot be determined with any accuracy. The credit of being the first to collect statistics as to the number and location of lepers is due to the American Dermatological Association. According to these statistics and those of others, it may be said that the cases of leprosy in the United States have been distributed as follows: Arkansas, 3; California, 158; Dakota, 2; Florida, 6; Georgia, 1; Idaho, 2; Illinois, 13; Indiana, 2; Iowa, 20; Louisiana, 83; Maryland, 4; Massachusetts, 5; Minnesota, 120; Missouri, 2; Mississippi, 2; New York, 100; New Jersey, 1; Oregon, 3; Pennsylvania, 6; Utah, 3; Wisconsin, 20—making a total of 560. The accumulation of cases is found to be principally at points of commercial activity. The number of lepers in this country at the present time cannot be definitely stated.

These facts call for intelligent discussion and for wise provision looking after the needs of the unfortunate leper and for the safety of the community in which the infected are now living. Tuberculosis alone, at the present, exposes to a greater danger than leprosy the health of our population. The presence of leprosy in this country offers a constant menace to its inhabitants and constitutes a problem in state and sanitary science which the general government alone can readily solve.

Dr. James C. White, of Boston, read a paper entitled "The Contagiousness, Prophylaxis, and Control of Leprosy," in which he contended that the establishment of the proof of the contagiousness of a disease should be based upon the following points: 1. The history of its action upon communities or nations. 2. The study of its action upon individuals. 3. Its resemblance to other affections generally regarded as contagious. 4. The establishment of a satisfactory cause for such contagion. 5. The influence of control upon its history and course. These tests were then applied to the disease under consideration.

1. The history of its action upon communities and nations. Reference was made to its course in medieval Europe, where, introduced from the East, it became a pestilence of such overwhelming proportions that no influence of heredity alone could account for its spread. Belief in its contagious nature was then universal. In our own day, the extraordinary rapidity of the spread of the disease in the Hawaiian Islands can be accounted for on no other grounds than its infectious nature. The same is true of its introduction and spread in British Guiania, Trinidad, and other places.

2. The study of its action upon individuals. Great difficulty is here met with on account of the long period of incubation of leprosy, which may be of two, five, or even ten years' duration. Such a retardation of the tangible effects of the contagion renders direct historic proof in individual cases almost an impossibility. Again, the tissues of animals other than man thus far studied show themselves indifferent to inoculation-experiments. The possibility of using human tissues for such demonstration in satisfactory sufficiency is too remote for serious consideration. In one case a condemned crim-

inal was inoculated and three years later leprosy appeared. Reliance must, therefore, be placed upon a careful study of the beginning of endemics in small communities. Another kind of evidence is the acquisition of the disease by immigrants of non-leprous nationality into leprous countries. Of this there are many instances on record. Another important fact is the development of leprosy among the personal attendants of lepers. Of this several instances were cited.

3. Resemblance to other affections generally regarded as contagious. Under this head reference was made to the many points of resemblance between leprosy and syphilis and tuberculosis, and it was held that these strong resemblances suggested an intimate relationship in etiology and pathology.

4. Establishment of a satisfactory explanation of its contagiousness. With the discovery of the bacillus lepræ, the cause of the contagious nature of leprosy was demonstrated as clearly as was that of tuberculosis by the discovery of the bacillus tuberculosis. Leprosy is preëminently a bacillary disease, for this organism is found in profusion in the tissues.

5. Influence of control upon its history and course. In medieval Europe when the disease was regarded as infectious, the leper was segregated and placed in lazarettos. In later centuries, when the disease had been thus controlled and confined to a few districts, the belief grew up that the disease was not contagious, but was hereditary, and scarcely anyone thought of questioning this dictum. At the International Medical Congress in 1876, Dr. White called attention to the prevalence of the disease in the United States. In 1882, he again called attention to the subject in a paper presented to the American Dermatological Association. His conclusions that the disease was increasing to an alarming extent, and that it was contagious, at that time found few supporters, but since then professional opinion has greatly changed. A study of the disease in other countries shows that where laws for its control have been enacted there has been a great diminution in the number of cases, and that where it has been given free license, the number of cases has rapidly increased.

While not denying the possibility of the hereditary transmission of leprosy, Dr. White held that its apparent occurrence in any instance should not be accepted without the absolute demonstration of the impossibility of inoculation after birth. He believed the theory of heredity to be a dangerous one, and that the sterner judgment of the middle ages, which made the leper individually, rather than the progenitor, the responsible agent, must again be adopted before the affection can be exterminated.

With regard to the prevention and control of leprosy in the United States, the consideration of the following propositions was recommended :

1. Every physician should be compelled by State law to report to the nearest Board of Health the existence of a case of the disease, and neglect to do so on the part of the medical attendant, or a member of the leper's family, should be a penal offence.

2. Immigrants affected with the disease should be arrested at ports of entry and along our border, and turned back to their previous homes by the authority of the National Board of Health.

3. Graded hospitals should be established by the National Government, in insular localities, if possible, within which both suspected and confirmed cases should be confined, and to which all access should be prohibited, excepting under proper restrictions.

Such compulsory isolation may be considered cruel to the few, but its longer neglect on our part is certainly a greater cruelty to the many, for in no other way shall we exterminate this most miserable disease.

In the general discussion, DR. GEORGE H. FOX, of New York, said that whatever might be the result of inoculation-experiments he was sure that those who had given special attention to the study of leprosy would agree that the disease was communicable, but that the danger of infection from association with the leper is extremely slight. In the United States the disease has never shown any tendency to spread among those brought in contact with communities of lepers. He thought that there was no necessity for the segregation of the lepers to be found in the United States. To forcibly take these individuals from their homes would be an injustice which the slight menace to the general health would not warrant. Syphilis and tuberculosis are much more liable to be communicated to others than is leprosy. He believed that many cases of leprosy are amenable to treatment and capable of being cured, and he would be in favor of the establishment of hospitals for leprosy where these cases could be studied.

DR. JOSEPH D. BRYANT, of New York, advocated the institution of active measures because such a course would be a humane one as far as the leper is concerned; it would be conducive to public security and confidence, and it would secure good sanitation and better therapy. He offered the following propositions: (1) that a wise public policy and humane considerations demand that lepers be not permitted to associate with the unaffected; (2) that the exercise of local authority for their segregation is unwise and unsanitary, as establishing innumerable abiding places for the disease at great expense and without the assurance of proper surveillance; (3) that a safe, prudent, and humane policy demands that lepers be properly segregated under the care and control of the general government.

DR. WALTER G. WYMAN, Surgeon-General U. S. Marine-Hospital Service, read a paper on the "National Control of Leprosy," which will appear in a future number of THE MEDICAL NEWS.

DR. ARTHUR VAN HARLINGEN, of Philadelphia, dwelt upon the importance of all physicians studying leprosy so as to be able to recognize its earlier manifestations, which are frequently overlooked. He had good reason for saying that, notwithstanding the rigid quarantine-laws, many cases of leprosy had gained access to the country, although they had been subjected to some sort of an examination. This is due to a failure to recognize the early manifestations of the disease.

A paper on "The Diagnostic Features and Treatment of Leprosy," by DR. P. A. MORROW, of New York, was read by title.

(Continued on page 622.)

Dr. J. Madison Taylor has resigned the position of Clinical Professor of the Diseases of Children in the Medico-Chirurgical College.

Dr. W. W. Keen has been appointed a member of the Board of Visitors of the West Point Military Academy.

AMERICAN SURGICAL ASSOCIATION.

(Continued from p. 609.)

SECOND DAY—MAY 30TH.

DR. J. S. BILLINGS read a paper entitled "Methods of Teaching Surgery," which appears elsewhere in the present number of THE NEWS. (See p. 593.)

This was followed by a communication from DR. JOHN CHIENE, of Edinburgh, on "The Teaching of Surgery."

In discussing this subject one must begin with a warning; the personal equation, relating to himself, and the traditional equation, relating to his school, must be allowed for and discounted.

The teaching of surgery resolves itself into two divisions: 1. Systematic consideration of general principles, illustrated by clinical examples. 2. A clinical (bedside) opportunity given to observe, to use and to educate all the faculties, physical and psychic. Under either head the teacher must be a learner; the student must be a teacher. The teacher has constantly to warn the student against a blind belief and at the same time he has to speak most decidedly in giving his opinion. The practice of surgery, to be successful must be dogmatic. It has been objected to systematic lectures that, now that we have books, there is no need of a hundred lectures on any subject. Those who hold these views can never have known the stimulus of speech; can never have felt the electric impulse passing between hearer and speaker.

The method of teaching surgery in Edinburgh was then described.

A final word was added with reference to the teacher of surgery. Dr. Chiene believes in a fallow time, in a time of rest from mental activity. The best rest is change of scene. He suggested the advantages that would accrue from an interchange of chairs in the great English-speaking educational centers. In this way a teacher would once in seven years leave his alma mater for a session and speak to the students of another school. Or the fallow might take another aspect: give a teacher a session off every seven years and let him do in it what seems to him good.

The discussion of these papers was participated in by Dr. J. Collins Warren, of Boston; Dr. W. W. Keen, of Philadelphia; Dr. Hunter McGuire, of Richmond, Va.; Dr. Charles B. Nancrede, of Ann Arbor, Mich.; Dr. P. S. Conner, of Cincinatti; Dr. W. S. Forbes, of Philadelphia; Dr. Robert F. Weir, of New York; Dr. T. F. Prewitt, of St. Louis; and Dr. John E. Owens, of Chicago.

"The Surgery of the Kidney" was the title of a paper by DR. L. MCLANE TIFFANY, of Baltimore. Only those points were considered that offer opportunity for differences of opinion. In the human body bilateral organs are more than sufficient for the carrying on of life; not only may one such organ be removed without interfering with existence, but even the remaining organ may be more or less damaged and yet life be carried on. Any paper on the surgery of the kidney at the present day must take into consideration the influence of disease of the kidney on various operations in general surgery. The influence of anesthesia on the healthy kidney should be considered. In 150 cases of operation in which healthy kidneys were present albumin was found in the urine in only two per cent. of the cases after operation. Every case of railway accident and in some other cases in which the patients had been exposed for a certain time, showed albuminous urine on admission to the hospital. In these cases operation has not been deferred on this account. Cases of advanced diabetes have not been operated on. In cases with healthy kidneys the amount of urine passed in twenty-four hours following operation is diminished in quantity, the specific gravity being usually a little higher.

There is no good reason why the kidney should be separated from the rest of the body and require different surgical treatment. A kidney-wound should be exposed, sutured, drained, tamponed with gauze or a piece of it excised in injury beyond repair, or drained, as the case may be, and not the whole kidney sacrificed.

Nephritis and pyelo-nephritis (so-called surgical kidney) are generally met with by the surgeon and inflammation (organic) resulting from extention upward of inflammation from urethra or bladder due to the presence of bacteria; the bacteriology of the trouble in question is yet to be written. Of so-called pyelo-nephritis, beginning in the kidney, the most frequent cause is stone. The surgeon has especially to deal with the ascending inflammation from the urinary channel below, more often obstructive. The diagnosis is usually not difficult when the disease is advanced. In the early stages the difficulty of diagnosis is great; especially is it difficult to recognize whether the trouble affects one kidney or both. Here it is that the cystoscope offers a great opportunity. A moderate amount of urine, with a low specific gravity and an habitual low temperature, independently of the condition of the pulse, are danger-signals more important than any other. In the recognition of the kidney affected we have to rely on pain, pressure, and the cystoscope. The treatment before operation consists in exciting the kidneys to secrete by means of infusion of digitalis, potassium acetate, and infusion of buchu. Acid urine, and pus suggest pyelo-nephritis very strongly. It is Dr. Tiffany's habit not to operate until the patient's kidneys are acting well. After operation strychnin hypodermatically is a useful addition to the previous treatment. The hot-air bath has proved unsatisfactory in chronic cases. In acute cases it is beneficial. Free purgation is invariably of advantage.

When an operation on the bladder is called for, and there is evidence of disease of one kidney or decided pain in one kidney suggesting disease, that kidney should be operated on at the same time as the bladder. Twice Dr. Tiffany has done lithotomy for stone in the bladder, the lithotomy being done and the kidney opened at the same sitting. All went well. In two other stone-cases, acute suppurative inflammation took place within two weeks, and was followed by death.

DR. ROBERT F. WEIR, of New York, read a paper entitled "The Surgical Treatment of Surgical Kidney." He said that suppurative pyelo-nephritis, suppurative interstitial nephritis, and surgical kidney, are the ordinary names given to a disease that originates, as a rule, in the bladder, and that generally affects both kidneys. In this affection the kidneys are congested and studded

with foci of pus. Dr. Delafield states that "so far as I know, all cases die." While this may be the general result, Dr. Weir reported a case showing that some modification of this prognosis must be made.

A man, twenty-five years old, was admitted to the surgical wards of the New York Hospital on April 2, 1894, with a history of having suffered, four years previously, from an attack of scarlet fever, followed by nephritis. About one year ago he had a mild attack of urethritis. Three months ago he had a severe attack of urethritis, the inflammation also invading the bladder; gonococci were present in the discharge. This gradually subsided under treatment. Twelve days prior to admission to the hospital he had, without assignable cause, a chill, followed by fever. The following day there was pain in the loins, with subsidence of the fever, but the next day the temperature reached 103° F. There was no increase in frequency of urination. The lumbar tenderness gradually increased. He was admitted to the medical wards of the New York Hospital on March 28th; during the next seven days he had four chills, the temperature ranging between 103° and 105°. The patient was seen by Dr. Weir on April 3d. His condition was a most serious one. The urine contained pus, and was fifty or sixty ounces in amount. There was pain in the right lumbar region, with tenderness on pressure. It was thought that some enlargement of the right kidney could be made out. The impression made was that there was an abscess of the kidney, or possibly several sacs of considerable size. It was not thought that the condition was one of "surgical kidney," on account of its one-sided character. On April 4th the kidney was exposed in the usual manner. Puncture in two or three places gave no evidence of pus. An incision was made into the kidney, disclosing numerous miliary abscesses, showing that there was the ordinary surgical kidney. It was then decided to extirpate the diseased organ. Immediately after the operation the temperature fell from 105° to 99°, and the patient made an uninterrupted and rapid recovery, being discharged on April 20th.

It is difficult to say how often the affection is limited to one kidney, but such limitation may not be infrequent. Even when both organs are involved it may be that something can be done for the relief of tension and the egress of pus by the means of a free incision made into the kidney-substance. With the happy experience of this case, Dr. Weir considered it hereafter justifiable, if the patient's general condition warrants it, in a case of acute septic invasion of the kidneys, to make on one or both sides an exploratory incision, not only in the hope of relieving the acute interstitial invasion, but also perhaps of encountering a larger and well-defined focus of pus—a pathologic condition that cannot always be readily discriminated from the more dangerous lesions of the veritable surgical kidney. Should the symptoms point, as in the case narrated, to one kidney only, or should a double exploratory incision yield the same result, a nephrectomy may with some hope be resorted to.

The next paper was on "Surgery of the Ureters," by DR. CHRISTIAN FENGER, of Chicago. He said that accidental wounds and subcutaneous ruptures of the ureter have not as yet been objects of direct surgical procedure upon the ureter at the seat of lesion. Catheterization of the ureters from the bladder for the purpose of diagnosis has given valuable information. The procedure is reasonably practicable in the female. In man catheterization is practicable only through epicystotomy. Catheterization of the ureter from the bladder as a curative measure for the evacuation of a hydronephrosis or a pyonephrosis has occasionally been performed. This is more difficult and uncertain than nephrotomy and the attempt to find and remedy the stenosis of the ureter from the pelvis of the kidney. Dilatation of strictures of the female ureters through the bladder by means of elastic bougies has been tried with temporary success, and through the pelvis of the kidney successfully. Permanent catheterization of the ureter through the bladder, a fistula or implanted ureter is often tolerated only for a limited time and must be attempted with caution. Uretero-lithotomy by the extra-peritoneal method is a safe operation. Intra-peritoneal ureterotomy should be done only when access outside of the peritoneal cavity is impossible, and should be completed by careful suturing, covering with omentum or peritoneal flap and drainage.

Opening the peritoneal cavity to locate the seat of stone may occasionally be necessary, but when the diagnosis is once made ureterotomy should be done by the extra-peritoneal method. In valve-formation or stricture of the ureter causing pyonephrosis or hydronephrosis or a permant renal fistula, nephrectomy should be followed by exploration of the ureter. This is to be effected by a long, flexible silver probe or an elastic bougie. The size of a bougie that will pass a healthy ureter is from No. 9 to No. 10 of the French scale. Operation for valve-formation should be done through the wound in the pelvis. A stricture in the ureter, if not extensive, can be treated by a plastic operation. Resection of the upper end of the ureter and implantation of the distal end into the pelvis has been done with success.

Uretero-uterine fistulas can be treated satisfactorily by plastic closure of the vagina or by nephrectomy. Implantation of the ureter into the bladder is, under favorable circumstances, the operation of the future for this condition. Uretero-vaginal fistulas should be treated by vaginal plastic operation for displacement of the distal end of the ureter into the bladder.

Complete transverse wounds in the continuity of the ureter should be treated by uretero-ureterostomy after the method of lateral implantation if possible. Complete transverse wounds of the upper end of the ureter should be treated by implantation of the ureter into the pelvis of the kidney. Complete transverse wounds of the ureter near the bladder should be treated by implantation into the bladder. Loss of substance of the ureter too extensive to permit of uretero-ureterostomy or too high up to permit of implantation into the bladder may be treated by implantation on the skin or into the bowel. Implantation into the bowel is objectionable. Implantation on the skin in the lumbar region may have to be followed by secondary nephrectomy; this procedure, however, is much less dangerous than the primary operation.

The discussion of these papers was postponed until Thursday morning.

ASSOCIATION OF AMERICAN PHYSICIANS.

(Continued from page 611.)

Second Day—May 30th.

Dr. Theobald Smith, of Washington, read a paper on the "Modification, Temporary and Permanent, of Physiological Characters of Bacteria in Mixed Cultures." He dwelt on the antagonism between living bacteria and the products of their activity in the body, and considered the effects of concurrent inoculation in one animal of the germs of two diseases, as hog-cholera and tuberculosis, or of two varieties of one germ. He showed that when the bacilli of hog-cholera as occurring in different portions of the country are mixed and the product of this mixed culture is injected into an animal, the virulence of the disease is diminished. He also stated that when the virulence of hog-cholera is once diminished, it took as long for that virulence to be restored as it had taken for it to be destroyed. He thought that the typhoid-like lesion of hog-cholera is a result either of an attenuation of the virus or of increased resisting power of the animal.

"The Effect of Various Metals on the Growth of Pathogenic Bacteria" was the title of the paper read next, by Dr. Meade Bolton, of Baltimore. In a series of investigations he has found that certain metals have no marked effect on the growth of bacteria, while others display certain peculiar actions. Metals readily attacked by the chemic reagents possess a marked inhibitory action on the growth of bacteria, and this is due to the fact that the metals are dissolved, and are brought in a soluble form into contact with the bacteria, and in this way the clear zone around the metal is produced.

Dr. Welch, of Baltimore, expressed the opinion that in the intensified ring immediately surrounding the clear zone there is a minimum amount of the metal, while in the clear zone around the metal there is an excess of the soluble oxid of the metal. He was unable to explain the formation of the clear zone surrounding the intensified zone.

Dr. W. Gilman Thompson, of New York, presented a "Note on the Observation of Malarial Organisms in Connection with Typhoid Fever." He stated that in the South typhoid fever in all of its clinical manifestations seems to be more or less complicated by malarial fever, while in New York and the North generally, it is quite rare to find such a complication. He reported three cases of typhoid fever thus complicated. He thought that in those individuals who have been subject to malarial paroxysms the pathogenic organism frequently takes advantage of the patient's reduced condition and manifests its presence during these periods of depression. He would offer this suggestion as a possible explanation of the occurrence of the malarial complications of enteric fever. While he believed that it would be unwise to accept the term "typho-malarial" as representative of a third form of disease, he is confident that the two diseases may coëxist in the same patient.

Dr. William Osler, of Baltimore, thought it a mistake to regard all cases of typhoid fever attended with chills as complicated with malaria. Chills are quite common in typhoid fever, and in the cases in which they occur, examination of the blood shows a freedom from the germs of malaria. He stated that he had seen a case of croupous pneumonia complicated by malaria which was controlled by the use of quinin.

Dr. G. M. Sternberg, of Washington, considered the so-called cases of typho-malarial fever occurring over the country as mild cases of typhoid fever.

Dr. J. C. Wilson, of Philadelphia, thought that the term typho-malarial has done incalculable harm in delaying for more than a generation a clear knowledge of the fevers of the South. It is also an unfortunate term, in that it has concealed obscure cases of true typhoid fever and prevented the observance of proper prophylactic measures. He hoped that the Association would not permit itself to go on record as sanctioning a return to the old term of "typho-malarial."

Dr. Frederick C. Shattuck, of Boston, suggested the probability of the existence of inflammation of some of the internal veins as the cause of the chills of typhoid fever.

Dr. Reeves, of Chattanooga, thought it probable that there is a species of fever intermediate between typhoid and malarial fever, to which the term typho-malarial is applicable. Cases thus affected have no diarrhea, no epistaxis; there is a typical rise and fall of temperature, and the course of the disease throughout is different from that of typhoid fever. Typho-malarial fever occurs most commonly among children.

Dr. George Dock, of Ann Arbor, remarked that the common view held is that typho-malarial fever is milder than true typhoid fever; he does not believe that this view is correct. He had failed to discover any case of typho-malarial fever while practising in Texas. It is a mistake to think that the term "typho-malarial fever" is used only in the South. He has repeatedly met with cases so designated in the North which were, in fact, cases of true typhoid fever.

In closing, Dr. Thompson said that he would emphasize the value of routine examinations of the blood in all cases of fever, and the administration of quinin in those cases in which the malarial organisms were discovered.

Dr. George Dock, of Ann Arbor, read a paper entitled "Experiments in Artificial Melanosis." He said that he had been led to make these experiments because of the recognized difficulty in determining the relationship existing between phagocytosis and malaria. He had repeated Ponfick's experiments in the hope of learning more of this interesting process. He employed lampblack in place of cinnabar, which was used by previous experimenters. A suspension of lampblack in a physiologic salt-solution was injected in animals, and sections of the organs made immediately after death. The injecting fluid was made as dense as possible, and injections of two drams were made into the veins of the legs of dogs. The animals were allowed to live one or two weeks, when they were killed. In some instances eight successive injections were made in as many days, so that considerable pigment was introduced into the circulation. In dogs the leukocytes are largely polynuclear cells, closely resembling the polynuclear cells of man. The pigment was found in the circulation within an early period, but it was not found in the leukocytes before fifteen minutes had elapsed, and usually not before thirty minutes. The results were always the same, namely, the pigment was found only in the polynuclear cells. The pigmented leukocytes

circulated for from one to three days. The pigment was found in the largest quantity in the lungs, next in the spleen, and finally in the liver. In the other organs the amount was very small or the pigment was entirely absent. There was very little found in the kidneys and lymph-glands; there was usually none in the brain, and in the intestines and stomach there was very little found. Most of the pigment in the organs was found, as elsewhere, in the polynuclear cells. A curious feature was the distribution in the liver. The pigment in that organ was at first found in the portal area, and here it remained for some time, free in the hepatic capillaries. Later it made its way toward the central vein and the radicles leading into this vein, forming in this way a stellate arrangement. The pigment in this organ was not only free, but also apparently was found in the endothelial cells, and also in the cells of Kupfer.

DR. THOMAS M. ROTCH, of Boston, presented a paper on "Some of the Chemical and Bacteriological Characteristics of Milk." In order to arrive at a more accurate knowledge of the composition of human milk, he had collected a liter and a half of milk freshly drawn from the breast. This had been submitted to a chemist for estimation as to its mineral constituents, and the presence of silicon and other constituents in milk had for the first time been demonstrated.

(To be concluded.)

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

(Continued from p. 613.)

SECOND DAY—MAY 30TH.

The business meeting was held at 9 o'clock A.M., when the following officers were elected for the ensuing year: President, L. Bolton Bangs, of New York City; Vice-President, Francis S. Watson, of Boston; Secretary, William K. Otis, of New York City; Member of Council-at-Large, Dr. J. A. Fordyce, of New York City.

The next meeting of the society will be held at Niagara Falls during the last week of May, 1895.

The usual morning session was called to order at 10 o'clock.

The first speaker of the day was DR. WILLIAM K. OTIS, of New York City, who read a paper entitled "Aëro-urethroscopy with a New Instrument." Attention was called to the unsatisfactory results attending the use of the ordinary urethroscope. Von Antal in 1887 conceived the idea of distending the urethra with air, which would thus permit of the inspection of every portion. Dr. Tilden Brown independently devised an instrument for the same purpose. The instrument of Brown has been modified by Fenwick. Dr. Otis has further modified the instrument so that it is light in weight and much simplified in construction. Although this is a distinct advance in urethroscopy, the view is still not so satisfactory as could be desired. It is serviceable in certain cases, however, that have heretofore been most difficult to treat.

In view of the fact that the instrument for catheterizing the male ureters has not been completed, Dr. Otis withdrew the formal paper on that subject, and described briefly the principle of the new instrument.

DR. BELFIELD showed instruments for inspecting the deep urethra and the neck of the bladder in the region of the trigone.

DR. EDWARD MARTIN concurred in the remarks of Dr. Otis on aëro-urethroscopy. Respecting catheterization of the male ureters, his experience has not been uniformly satisfactory.

DR. F. TILDEN BROWN, of New York City, described "New Instruments and Apparatus." The first instrument was a silver spring-catch, to hold the catheter in place in cases in which it is necessary to maintain drainage after perineal cystotomy. The catch is held in place by tapes. The second instrument was an improved needle-holder for Hagedorn's needles. The next was a modification of Clover's crutch. It has a rectangular bar, and is composed entirely of metal and canvas straps. The strain usually borne by the neck is transferred to the shoulders, and is thus much less irksome. An appliance accompanies the instrument to keep the feet out of the field of vision in class-room demonstration.

In the discussion, DR. BRYSON said that he has found that the best method of draining the bladder through the perineum is by means of an instrument with an eye similar to that in Bigelow's evacuator.

DR. WILLIAM H. HINGSTON, of Montreal, Canada, read a paper on "Stone in the Bladder; Choice of Operation." He dwelt particularly upon the much wider applicability of litholapaxy than was formerly thought to be the case. He believes that in disease of the bladder, or of the kidney, or in the presence of unhealthy urine, the lithotrite is as safe as the lithotomist's knife. Neither is old age or youth a contra-indication: "Lithotritize (Bigelow's operation) in all cases of adults if the stone is not too large or too hard; lithotritize in adults if the urethra is or can be made of proper size to admit the instrument; lithotritize all children if an instrument can be passed." The capacity of the urethra in the child is greater than inspection would indicate. In old age, if a cutting operation is necessary on account of enlarged prostate or tumor, the supra-pubic operation should always be resorted to. In other cases the lateral perineal operation, when applicable, is the best of the cutting methods.

In the discussion, DR. CHISMORE coincided in most respects with the views expressed by Dr. Hingston. Particular stress was laid upon the advantage of the supra-pubic route in cutting for stone in cases with enlarged prostate glands.

DR. BANGS stated that in some of these cases it is necessary not only to remove the stone, but also to treat the stone-disease. For this reason he thinks it frequently becomes necessary to do some cutting operation for the purpose of draining both the bladder and the kidneys.

DR. WIILLIAM JUDKINS reported the case of a boy from whom he had removed a vesical calculus by the supra-pubic method. On the second day pneumonia developed, and on account of the coughing and straining some of the stitches gave way. However, the patient recovered, and some time later passed *per urethram* a stitch covered with a phosphatic deposit. There is now a repetition of the vesical irritation, and it is probable that other stitches have found their way into the bladder and that they are causing the symptoms.

DR. JOHN P. BRYSON, of St. Louis, read an article

entitled "Urine-leakage and Stricture-formation." Attention was called to the erroneous description of the histology of the tissue composing strictures of the urethra, and the tissue surrounding urinary fistulæ, as heretofore given and so widely copied. Drawings from microscopic sections of the two tissues exhibited showed that in each the essential conditions are the same; the minor differences are only such as may well be explained by differing conditions. The following conclusions were expressed:

1. The close resemblance in the tissue-elements, their arrangement, and effects upon the related normal structures point to the identity of the etiologic factor and give support to the doctrine of urine-leakage.

2. Observing the prolongation of the urethral epithelium on the fistula-wall, in an effort to create an adequate artificial channel for urine, and seeing that the epithelium lining the stricture also participates in the battle against urine-leakage, we may take fresh hope of radically curing strictures, even of the pendulous urethra, by such means as tend to restore or rehabilitate the urethral lining.

3. Merely diverting the stream of urine for a time, without such restoration of the lining mucous membrane, would fall into the category of palliative treatment, along with urethrotomy and the various methods of dilatation.

DR. J. BLAKE WHITE, of New York City, next read a paper upon the subject of "The Possibility of Overcoming Permanent Stricture of the Deep Urethra without resort to External Urethrotomy." He called attention to the frequently-observed fact that an anterior stricture of large caliber, or a contracted meatus, will cause spasm of the deep urethra, which will effectually prevent the passage of any instrument. Two cases were reported, in each of which, although intense spasm existed, deep organic stricture also was present, appearing to demand external perineal urethrotomy. The spasm was found to relax completely on enlarging the meatus to the proper size. The treatment of the deep strictures by gradual dilatation could then be proceeded with.

In the discussion, DR. EDWARD MARTIN assented to the views expressed by Dr. White. He thought too frequent recourse to the knife had been the tendency of recent years, and he related cases affording convincing proof of the value of dilatation, up to full size, in the treatment of stricture.

DR. BRYSON also thought that division is practised in the treatment of strictures with unnecessary frequency.

DR. ALEXANDER W. STEIN, of New York, presented a communication upon "Some Infrequent Symptoms of Disease of the Urinary Tract." He referred to cases of membranous casts from the bladder and urethra. The cause usually given is retention of urine. Of fifty reported cases, forty-five were in women and five in men. The causes of retention in the females was either a retroverted uterus or pressure of the child's head during prolonged parturition. The prognosis is usually good; of forty-five cases, but nine terminated fatally. The case was reported of a man, twenty-six years old, who had frequent attacks of renal colic on the left side, and who on one occasion had retention for twenty hours; finally he passed a stone *per urethram* with relief of the retention. The attacks of renal colic continued. Later, he was subjected to litholapaxy for stone in the bladder. Still later, he began to pass "fleshy" masses of large size. The urine was loaded with pus and was offensive. Improvement followed antiseptic irrigations of the bladder. The patient was lost to observation, and it was reported that he afterward died. The cause of death could not be learned, but as the termination was preceded by stupor, it was possibly uremia.

(To be concluded.)

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Sixteenth Annual Session, held at Washington, D. C., May 30th, 31st, and June 1st.

FIRST DAY—MAY 30TH.

DR. D. BRYSON DELAVAN, of New York, delivered the President's Address.

He pointed out that the history of the Association is in reality the history of laryngology, for Manuel Garcia, the discoverer of the laryngoscope, is still living, while the list of Corresponding Fellows has contained the names of the most distinguished specialists of the age. The laryngoscope was first introduced into this country in 1860. Sixteen years later its use was taught in twenty-five different institutions, and this special line of work had attained a position of acknowledged responsibility. In 1878 the inaugural meeting of the Association was held in Buffalo, and its first President was Dr. Louis Elsberg.

The foundation of the Society was a pre-conceived movement in the direction of a higher and broader education. It was a vigorous effort to advance and disseminate the knowledge of laryngologic work. The meetings have always been well attended, the papers contributed scientific, and the discussions vigorous. These facts are attested by the fifteen creditable volumes of *Transactions* for which this Society stands sponsor. The honor of establishing the first laryngological society, either here or abroad, belongs to New York city. This Society (The New York Laryngological Society) was founded in October, 1873, at the suggestion of Dr. Clinton Wagner. The effect of centralized effort, of that healthful competition which is the inevitable and invaluable result of the free intercourse and friendly rivalry made possible by these societies, has nowhere shown its influence more conspicuously than in England. In that country the study of laryngology has been advanced with the energy and enthusiasm of a true renaissance. It is therefore a great satisfaction that this strong and onward movement has seen America in the van; but this very success imposes its own peculiar responsibilities, and if we are to maintain our present position we must still strive for superiority.

Coincident with the growth on the practical side of laryngology has been its increased recognition in the columns of the general medical journals, in the establishment of journals devoted to the special work, and in the production of a large number of epoch-making treatises.

The motto of this Association is "*Docendo discimus*—by teaching we learn." To reach the higher usefulness we must be teachers, and the maintenance of the high place which the Association at present occupies necessitates the thorough carrying out of this idea. We must

qualify ourselves by absolute purity of purpose, oneness of aim, and actual scientific superiority. Then we must proceed to study and carry out such plans as shall place the greatest amount of sound learning in the hands of the largest number of well-qualified men. The question of education, in other words, is by far the most important problem before the medical profession to-day. In it are involved all hopes for the future, not only as to professional reputation, but also (what is of far more importance) as to the beneficent ends to which it is hoped laryngology may attain. The most opportune office of the Association has always been and always must be teaching. The very fact that its membership includes the leading teachers of this country imposes the obligation to the profession at large, which cannot be under-estimated, and still less cannot be set aside.

Undergraduate instruction has in this country reached a high degree of perfection, and at least one institution stands concededly superior to any other, both as to its plan of instruction, its equipment and its general discipline; but many other schools also, in different parts of the country, are doing good work. This question, therefore, of instruction, so far as it relates to undergraduates, may be said to have been fairly considered and successfully met.

But undergraduate institutions have at points failed to answer all the needs of the higher medical education, and there have, therefore, sprung up the various schools of instruction for graduates. It is in this way that laryngology has received a startling popularity, to which the great growth of special literature has largely contributed. The problem thus created is perhaps the most important one of to-day, and it cannot be so easily solved as has been that of the undergraduates, because the students at these graduating schools present a vastly greater variety of personal needs and professional attainments. They are in addition frequently hampered in their progress by pre-conceived ideas that have been honestly derived from their own professional experience. The meeting of these diversified needs imposes upon the instructor a weighty task. The ideal instruction for graduates pre-supposes three things: (1) a higher and more thorough general medical education on the part of the student; (2) a more careful selection in the choice of instructors; (3) a modification of the best undergraduate methods to satisfy the needs of the older men.

DR. W. E. CASSELBERRY, of Chicago, read a paper on "Nasal Polypus; its Treatment by Resection of the Middle Turbinated Bone," giving an analysis of forty cases. Nasal polypus is to be regarded not so much as a disease in itself as symptomatic of other nasal affections. The most frequent of these are the various forms of ethmoiditis. Vigorous surgical treatment was advised, with the object of gaining access to the vicinity of the hiatus semilunaris, from which region polyps generally grow. He prefers the curet to the galvano-cautery for destroying the attachments of the growths. More recently he has advocated the resection of the antero-inferior part of the middle turbinated bone in order the more efficiently to bring about this result. He classifies the various conditions found associated with and underlying the polyp-formation as follows:

I. *Nasal polypus, with hypertrophic rhinitis.* Here there is no evidence of ethmoiditis, though it is suggested by the pressure of the polypus. Defective drainage and the accumulation of muco-pus in the middle meatus predispose to such polyp-formation. Removal of the polyps is followed by recovery without recurrence, the cautery being applied to the hypertrophied bodies of the turbinates. Six of the forty cases reported were of this class.

II. *Nasal polypus, with simple myxomatous ethmoiditis.* Here the turbinates have a glistening appearance and a pultaceous feel. Pressure results in the ethmoid region, with its various symptoms. The middle part of the bone should be resected and the myxomatous area thereby laid bare. Fourteen of the cases belonged to this group.

III. *Nasal polypus, with vasomotor ethmoiditis.* This is a variation of the preceding type. This group comprised nine cases. Four suffered from hay-fever, indicating the presence of a neurotic habit, and in all asthma was present. All were especially sensitive to excitants through the olfactory sense.

IV. *Nasal polypus with suppurative ethmoiditis.* Here there is a purulent discharge from the ethmoid cells, frequently coëxisting with empyema of some one of the accessory sinuses. The condition is a sequel of the preceding varieties, suppuration occurring only after the myxomatous tissue has accumulated sufficiently to obliterate the natural drainage. Six cases came under this heading.

V. *Nasal polypus with necrosing ethmoiditis.* Dr. Casselberry expressed his adherence to the views of Woakes to a certain extent, but regarded caries of the ethmoid as a usual accompaniment of polyps. Only five cases were found with unmistakable bone-necrosis. To such, and such only, should the term "necrosing ethmoiditis" be applied.

In all, the establishment of free drainage is a *sine qua non* of successful treatment. This often necessitates the removal of a portion of the middle turbinated. To effect this Dr. Casselberry has devised curved, serrated scissors, the use of which can be supplemented, if need be, by the snare or sharp forceps. Several sittings may be necessary to complete the operation; but if the middle turbinated presents no obstacle to normal drainage there is no occasion to remove it.

The discussion upon this paper was general, and the speakers all decried reckless and unnecessary surgical procedures in the nose, but there was a general unanimity that nothing short of radical measures would cure the chronic cases. Severe hemorrhage has resulted from the procedure recommended by Dr. Casselberry, and one (doubtful) case of cerebral abscess. Acute cases of ethmoidal trouble will frequently subside of themselves if local antiphlogistic measures alone are employed.

DR. JONATHAN WRIGHT, of Brooklyn, read a paper entitled "Papillary Hypertrophy of the Nasal Mucous Membrane Compared with a True Papilloma." He exhibited drawings showing the differences between these two conditions. True papilloma of the nose is very rare. The typical specimen described in the paper was removed from the uvula and the nasal specimen from the middle of the inferior turbinated bone. The papilloma consisted of a thick stem with irregular sprouts, some simply conical, springing directly from the central stem, but the larger number sub-divided into their own stem

and sprouts. The whole resembled a budding tuberous vegetable. The mass was without glands and had only small capillaries and a slight branching framework of connective tissue. This latter was covered everywhere with a large number of regularly striated layers of flat epithelial cells.

A drawing of the nasal growth showed a symmetrically rounded mass with cross-lines dividing it into more or less regular portions, resembling the "mulberry" hypertrophy which is so often found on the posterior portions of the inferior turbinated bones. In this particular instance, the mass was sessile but movable. Nearly an hour was occupied in its removal by the cold snare, but a sharp secondary hemorrhage resulted three hours later.

As contrasted with true papilloma, almost any fold of the nasal specimen was in connection with the central mass, without any appearance of the budding process. The line of surface epithelium was not especially thickened or irregular. The growth consisted, in fact, of all the constituent parts of the nasal mucous membrane of the inferior turbinated. The venous sinuses were markedly dilated. Glands were present, but only in small numbers. A great increase in fibrous connective tissue was noticeable. This was divided at the periphery into distinct processes covered by epithelium, and the intervening depressions gave the whole a nodular appearance.

Such growths are true papillary hypertrophies of the erectile sinuses of the bone-covering, and are due to the results of chronic inflammation. This latter causes a continuous and exaggerated contraction and dilatation of the sinuses in a stroma deprived of much of its muscular and elastic support.

"The Use of Metallic Electrodes in the Treatment of Nasal and Post-nasal Disease," was the title of a paper read by DR. CLARENCE C. RICE, of New York. His plan is to make use of the galvanic current, and to construct the positive electrode of some oxidizable substance, such as copper. This pole may be made in various shapes suited to the nose and naso-pharynx, and varying with the end aimed at. The negative electrode is the usual flat sponge, placed at some indifferent point, preferably the nape of the neck. When the current passes, the copper is dissolved and a new salt thereof, the oxychlorid, is formed and carried into the tissues. This is called "metallic," or "interstitial" electrolysis. Lime and iron can be used instead of copper, if desired. This plan of treatment has been elaborated by Gautier, Morton, Cleaves, and others, and is suggested by the well-known phenomena of cataphoresis.

It claimed that the salt is actually carried into the tissues, that hypersecretion action in this way is much more efficient than when it is merely applied in solution to the surface and that its influence is exerted upon the sub-mucous soil which is the seat of the pathologic process. The advantages are really three-fold, as we have the usual electrolysis of the tissues and the stimulating effect of the current.

The class of cases in which Dr. Rice had found the treatment of especial benefit included several of hypersecretion from the nasal mucosa, irritable cough from laryngeal and pharyngeal catarrh, and enlarged turbinated bones. In the latter instance the pole could advantageously take the shape of a copper needle. He had found the latter preferable to the galvano-cautery tip in checking bleeding from erosions of the nasal septum, and preferable to the caustic acids in reducing enlarged turbinated bones. He had not exceeded from 5 to 10 milliampères in the actual application of the current. Of twenty cases of the foregoing diseases treated six had been cured and three-fourths of the remainder distinctly benefited. Cocain was used if necessary.

(To be concluded.)

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(Continued from page 615.)

THIRD DAY—MAY 31ST.

The first part of this session was under the care of the American Association of Genito urinary Surgeons.

DR. E. L. KEYES, of New York, read a paper on "Nephritis in Its Surgical Aspects." He confined himself to a consideration of that form of surgical nephritis in which suppuration occurs, either spontaneously in the course of suppurative disease of the urinary tract below (ascending pyelonephritis), or originating below as a result of infection by the surgeon, or in the blood (the descending variety)—all the various forms of so-called surgical kidney. It was first shown that without microbic infection suppuration in the kidney is impossible. The bacilli found most often are, notably, the bacterium coli commune, less often (alone or in company with the bacterium coli) the staphylococcus pyogenes aureus and the streptococcus pyogenes. These bacilli find entrance in a variety of alleged ways. The introduction alone of these bacilli does not occasion ascending pyelitis, or even necessarily cystitis. It is as much a question of soil as it is of seed. The soil is made receptive for microbic invasion by a variety of local physical maladies, by anything that interferes with free urinary outflow, by over-distention or tension, and also by traumatism and failure of the general vitality. The kidney is especially prepared for invasion by dilatation of the ureters, a condition always taking place from above downward, always due to a moderate obstruction of urinary outflow below—never to sudden stoppage of the urinary drainage, never due to back pressure of the urine.

The bacteriologic part was conducted by Prof. Dunham, of Bellevue Hospital Medical College, under Dr. Keyes' direction, to determine the destructive or inhibitive power over the three bacilli under consideration of a great variety of medical substances often used for local antiseptic purposes in the treatment of vesical suppuration and of a variety of urines medicated by the ingestion of a number of different drugs. About five thousand tubes were examined, the conclusions generalized and tabulated, with the result of showing theoretically which drugs possessed the greatest value under varying conditions, those of direct infection by the surgeon, the tissues not being involved, and those in which, chronic suppuration already existing, the bacilli were protected from the action of the antiseptic. These conditions were reproduced in the laboratory, a method of investigation apparently novel and yielding suggestive results. This investigation showed that silver nitrate is by far the most reliable

agent we possess in counteracting the effects of local contamination, while corrosive sublimate is more reliable when the tissues are involved. Salicylic acid was shown to be a very reliable antiseptic. Boric acid has little or no value, common salt being about as good.

The following general conclusions were presented: 1. Healthy urine is sterile. 2. Purulent urine is always microbic. 3. Microbic infection takes place from within the body by a number of methods in the course of disease; it is often brought about by instrumental manœuvers on the part of the surgeon. 4. A healthy organism and a vigorous bladder can cope successfully with microbic invasion and rid themselves, spontaneously or with a little aid, of all damage arising therefrom, showing little or even no inflammatory response. 5. A suitable condition of the patient's soil is essential to the propagation and perpetuation of the inflammatory phenomena upon the urinary tract after microbic invasion. 6. This condition, intensified by traumatism and physical weakness, notably of the degenerative variety, is most intense when there is vesical distention, with atony, and when the ureters are dilated and the kidneys involved in the changes incident to tension below, namely, atrophy, and sclerosis above, with or without superficial catarrh. 7. Under these circumstances surgical pyelonephritis is most likely to declare itself as a result of microbic infection from below (occasionally from above) in the course of suppurative disease. 8. Asepsis, antisepsis, and sterilization of urine are ends to be aimed at in genito-urinary surgery, but like all other "greatest goods," have not yet been attained in perfection. Much, however, can be done by local means in a prophylactic and curative way, little by internal medication, and possibly as much or more than by other means by flushing the urinary passages with natural mineral waters.

DR. GEORGE M. STERNBERG, Surgeon-General U. S. A., read a paper on "The Bacteriology of Pyelonephritis." He pointed out that ascending nephritis or pyelonephritis is very commonly secondary to cystitis of long standing. Recent researches show that the bacillus coli communis is found more frequently than any other microörganism in the so-called "surgical kidney." This bacillus is now known to be the usual cause of peritonitis. It has been obtained in pure culture in a number of cases of abscess of the liver, from urinary abscesses, and from the pleural cavity in certain cases of pleurisy.

Injections of a pure culture into the ureter after tying this below the point of injection have been shown to give rise to pyelo-nephritis, and the changes induced are said to correspond with those seen in the "surgical kidney" of man. Non-liquefying bacilli have been found in the urine of cases of chronic cystitis and of pyelonephritis, which appear to be identical with the bacillus coli communis, which has been shown to be very variable in its growth in various culture-media—upon gelatin the growth is sometimes transparent and sometimes opaque.

The bacillus coli communis has also been found in a considerable number of cases of cystitis.

In view of these facts the etiologic relation of this bacillus to ascending nephritis seems extremely probable. Certain cases appear to be due also to the presence of one or more species of proteus, and possibly to other microörganisms.

The second part of the session was under the care of the American Gynecological Society.

DR. WILLIAM GOODELL, of Philadelphia, said that he had taken the liberty of changing the title of his remarks from "The Conservative Surgery" to "The Conservative *Treatment* of the Female Pelvic Organs." This enlarged the scope of the subject and was more in keeping with his views; for he held that besides strictly surgical ones, there were other kinds of conservative treatment which are especially adapted to the ailing female organs. He considered the whole question of the proper treatment of those disorders to hinge on the effect of castration on women. These effects are prolonged and distressing vasomotor disturbances, and a tendency to morbid brooding, low spirits, melancholy, suicidal impulses, and even to insanity. Then again castrated women are liable to become unsexed to that extent as to lose all sexual feeling, or to have this greatly blunted. In some cases senile atrophy of the genitalia takes place, or a hypertrophic condition of the vulva occurs which forbids coition and causes much domestic unhappiness. An inevitable and deplorable result is sterility, which is often a cause of great sorrow. Stress was laid upon the prevalent lay opinion that women deprived of their ovaries are thereby wholly unsexed. Castration in the male and in the female is alike regarded as a sexual mutilation to which is attached a stigma. No woman would marry a eunuch and few men would wed a woman without ovaries. It is then manifest that during the period of woman's menstrual life her mental, physical, and social welfare depends largely upon the continuance of the catamenial and reproductive functions. Hence the conservation of those organs which preside over these functions is of the utmost importance.

Hasty operative interference, based on the plea that chronically diseased appendages are dangerous to life, is reprehensible, as few women perish from chronic disorder of these organs, even when pus is present. More women die from the radical operation than from the disease itself. To restore such women to health, abdominal section is by no means always necessary. Many have been cured by curetting and draining the womb. Others get well under the use of rest, massage, electricity, alteratives, and local applications, even when removal of their appendages has been recommended. In some instances this treatment is followed by conception and pregnancy.

The possibility of a closed-up Fallopian tube regaining its lumen is warmly disputed; but as uterine fibroids of large size spontaneously disappear through retrogressive metamorphosis, why may not the thin tubal septa of inflammatory origin also melt away with restoration of the bore of the tube? Examples were cited in which great disorganization of the tubes and ovaries did not prevent conception. Cases were also related in which a small fragment of an ovary or a short stump of a tube was left behind and pregnancy subsequently took place.

In view of these interesting facts, Dr. Goodell advised that when medicinal measures fail and the final appeal is made to the knife, as little as possible of the appendages should be taken away. If the tubes and ovaries are simply adherent and not otherwise damaged, they should merely be freed from these adhesions and not

extirpated. If they are diseased, only the unhealthy portions should be removed. He had found that a piece of ovary not larger than a small bean was quite ample to maintain intact menstruation and the sexual feelings.

He contended that the aim of modern surgery is conservation. Limbs, members, and organs are now saved which formerly would have been sacrificed. This is its glory, and this has been brought about by antisepsis. On the other hand, antisepsis by the glamor of success so dazzled modern gynecology as to make it a spoiler rather than a conservator. Reform here is greatly needed, the reform of conservative gynecology.

(To be concluded.)

CORRESPONDENCE.

PNEUMONIA FOLLOWED BY MANIA.

To the Editor of The Medical News,

Sir: In The Medical News of March 3, 1894, p. 236, Dr. J. B. Campbell reports three cases of pneumonia followed by mania. His report prompts me to relate the following case: On the night of December 21, 1893, I was telegraphed for from Arlington, thirty miles distant, to see Mrs. J. There being no roads to drive on and no train until morning, I reached the case at 8 A.M. on the 22d. The woman was a Norwegian about thirty-five years old, the mother of four children. She was sitting up in bed, her clothing literally torn from her body, clutching her hair and spitting spitefully—in short, a raving maniac. Her husband and a neighbor were trying to hold her and informed me that she had been in this condition all night. Without any ceremony I injected one-fourth grain of morphin. In about half an hour the woman quieted down and dropped asleep. Her pulse was 120, her temperature 102.5°. I elicited the following history from her husband: Ten or twelve days before, she was seized with a chill followed by pain in the chest, a severe cough, and expectoration of bloody sputa. The tongue was heavily coated with a dark fur, the cheeks were hectic, and the appetite lost. It was thought the woman had influenza. These symptoms finally abated and seemed to be getting well. She had been asleep on the afternoon of the 21st, and suddenly awoke, screaming "fire." The delirium continued until I injected the morphin. Physical examination showed the middle and lower lobes of the right lung to be in a state of hepatization. I prescribed ammonium carbonate, ʒij; infusion of digitalis, syrup. pruni virginianæ, āā ʒjss, a teaspoonful of the mixture to be taken every four hours. The woman made an uninterrupted recovery. I confess, had I known of the existence of pneumonia I should have been a little more conservative in the use of morphin, although in a similar case I should not hesitate to use it again.

Yours truly,

M. B. Mattice.

Sedro, Washington.

NEWS ITEMS.

A Summer Course in Neurology and Psychiatry will be given at the Illinois Eastern Hospital for the Insane, at Kankakee, Illinois, commencing June 4, 1894, and continuing six weeks. It will be conducted under the direction of Dr. Clarke Gapen, Superintendent, by Dr. Adolph Meyer, Pathologist to the Illinois Eastern Hospital, with the assistance of the Medical Staff.

It has been arranged to have a full course with daily lectures and practical work in the laboratory and wards, and an abridged course with two lectures a week.

Recent Appointments at Jefferson Medical College.—At a recent meeting of the Board of Trustees of Jefferson Medical College, Dr. W. Joseph Hearn was elected Clinical Professor of Surgery; Dr. Edward P. Davis, Clinical Professor of Obstetrics; and Dr. S. MacCuen Smith, Clinical Professor of Otology.

Books and Pamphlets Received.

The Measured Effects of Certain Therapeutic Agents, among which especially are Lavage, HCl, and Intra-gastric Electricity, upon the Secretory and Motor Functions of the Stomach in Cases of Chronic Catarrh (Glandular Gastritis). By D. D. Stewart, M.D. Reprinted from the Therapeutic Gazette, 1893.

Atlas of Head Sections. Fifty-three Engraved Copper Plates of Frozen Sections of the Head, and Fifty-three Key Plates with Descriptive Texts. By William MacEwen, M.D. New York: MacMillan & Co., 1893.

The Pathological Signification of Immunity. By A. L. Chapman, A.M., M.D. Reprinted from the Kansas City Medical Record, 1893.

Shipowners and Ships' Surgeons. Including Truth's Article, "Doctors at Sea." By Charles Henry Leet. Pamphlet. Liverpool: Seaforth, 1893.

Mechanical Aids in the Treatment of Chronic Forms of Disease. By George H. Taylor, M.D. Pamphlet. New York: George W. Rodgers, Publisher, 1893.

Two Cases of Hyaline Formations in the Optic Nerve. By John T. Carpenter, Jr., M.D. Reprinted from the International Medical Magazine, 1893.

The Students' Quiz Series. Surgery: A Manual for Students and Practitioners. By Bern B Gallaudet, M.D, and Charles N. Dixon-Jones, B.S., M.D. Philadelphia: Lea Brothers & Co., 1893.

Is the Philosophical Practice of Medicine not Jeopardized by the Modern Methods of Venders of Drugs? By Henry L. Coit, M.D. Pamphlet, 1893.

Recent Progress in Electro-gynecology. By G. Betton Massey, M.D. Reprinted from the Journal of the American Medical Association, 1893.

Prevalent Errors in the Treatment of the Diseases of Women. By G. Betton Massey, M.D. Reprinted from the Therapeutic Gazette, 1893.

Changes in the Urine Subsequent to Nephrectomy; Two Cases. By P. Max Foshay, M.S., M.D. Reprinted from the International Medical Magazine, 1893.

A Text-book of Physiology. By M. Foster, M.D., LL.D., F.R.S. Sixth edition. Part I, Comprising Book I. New York and London: MacMillan & Co., 1893.

Traumatisms and Traumatic Aneurisms of the Vertebral Artery and their Surgical Treatment, with the Report of a Cured Case. By Rudolph Matas, M.D. Reprinted from the Annals of Surgery, 1893.

Manual of Physical Diagnosis for the Use of Students and Physicians. By James Tyson, M.D. Philadelphia: P. Blakiston, Son & Co., 1893.

ORIGINAL ADDRESSES.

PRESIDENT'S ADDRESS.[1]

BY JAMES F. HIBBERD, M.D., LL.D.,
OF RICHMOND, IND.

AT every annual meeting the officers of the Association, particularly the permanent Secretary and the Treasurer, have difficulty in appeasing delegates who are not received because the credentials presented by them have not been issued by a society entitled to representation in the Association. The law regulating this matter is plain, to wit: "The delegates shall receive their appointment from permanently organized State Medical Societies, and such county and district Medical Societies as are recognized *by representation* in their respective State Societies."

The difficulty lies in the fact that some of the State Societies are not representative bodies, and consequently this constitutional provision cuts off all delegates from such States except those commissioned by the State Society itself. While this is the letter of the law it is not the spirit that animates the organization of the Association. The constitution should be revised in this particular at least. There are two ways of overcoming the trouble; 1. Strike out the words "representation in" from the constitution where it prescribes the qualifications of delegates, leaving all such county and district Medical Societies as are recognized by their respective State Societies fully authorized to commission delegates to this Association. The other and better plan would be for every county society in each State to be represented in its State Society. Facile methods of accomplishing this can readily be selected. Perhaps the plan of organization so long in successful and satisfactory operation in Indiana might serve as a paradigm. There each county has its society, known by the name of the county, and the State Society is composed of all the members of all the county societies. Annually each county society selects delegates to the State Society, and at the same time nominates delegates to the American Medical Association who are commissioned by the State Society. This simple plan secures substantial autonomy to the county societies and provides for equal representation to the Association from every part of the State. Every member of every county society can attend the meetings of the State Society and participate in all business except voting. This seems to me both theoretically and practically adapted to a complete organization of the profession in every part of the Union, and if this Association, at this session, would formulate a scheme similar in spirit and in terms recommend it to the consideration of such State Societies as do not now have an equally serviciable organization, it would, in my judgment, be doing a good work, sowing seed that would bring forth sound fruit in the future. In Indiana the State Society and each county society are legal corporations, and while this is not essential to its method of organization of the profession of the State it is to my mind desirable.

In this connection I desire to lay before you some thoughts touching the arrangement of subordinate medical societies in their relation to the American Medical Association. Every medical man who belongs to any medical society should belong to a county or an equivalent medical society, and every member of a county society should be, *ipso facto*, a member of his State Society, and this an *open sesame* to the American Medical Association. By this arrangement all reputable physicians in the United States would be brought together in a common guild whose power to do good within its legitimate sphere would be limited only by its aggregate wit and energy. Such a consummation would place this Association in a position to fulfil the mission hopefully anticipated for it by its earnest and patriotic founders, and would elevate the American profession to a plane for useful work, the highest conceivable for the disciples of scientific medicine.

This would in no wise interfere with the organization of medical men devoted to special lines of practice or investigation; indeed, the more of these, and the more special their fields of labor and inquiry, the more rapid will be the development of medical knowledge, the nearer will expert art approach to perfection, and the greater will be the blessing to humankind. In these special and limited societies there will be a concentration of thought and labor that will yield results advanced and true to a degree beyond hope from a more promiscuous assembly.

All the adherents of the special organizations will be members of county societies, and thereby of their respective State societies, whence, for the asking, they can step through the portals of this Association, and find in our sections a department already organized and at work, into which they can enter, each according to his tastes or qualifications, and feel at home among fellow-laborers.

A member of either of these special organizations entering the appropriate section will find himself in the midst of all the members of the Association whose tastes run parallel with his own, whether specialist or general practitioner; and it is this mingling of these sundry classes of investigators and practitioners, exchanging views and detailing experience, that creates the vast stores of profit and pleasure so much enjoyed at our annual meetings. In this scheme for the organization of the American Medical profession is there not promise enough to make us hope and labor for its early consummation?

[1] Delivered before the American Medical Association at the forty-fifth annual meeting held at San Francisco, June 5, 1894.—Abridged.

A sentiment was expressed last year at Milwaukee by a member, and has, I think, some currency among other members, that indicated a misconception of the character and *personnel* of the sections as I view them. The sentiment was uttered in a private discussion of the propriety of conferring on the Business Committee the functions of the Nominating Committee, and was substantially this: My colloquist said: "The Business Committee is made up of ex-chairmen of sections; the sections are in the hands of the specialists; the specialists reside in the greater cities, and consequently the Business Committee will be constituted of special practitioners who hail from the greater cities, and some of the cities are great enough to furnish half a dozen chairmen at once. This will not only exclude general practitioners from a voice in the selection of officers of the Association, but may by chance or design place the general business of the Association under the management of specialists from a few of the more important cities of the country." The error of this misrepresentation lies in the fact that its entertainers fail to recognize that the aggregate membership of the sections of each annual session is the total membership of the Association in attendance.

True, in each section there will be members of the special society whose work is the same as that to which the section is devoted, and there will be others whose engagements are limited to the same line of practice; but these combined, except in two or three sections, will not number more than a small minority, probably not a tenth of those enrolled in the section; the other nine-tenths will be general practitioners whose professional proclivities have directed them to the section; and these general practitioners have the power by their votes, the right by virtue of their membership, and the obligation under their duty to the Association, to elect the best man in the section to its chairmanship, without inquiry whether he lives in a big city, a little city, or a hamlet, and in so doing will make it patent to every thoughtful mind that the *personnel* of the Business Committee will be selected under conditions to insure as intelligent, as well distributed, and as trustworthy a committee as the Association can secure. And, moreover, the function of a nominating committee is to nominate—not elect; confirmation or substitution is in the authority of, and always exercised by, the Association. I am led to present this subject in this light and to this extent because I feel that a majority of the members recognize the imperfections of our present mode of selecting the Nominating Committee, and realize that the welfare of the Association calls for a committee to exercise the important functions of the Nominating Committee, which has elements of permanence in its organization, and whose *personnel* has been selected with something of deliberation.

When Dr. George M. Sternberg was appointed Surgeon-General of the Army, in May of last year, he made two innovations in the administration of the affairs of the office: First, in establishing an Army Medical School, to give passed candidates for appointment to the Army laboratory practice in bacteriology, sanitary chemistry, and other essential instructions for military service; second, in filling the position of attending surgeon in cities having good facilities for medical improvement with young men who were preparing for promotion.

These changes did an excellent work that was accomplished without additional expense to the Government; the Museum and Library Building furnished the rooms, and the medical officers on duty in Washington did the teaching in addition to their regular work. But the number of active young surgeons about Washington and other cities attracted observation, and led the chairman of the Committee on Military Affairs to conclude there was a surplus of assistant surgeons, and in his report to the House he reduced the number from 125 to 90, thus inhibiting fresh appointments until the number shall be so reduced. This recommendation has passed the House, and if it should be approved by the Senate will greatly embarrass the medical service of the Army, and in the end be a detriment to the country, because many military posts will have to depend on civil physicians for medical attendance, and in case of war these would not take the field, and the Army would be without trained medical officers, which would be as serious an evil as unskilled officers in any other department. When these facts were pointed out to the chairman of the committee by other members with better knowledge of practical military affairs, the chairman replied that no one outside the Army surgeons had complained—not a single medical society had claimed that injury would be the result.

Let the American Medical Association at once call the attention of Congress to the mistake threatened.

Many of you may remember that the last Congress of the United States was about to refuse an appropriation to continue and complete the publication of the *Index-Catalogue* of the Library of the Surgeon-General's Office, the venerable chairman of the House Appropriation Committee alleging that the medical fraternity was demanding too much, in fact had already received more than the lawyers or any other professional guild. This state of affairs becoming a matter of common fame, some physicians interested their Representatives in the House by presenting to them the true state of affairs, with the result of a concerted effort being made in the House to enlighten the assembly to the extent of convincing the members that this was not an appropriation for the benefit of medical men, but to complete a great educational work for the benefit of the whole people, the doctors' relation to it being that they must do the work, because no other class of men were trained to the service. The appropriation was saved and the *Catalogue* is nearing completion.

But there is still a point in connection with the appropriation for the Library that needs attention, that can probably be better given by this Association than otherwise, and that is the restoration of a part of the appropriation for support of the Library which was dropped by the last Congress and the cut continued in the Military Bill before the present House. For twelve years the appropriation was $10,000, but the last Congress reduced it to $7000, and the present Congress proposes to continue the reduction. Doubtless most Congressmen, and possibly some physicians, regard the Library of the Surgeon-General's Office as an ordinary department library, intended mainly for the use of the medical officers of the Army; but in truth it is the National Medical Library, open to and used by physicians from all parts of the country, and the possibility of finding at one place in this coun-

try the greater part of the literature on any medical subject has exercised a powerful influence on American medical literature and education.

The Library aims to obtain every medical book, periodical, and report published in any country or language as soon as possible after its issue, and have it at once catalogued and indexed and made available for use. This requires about $7500 annually. There are still between twenty and thirty thousand volumes of medical books published years ago required to complete its equipment to meet all calls made upon it. These volumes are out of print and only to be obtained from secondhand booksellers and auction sales as opportunity offers, and will involve say $2500 spent annually for perhaps ten years. Does not this condition of the Library and its support make a demand on this Association for aid, either as an organization or through the influence of its individual members on their respective members of Congress?

The desirability of supervision of public health by the General Government has been recognized by this Association for many years and manifested in various ways. Four years ago a committee, with Dr. C. G. Comegys chairman, was appointed to prepare a bill and petition Congress on behalf of the Association to establish a Department of Public Health, with a Secretary for its chief, who should be a member of the President's Cabinet. This committee has done much earnest work, drafted a bill and presented it to Congress, devoted labor and time personally to its advocacy before committees and members of Congress. The committee has been continued, somewhat modified, and has reported annually to the Association, and will present an interesting report to this meeting, to which I invite your thoughtful attention. Last year the Association appointed another committee, with Dr. U. O. B. Wingate as chairman, to consult with a like committee of the American Public Health Association, which has for several years been engaged in an effort to induce Congress to enact a law placing the supervision of the public health in charge of the General Government. This committee will also submit a report for your consideration.

Other organizations have likewise entered Congress with petitions asking that the General Government be clothed with authority to execute measures to assist in protecting public health. Much good may be anticipated from the attention these several sanitary organizations will excite both in the Congressional and public mind, and I doubt not that when the agitation has accomplished the valuable result of cultivating a knowledge of what is essential to the public welfare it will lead to a union of effort on the part of all workers that will insure satisfactory results.

My interest in the premises is such that, during the year I have sought, through personal intercourse and a wide range of correspondence, to ferret out the best plan for supervision of public health that we can hope to have Congress crystallize into a working law. Without rehearsing details, I feel free to declare my conviction that enough has been ascertained of the sentiment of the executive and legislative departments of the Government to rob us of all hope of the establishment of a Department of Public Health within the remainder of the nineteenth century.

A bureau of public health, with a commissioner as its chief, within one of the existing departments of the government, was apparently within reach of a united, harmonious, aggressive effort of the profession for a year or two previous to the enlargement of the power of the Marine Hospital service by the last preceding Congress, but the excellent work of that service at home and abroad since its increase of authority and means has lessened the anxiety of the Government and the apprehension of the public in such degree as to make those in power less attentive to appeals to do what should yet be accomplished.

The outlook at this time for securing a Bureau of Public Health during this session of Congress is not encouraging, but if the problems in silver, and tariff, and national revenue should be speedily and satisfactorily solved there might appear a ray of hope for a bureau within the life of the present Congress, provided the medical and sanitary professions would make common and joint effort in demanding it.

At present there is no measure formulated in this behalf so worthy of support as the New York Academy of Medicine bill now in the hands of Congress, and in making this declaration I by no means ignore the fact that strong opposition to that bill has been made by strong men, but I well know that no important measure like that can be inaugurated without challenging adverse criticism, but my abiding faith in the fitness of sanitary human nature for great things is such that I harbor no doubt that if the opponents of this bill present a better one than it, its friends will accept it, and if this bill sustains its present status under severest scrutiny its opponents will join in urging its enactment into a law, and thereby vindicate characters at once wise and patriotic.

While a century of experience has convinced the great body of intelligent people that vaccination is the true and only prophylatic for smallpox, it has not carried conviction to the extent its merits deserve and the welfare of the people demands. The causes of this are not difficult to discern; vaccination and other forms of sanitation have prevented a visitation of the epidemic of smallpox in this country for a generation, and people have lost the fear of its contagion through ignorance of its nature while progressing, and its sequelæ if its victim survives. Add to this the disorders that sometimes follow the insertion of pure vaccine in a cachectic system, and the greater evils arising from the use of spurious or imperfect vaccine and careless vaccination, all open to the observation of the public and subject to amplification by cranks and the maliciously ignorant, and we cannot marvel that there is a positive distaste for vaccination among a considerable portion of our population, and a carelessness about securing it on the part of a much larger number. A knowledge of these facts should only inspire physicians and other sanitarians who are the custodians of the knowledge of the value of vaccination to redoubled activity in devising and executing popular methods of instruction as to the entire reliability of vaccination to protect from smallpox, as much so as smallpox itself, and that with pure vaccine inserted under proper conditions into the tissues of a person fit to receive it there is positively no shadow of evil, but a promise of good not surpassed by any other single measure of preventive medicine.

Evidence accumulates that the undetermined conditions that conduce to the propagation of smallpox are now, and for at least two years have been, prevalent in this country, resulting in outbreaks of the disease more or less serious in various parts of the country, and too often leaving foci from which fresh infection is distributed. Under these circumstances it seems to me the reasonable duty of this Association at this time to declare and proclaim its unabated faith in the virtue of vaccination to protect from smallpox, to render persons as immune against variola as an attack of variola itself, and that it is innocent of all mischief when the vaccination is done by a vaccinator who is a competent judge of both the purity of the vaccine and the fitness of the vaccinee.

Let us abide in the hope that the Jenner centennial celebration provided by this Association, and to be a part of its exercises at the annual meeting in 1896, may bring out the boundless blessing of the discovery of the immortal Jenner in such wise that all men shall see and acknowledge its protecting power, and even the wayfaring man, though a fool, may not err by further causeless cavil.

Two leading purposes the fathers of this Association had in view at its organization, demanding its serious consideration, were the elevation of the standard of medical education and that the authority to decide upon the sufficiency of the qualifications of a candidate for a diploma should not rest with his teachers.

Much has been done in advancing the extent and character of the collegiate instruction of medical students; the examination of candidates for diplomas is still conducted by teachers who instructed them, as was done then, and is no more satisfactory to the thoughtful minority of the profession now than it was then. Forty-eight years ago seven professors formed the conventional number of the faculty for medical colleges, and the annual term was twenty weeks, and in the two terms required for graduation the students heard the same lectures each year. Now there are medical colleges requiring attendance four years of seven months each, on graded courses under, in some instances, as many as forty-eight instructors. This for the equipment for graduation, while one post-graduate school announces one hundred and sixty-four instructors. Certainly the Association has ground to congratulate itself on the fruits of its persevering labors to secure more thorough medical education; but this has been the theme of so much of the literature of the Association that I drop the general subject and confine my remarks to one suggestion as to a particular line of instruction.

The progress of medicine in the immediate future must be along biologic lines, and to me it seems desirable that every medical college should have a chair devoted specially to instruction in biology. Within the current year, responding to an invitation to make some remarks on matters pertinent to a lecture on bacteria which had just been delivered, a genteman of superior culture, of extensive travel, and acute observation, a lawyer by profession and a statesman by practice, said that the status of physicians had within comparatively few years undergone a marked change. In earlier historic times the priests were accounted of highest rank and worth in the civil professions; then came a period when the devotees of statecraft received highest honor, and exercised most potent influence in the affairs of men; physicians held subordinate rank and position both in war and in peace; but in the last few decades the relations of these professions among themselves, and in their standing before the world, have undergone significant change, until, from being the lowest, physicians are now rising above the other liberal professions, and will steadily move forward until they are accorded the first place among honored people of the world, and this for the reason that they have devoted themselves by rigid scientific investigations to make patent the causes of disease, and to determining exact measures for emasculating these causes, and for neutralizing their effects when they have eluded detection or escaped emasculation. My own sentiments accord entirely with the spirit of the views enunciated by the learned gentlemen, and my estimate is based on the result of the more exact methods applied to the investigations of the laws by which the omnipotent Creator has fashioned the world and continues its government. The microscope in skilled hands, and its revelations compared and classified with scientific acumen, have revolutionized our knowedge of the world of living things below the world of macroscopic living things, and in this minor, and, to us, newly revealed world, have been discovered the generators of the most extensive, persistent, and malignant epidemics that periodically decimate the earth, as well as many of the most frequent, and intractable, and fatal disorders that we have always with us. All this knowledge has been wrought out by the devotees of one branch of biology, and another line of biologic workers have carried us back through the morphology of organs, tissues, and cells to the origin of vital activity in protoplasm, and, still more important in doing so, have given us glimpses of the origin and development of the somatic mind that will, when the scheme of nervous organization and function shall be clearly portrayed, dissolve the mystery that has in the past obscured our realization of the true nature of hypnotism, Christian science, and other anomalous neuroses which the sciolists, and in an especial manner those claiming to be doctors, are promulgating and practising, to the discredit of true scientists and the injury of the ignorant and weak-minded classes.

We should apotheosize protoplasm, the dividing line between inorganic and organized matter, itself at once the result of the law of perpetual motion with which the Creator endowed the atoms of elemental matter, and the beginning of that phase of energy known as vital activity, which, in its development, as now presented to us, constitutes the entire vegetable and animal kingdom.

No one people or class of people can claim exclusively to have opened the way into this more primitive arcana of Nature. The physicists of all nations, botanists, zoölogists, anatomists, physiologists and their congeners have all participated in this progress. Schwann and Virchow and Ferrier and Jackson and Pasteur and Koch and Sternberg may be mentoned, without prejudice to the labor, name or fame of their many coadjutors, as examples of what benefactors to our race scientists may become whose genius lifts them to a plane of investigation not covered by the curricula enforced in the medical schools of their day, and their distinction is due to their advanced study of biology.

This review impresses me with the importance of es-

tablishing in each of our medical colleges where a finished education is intended, a chair especially devoted to teaching the principles and practice of biology on the lines and to the extent herein indicated, from whose alumni we shall have more quickly arise neophyte Virchows, Pasteurs, Jacksons, and Sternbergs, whose labor, when further advanced, shall hasten the day when the world shall recognize the medical profession as the paramount benefactors of the human race, by virtue of suppressing the causes of all preventable disease and alleviating the suffering, shortening the duration, and lessening the ravages of such as cannot be prevented. And with this higher estate of the disciples of Æsculapius will come such insignia of real knowledge, such fruit of expert skill, that he who runs may read the lines that broadly separate the true physician from ignorant or unscrupulous pretenders.

Amendments to the constitution are always pending, sometimes many, sometimes few; those submitted the preceding year are disposed of at each annual session, but others take their place for consideration at the succeeding meeting. Few of these are approved by the Association, being lost through failure to receive the support of three-fourths of the delegates present, or by not being called up by their authors or others.

Last year a special committee, appointed at the last preceding meeting, made a report remodeling the entire constitution, which necessarily laid over until this meeting, and the committee, being continued, will make further report here, and the whole subject will come up for final disposition at this meeting. It is apparent to all who have given attention to the matter that there is much feeling among the members who have been active in working up the changes that will be offered as a substitute for the constitution as it now exists, and also among those who regard the innovation an evil instead of a benefit. But while these feelings are right and proper in themselves, they need not claim other than watchful attention to secure a fair and unbiased expression of the will of the Association according to the method prescribed by our laws, and in so doing there is nothing to excite passion or interfere with that calm deliberation that distinguishes the proceedings of an assembly composed of cultured and refined people seeking the welfare of the guild to which they belong. This may readily be done by taking a vote to determine whether the voters present desire any change in the existing constitution. If this decision is against any change the question is concluded for the nonce. If the decision expresses dissatisfaction with the constitution as it is, the next question should be: Is the report of the Committee of Revision precisely what the voters want as a substitute? An affirmative vote here settles the matter, and a negative vote will call for amendments that will adjust either the existing constitution or the committee's substitute until it conforms to the wish of the delegates. Is it not palpable to every considerate mind that all this may be done without excitement of any kind, and with a minimum waste of the time of the Association?

And so too with our Code of Ethics. For many years there has been a feeling among many most excellent and intelligent working members of our guild that the Code did not fairly accord with the demands of the advanced profession in their intercourse with each other, nor with the proper reciprocal relations between the profession and the public; while, on the other hand, many members equally intelligent and devoted to the Association have felt that the Code of Ethics that has guided the Association through nearly half a century prosperously and honorably, and is still a reliable guide in every advanced thought and action, cannot be bettered for our present status, and should not be disturbed. At Detroit, in 1892, this agitation culminated in the appointment of a committee to inquire into the expediency of revising the Code. This committee last year submitted two reports, the majority recommending an amended Code, and indicating the lines on which emendation should proceed. The committee was continued to complete its labors, and the fruit of its service will be before you in an extended report. The minority report claimed the sufficiency of the Code as it is, and recommended that it be left intact. Here also, even more than with remodeling the constitution, there is much warmth of feeling, and as in that case a little calm forethought will convince that a primary vote, involving the question whether or not the voters want any alteration of the Code, may end the consideration of the subject without excitement, confusion, or overwarmth of feeling by a decision to let the Code stand as it is, and a contrary decision will call for such further procedure as recited for the completion of an amended constitution, and in this, as in that, the work should be done as intelligent and fair-minded citizens transact important business, with decorum and without waste of time.

Touching the sufficiency of the Constitution and Code of Ethics of the American Medical Association as they are now, I have well settled convictions, the result of many years' observation, experience, and reflection, but I am not here to proselyte to my opinions. As I interpret my mission on this occasion, it is to exercise my influence and use my authority to secure to those here entitled to vote a clear expression of untrammeled judgment, and to encourage a cheerful acquiescence of all parties in whatever conclusion may be thus reached.

Shall I not have the co-operation of every friend of the American Medical Association present in this laudable effort?

ADDRESS OF THE CHAIRMAN OF THE SECTION OF OBSTETRICS AND DISEASES OF WOMEN, AMERICAN MEDICAL ASSOCIATION.[1]

BY JOSEPH EASTMAN, M.D., LL.D.,
FORMERLY PROFESSOR OF ANATOMY AND PROFESSOR OF GYNECOLOGY AND ABDOMINAL SURGERY, CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS, INDIANAPOLIS, INDIANA.

MR. CHAIRMAN, LADIES AND GENTLEMEN: It seems best on this occasion to turn aside from the usual custom of reporting progress in the department of Obstetrics and Gynecology, a subject which has been so often and so ably presented by my predecessors, and call your attention to the present status of suprapubic hysterectomy, as viewed from the standpoint of personal observation and clinical research, with the hope that I may contribute in some small measure to the profitable discussions which I am quite sure will follow the reading of the valuable papers on your program.

[1] Delivered at San Francisco, June 5, 1894.

It is not my intention to report a series of operations peformed for the removal of symmetrically formed pear-shaped tumors with well-defined broad ligaments, with uterine arteries easily accessible and pulsating in their anxiety to be ligated—tumor, ligaments, and arteries dealt with by some definite method, each operation performed in exactly so many minutes, and all the patients making uneventful recoveries. The literature of the subject is already cursed with such productions. Therefore, I would rather suggest such means and methods as experience has taught me will furnish the best possible results in dealing with tumors by no means symmetrically formed; with broad ligaments displaced and disorganized by nodular masses interfering with the ligation of arteries and the easy formation of pedicles.

Despite the efforts of some to name a distinct method of operating, because a flap is made here, or a ligature placed there, the problems of suprapubic hysterectomy are rapidly nearing their solution. Those engaged in the work are divided into two classes: First, those who have been and are yet satisfied with forming a pedicle and fixing it in the abdominal wound; second, those not satisfied that this method is the best that could be devised, and who have earnestly endeavored to reach some method that shall disregard the morphology of tumor, of broad ligaments, and the location of uterine arteries.

On February 3, 1887, knowing full well that abdominal fixation of the pedicle in suprapubic hysterectomy had at that time given the lowest rate of mortality, I decided not to operate in that way, but planned and executed an operation which in every essential feature was an extirpation of almost the entire cervix. A large cautery passed three times down through the cervix in reality destroyed a large portion of what little cervix was left. A rubber drainage-tube was inserted for vaginal drainage.

In a recent discussion in the *New York Journal of Obstetrics and Gynecology*, the operations by Stimson, Krug, Baer, and myself are spoken of as if they were all operations of total ablation of the uterus. If these operations are to be considered, then the operation of Stimson in November, 1888, was antedated by my determination to secure something better than the abdominal fixation of the pedicle, on February 3, 1887.

It is not my purpose to occupy time in discussing questions of priority, although the operation, including the use of my hysterectomy-staff, as I demonstrated it at the International Congress in Berlin, has since been performed many times by Chrobak, of Vienna, and by numerous American operators, with great satisfaction, and while I received many congratulatory letters from distinguished operators, on account of the rapidity and definiteness of the operation made possible by the use of the staff, I have been working to still further simplify and perfect the operation.

I concede the fact that when a given fibroid tumor has no nodular masses in the region in which we would form a pedicle or imbedded in the broad ligaments, and when the abdomen is not exceedingly fat, abdominal fixation has given results, in the hands of expert operators, in a very high degree satisfactory. So far as I have been enabled to read the writings of its warmest advocates, none of them has mentioned the very strongest point in its favor: namely, that in this method we have practically *one wound*, whereas in total or partial extirpation-methods we have two wounds, the one in the abdomen, the other in the pelvis, the latter extending, through connective tissue rich in lymphatics, down to the vagina, an incubator for many varieties of bacteria, and which cannot always be sterilized and maintained aseptic during an operation. Notwithstanding the strong points in favor of abdominal fixation of a pedicle, which I have mentioned, it has been the subject near my heart for nearly eight years to study out the anatomy and its displacements by pathologic neoplasms, and perfect a method as speedy of execution, followed by as successful results, as any or all other methods—a method applicable not only to tumors when a pedicle for abdominal fixation could be easily formed, but also to those cases in which nodular masses have completely disorganized the cervix, and intra-ligamentous masses are found in the broad ligaments of one or both sides.

I became well convinced a number of years ago that the use of the clamp of Keith or the serre-nœud of Koeberlé for controlling hemorrhage from the neck of the uterus was based upon the idea that the spiral or curling branches given off from the uterine arteries really penetrated the tissues of the uterus, including its cervix. Some seven text-books on anatomy, which I have examined, state that these branches penetrate the uterus. I have a number of times, with fingers on the broad ligaments and their contained vessels, cut directly through, seizing the spurting vessel, and securing it later. I have also peeled off the uterine arteries from the sides of the uterus and then cut off the cervix with little or no hemorrhage.

These studies were made for the purpose of reducing the number of ligatures,[1] long or short, to become encapsulated or slough off through the vagina, and also to economize the time required for their thorough application.

Here is a nodular mass, fed and nourished by a capsule—a capsule containing the venous and arterial capillaries. It is well known to every gynecic surgeon that these nodules can be peeled out of the capsule without ligating a single artery. What I have stated regarding the nourishment of this nodule by its network of capillaries, and not by the penetration of the arteries (for surgical purposes), holds true with reference to a uterus disorganized by a fibroid tumor or tumors, *no matter how large or how small;* not only the fibroid uterus, but the normal uterus as well; not only the uterus, but its *entire cervix down to the external os.*

I here present a specimen (a photograph of which can be seen in the *American Journal of Obstetrics and Diseases of Women* for the current month), and to my mind it marks a *new era in the removal of fibroid tumors by hysterectomy*, for the reason that the uterine arteries were not ligated at all. I went down between the uterine arteries and the uterus. The uterine arteries were absolutely left in the pelvis of the woman, not a single ligature being used except those which tied off

[1] A ligature to secure the uterine arteries will often secure a certain amount of muscular and connective tissue, and is one of the possible sources of infection of the wound; hence the importance of having as few ligatures constricting tissue in this work as possible.

the ovarian arteries and a small portion of the upper border of the broad ligaments.[1]

Then, in addition to solving the problem as to what to do with the pedicle, by deciding not to have any, we now solve the problem as to what to do with the broad ligaments and especially their contained uterine arteries, by simply leaving them in the pelvis of the patient.

In this case I simply controlled the circulation in the ovarian artery by ligating the upper portion of the broad ligaments with a strong ligature; then cutting the broad ligaments above the ligature, began with the serrated gouge to peel down the broad ligaments, keeping the gouge close to the tumor, being especially careful in the interspaces between the nodules not to puncture or tear the uterine artery or any of its branches. From time to time, nicking the edges of the peritoneum with button-pointed scissors, with the serrated cutting edge I pushed it forward under the peritoneum, anteriorly and posteriorly, so as to make anterior and posterior flaps. Then, pushing with the serrated gouge, I carefully worked around the tumor until I had reached the uterine cervix, and then proceeded with still greater caution not to cut the cervix or its capsule, but to push it down as I now slip my cuff toward my elbow with the fingers of my right hand. The enucleation of the lower portion of the uterus, including its cervix, reminds me of Professor Sayre's admonition when removing the head of the femur for hip-joint disease. He says, "I take this oyster-knife and work my way past the trochanters, major and minor, then make sure to get beneath the periosteum close to the bone." Then he used to say, "d——n the anatomy, stick close to the bone," and proceeded to peel off the periosteum until he had the entire head of the femur out of the acetabulum.

As I reached this lower part of the cervix my hysterectomy-staff was passed up the vagina by my son, Dr. Thomas B. Eastman. I then removed the entire cervix, cutting a little opening upon the staff, slipping a strip of gauze in the fenestra of the staff. When the staff was withdrawn this was brought down in the vagina, the upper portion of the gauze being packed into the pocket from which the cervix had been enucleated. The flaps which I had dissected off from the tumor and the cervix were brought together by buried suture over the ligatures, which had included the ovarian arteries, so that their raw ends also came into the wound. Several rows of buried suture were used, so that all raw edges made by peeling out the cervix were deeply buried so as to prevent leaking into the peritoneal cavity, the gauze being dragged down into the vagina a little each day, and facilitating perfect drainage in that direction. This operation is the *realization of the ideal.* Heretofore all of us had simply been *idealizing the real.* In a lecture delivered to the Post-Graduate School of Chicago, in July 1893, I closed with a series of conclusions. From them I quote the third, to wit: "When the neck of the uterus remains small, the abdomen not too fat, after the ovaries and tubes have been tied off the pedicle may be fastened in the lower angle of wound and give satisfactory results." To this conclusion, stated at this time, I have this to add: When such anatomic conditions exist, enucleation of the cervix can be done in less time than the manufacturing of the pedicle, the adjustment of the serre-nœud and elastic ligature. Furthermore, abdominal fixation of the pedicle cannot be accomplished in all cases.

In conversation with several distinguished abdominal surgeons, including Dr. Bantock, of London, I find that these gentlemen quite frequently meet with cases in which no pedicle can be formed to fix in the abdominal wound. It is to this class of cases I would invite the best directed efforts on the part of those who have a heartfelt interest in this class of suffering women.

One's percentage of recoveries would undoubtedly be much better if, after making a careful examination which discloses a tumor deeply imbedded in the pelvis, we would discourage operative procedure; but in my first one hundred hysterectomies I found a number of cases presenting gangrenous tumors and tumors containing gangrenous nodules, causing slow death in some cases and rapid death in others, from septicemia. Within the last six months I have operated on seven women who had either gangrenous fibroid tumors or fibroid tumors with gangrenous nodules. In five of the cases the nodular masses were deeply imbedded in the pelvis, and two of the cases were operated on within one week. In each case a nodule as large as a cocoanut was completely imbedded in the broad ligaments, having been developed from low down on the side of the uterus, and in both cases the nodular masses were in an advanced state of gangrene, in consequence of which there was an elevation of temperature ranging from 100° to 103°. In two other cases the subserous tumors had become gangrenous from small twisted pedicles.

In each case rapid and well-pronounced septicemia threatened the life of the patient. Surely the technique of suprapubic hysterectomy is not complete until it is guided by sound surgical principles. We have methods and means for this class of cases.

In this class of cases I have been pleased with the rapidity with which we can ligate the upper portion of the broad ligaments, cut the same loose from the tumor, peeling the peritoneal covering off from the tissue, leaving a little subserous tissue beneath it; enucleating nodular masses and directly find ourselves down on the uterine cervix close to the external os with only an occasional bleeding from some enlarged arterial twig.

The most serious question in my mind in these cases is how to properly drain the cavities from which the nodular masses have been enucleated. In a recent case I packed the cavity in the broad ligament, from which I had enucleated a gangrenous mass as large as a cocoanut, with iodoform-gauze, bringing the same out at the side of the pedicle, which I had fixed in the abdominal wound. In addition to the gauze I placed a metallic drainage-tube well down into the pocket. I wished to be absolutely certain that this cavity was thoroughly drained, believing that in other cases in which I had trusted to gauze alone for drainage it was not satisfactory. In the first forty-eight hours we pumped out of this drainage-tube fully a pint of black blood, which,

[1] Sauter, three-quarters of a century ago, removed the uterus per vaginam without clamp or ligature. (See article by Dr. Guido Bell, Indiana Med. Journal, February, 1894.) Further, the enucleation of the cervix per vaginam was made by Langenbeck in 1813; by Recamier in 1829, and by Malgaigne at a later date. (See letters by Dr. Robert Reyburn, THE MEDICAL NEWS, February 10, 1894, p. 146, February 24, 1894, p. 223, and May 12, 1894, p. 529.)

coming from the cavity occupied by this gangrenous nodule, emitted considerable odor, notwithstanding the thorough washing of the cavity through the drainage-tube. I believe it would be better in such cases to secure the most thorough vaginal drainage, not only through the opening made by the enucleation of the uterine cervix, the same being packed with gauze surrounding a drainage-tube, but by making a free and direct opening from the bottom of the cavity in the broad ligaments into the vagina. It has been taught that the dangers of removing cysts or fibroids from the broad ligaments lies in the disturbance of important plexuses of nerves. My observation leads me to believe that the shock is not materially great in such enucleations, and that the bad results following such operations are due to the use of drainage which does not properly drain. But while I secured the most perfect drainage in the case referred to, by bringing the drainage-tube up to the side of the pedicle, I would not advise abdominal fixation of a pedicle in cases in which nodular masses are enucleated from the broad ligaments and even imbedded in the region of the cervix, where we would form a pedicle, believing that these cases can be treated more successfully by removal of the entire cervix, with free vaginal drainage.

As I suggested at the beginning of this paper, one of the great objections to total extirpation of the cervix and vaginal drainage is that we make an additional wound and have a possibility of vaginal infection. I concede further, that it is not always possible to render the vagina surgically aseptic. I have had a number of cases in which I used the most thorough antiseptic douches, and then sought to wash out the cavity of the uterus for the purpose of packing the same with iodoform-gauze and also to close the external os by firm suture, and found the cervix and external os so retracted into one of the cul-de-sacs or behind the pubes that it was impossible to reach it with any form of speculum in such a manner as to enable me to pack the cervical cavity or stitch the same, so that during our handling of the tumor we found a large quantity of bloody purulent discharge in the vagina which had escaped from the external os. In a large percentage of cases a thorough washing of the uterine cavity, packing the same with iodoform-gauze, and then stitching the external os will prevent this purulent fluid from escaping into the vagina during our handling of the tumor. Then thoroughly washing and even scrubbing the vagina with a brush and packing the same, including all its cul-de-sacs, with iodoform-gauze, will give us a reasonable assurance that his canal has been made aseptic, and the dangers of infecting the peritoneal cavity reduced to the minimum.

In a conversation with Dr. Bantock, of London, I expressed the hope that in the near future we would be able to remove fibroid tumors with the same low rate of mortality that follows our work in removing ovarian cysts. The good doctor replied: "This can never be done, for the reason that the anatomical conditions are essentially different." Carefully reflecting over this statement, I have become thoroughly convinced that a more thorough study of the essential anatomic conditions that exist in an abdomen containing a fibroid tumor, as compared with one containing an ovarian cyst, would enable us to bring the mortality of the two operations to something approximating equality.

I have a number of times left the greater portion of the uterine arteries remaining in the pelvis of the patient, but from the results I had I was thinking that the possibility of infection through the rich chain of lymphatics at the side of the uterus was greater in such cases than when the broad ligaments were thoroughly constricted by ligature all the way down to the opening in the vagina. This led me to express, in the Chicago lecture already referred to, my preference for cutting around the cervix rather than enucleating it. But carefully reflecting upon the statement of Dr. Bantock, that the anatomic conditions are essentially different in fibroid tumors from what they are in ovarian cysts, I have also become convinced that we often charge the fault to the technique which we have used in treating the pedicle, when the cause of death ought to be explained in some other way. For example, when the parietes of the abdomen are rendered thin by the pressure of an ovarian cyst, the blood-supply is reduced so that all the intra-abdominal viscera are more or less anemic. This condition is in marked contrast with the hypernutrition often present in and about the pelvis which contains a fibroid tumor. I am quite sure that deaths occur in consequence of our losing our heads in the determination to make the pedicle and all pertaining thereunto as perfect as possible, and neglecting perfect approximation of the abdominal incision always as long as the tumor, including its peritoneum. I have many times cut through two inches of fat to reach a fibroid tumor, and unless such a wound be thoroughly closed by three rows of sutures, the internal one being of fine silk, with stitches not more than one-fourth of an inch apart, and then making absolute sero-serous approximation, there is danger of infecting the peritoneal cavity by discharges leaking into the abdomen. Too often we take extreme precautions to nicely adjust the outer integument, when it would be better, if any leakage from the wound is to occur, that it shall pour outward and not inward. Again, the more vascular condition of the peritoneal cavity and its contained viscera, in cases of fibroid tumors as compared with ovarian cysts, warns us of the greater intolerance of rough manipulation, making it necessary to protect intestines and viscera as much as possible during operation by hot sterilized towels or sponges, by temporarily bringing the wound together over the intestines with a temporary stitch or volsella, and, *above all and over all*, by the *most thorough irrigation* of the peritoneal cavity with water at a temperature not less than 110°, we should wash out, not only after the work has been completed, but at intervals during the work, so as to undo the harm we do to the vasomotor nerves distributed to the pelvic and abdominal viscera. Half a dozen pitcherfuls of water are none too many, and if we have produced material shock, as evidenced by the pulse, a few pitcherfuls of water poured through the drainage-tube and allowed to pass out again have at times, as I believe (*permit me to say, I absolutely know*), saved lives that otherwise would have been lost. The operator of to-day who seeks to do away with the "wash-out" and the drainage-tube on all occasions, on theoretic grounds, is rolling the wheels of progress backward. The skilful management of a patient during shock is of very great importance, indeed. The use of opium to put

the disturbed tissues at rest has the genuine ring of surgical wisdom. The use of strychnin to keep up the tone of the nerves distributed to the intestinal tract, and thereby counteract the tendency to gaseous distention of the bowels, is one of the precious comforts to the anxious abdominal surgeon when his patient is low in shock.

When Ephraim McDowell did his first ovariotomy the citizens surrounded his house, threatening his life because he was about to "butcher a woman." The sheriff of the county interfered. At first they refused to listen to his pleadings for the Doctor's life. Finally he struck a compromise, the mob agreeing to let the Doctor alone if the woman recovered, the sheriff agreeing not to interfere with the mob if the woman died. This was a crucial test of the Doctor's heroism. Other heroic surgeons for years did not hesitate to remove ovarian cysts, but allowed women to pass on to their graves if the diagnosis convinced them that the trouble was a fibroid tumor. Still later, surgeons removed fibroids if they were pear-shaped and a pedicle could easily be found, allowing women to pass on to their graves if the examination showed the tumor to be deeply imbedded in the pelvis by nodular masses. Even the great and noble Dr. Thomas Keith, after battling with fibroid tumors with as good a percentage of recoveries as anyone at that date, finally abandoned myomectomy, resorting to the use of electricity, and only wished that he had back from their graves the patients that had died from his operations for fibroids. Thank God, there were others to take up the work when he became discouraged. The old adage that the qualifications of a surgeon are "the head of an Apollo, the eye of an eagle, the heart of a lion, and the hand of a woman," is eminently true, especially as regards him who would seek to be successful in removing fibroid tumors. The head to plan and to meet the surprises which spring on us during such work; an eye to see quickly the exact constriction of every ligature and adjustment of every suture; the lion's heart to press forward in this aggressive work, when our percentage of recoveries might be better if we would let fibroid tumors alone, especially bad ones; the nimble wit in the end of the fingers, backed by an indomitable will to skilfully and speedily perfect the adjustment of the last suture with the same precision as the first, make a combination of qualifications suggesting that the surgical type of a man is not to be found thirteen times in a dozen.

No other operation so thoroughly demands that the trinity of surgery be carried out—thorough preparation of the patient, thorough operating, and skilful after-treatment. As American surgeons, we have a right to be proud that no nation leads us in the originality of methods or successful results in removing fibroid tumors. Almost every State of our Union has operators who would venture to give a woman with a fibroid tumor the chances of life which surgery offers.

With a more thorough and perfect understanding of the essential anatomic conditions which make an abdomen containing a fibroid tumor different from one containing an ovarian cyst, with the realization of the ideal method applicable alike to all fibroid tumors, regardless of their morphology—a method as successful in the hands of the many skilled operators as the few—may we not hope to say, with all sincerity, that fibroid tumors can be removed with the same low rate of mortality which has placed ovariotomy among the brilliant triumphs of the century. Then shall the torch lighted by McDowell in the midnight darkness shine forth with resplendent glory in this brilliant noonday of abdominal surgery. The century, which in a few years will have rolled on to the eternal past, has placed in the magnificent temple of medicine many pillars of surpassing beauty and grandeur, while its surgical columns have risen high toward Heaven, where as gilded towers they fain would vie with the God-given sunshine in dispelling the chill and gloom of human agony.

> Chirurgia's tower, thy lights respleudent blaze,
> Dries woman's tears and lengthens out her days.
> McDowell and Sims, of our Columbia's clime,
> Began the work, moved onward, nigh sublime.
> To woman, then, these blessings shall be given,
> Queen of the home, and home the type of Heaven.

Abdominal surgery is proud of her past because it is prophetic of her future. Even now, in the vital present, it shall stand forth unchallenged as the crowning glory of all science and of all art.

CLINICAL MEMORANDA.

LAMINECTOMY FOR FRACTURE OF DORSAL VERTEBRÆ.

BY CASPAR W. SHARPLES, M.D.,
OF SEATTLE, WASHINGTON.

THE case forming the subject of these notes is reported to add to the scant collection of such cases, and to offer a small degree of encouragement for operation upon similar ones. The case and its progress show only a partial success; it was operated upon by me through the courtesy of Dr. D. A. Mitchell, of this city.

C. B., twenty-eight years of age, on May 8, 1893, was injured in a peculiar manner. A very small steamboat was suspended by a rope passing under her stern and attached to the machinery of a pile-driver; the boat was raised so that a man could pass under it in a row-boat. While the patient was at work under her in this way, the rope broke and the steamboat fell on him, doubling him up in the boat, and sinking him and the small boat under the water. As he came up he caught the side of the boat, and thus was saved from drowning. His legs were paralyzed at this time and the pain around his body was intense.

On the next day I first saw him, and found complete paralysis of both motion and sensation from the waist down. The line of separation between esthesia and anesthesia was at the eleventh dorsal vertebra. The bladder and bowels were paralyzed. The pain was intense around his body, and it was aggravated very much by motion. The fracture was very evident by reason of lateral motion and the detection of the fragments at the eighth dorsal vertebra, although the swelling was very great. Blood was extravasated over a very large area, and, on opening the tissues, the clotted blood rolled out; so extensive was the fracture as to separate the tissues, so that it was not necessary to dissect them from the laminæ. The lower fragment of the column projected an inch posterior to the plane of the upper one.

To see the condition of the dura, and, if advisable, of the cord, the laminæ of three vertebræ were removed. The dura was found intact; the cord was bent at quite a sharp angle; pulsation was absent. On the under side of the cord were several small fragments of bone pressing upon its anterior surface. These were removed, together with a portion of the body of the eighth dorsal vertebra as large as a cube three-fourths of an inch in size. This was found free. Blood-clots were numerous in the canal.

The tissues were found to be separated from the anterior surface of the bodies of the vertebræ, so that a finger could be passed around. The dura was not opened. An attempt was made to fasten the bones in position by wiring, but this was futile. Free drainage was provided for. On account of the inability to dress in a plaster cast at once, long wooden splints were fastened around the man's body. For a few days the temperature was quite constant at 101°, rising once or twice quite suddenly. The day following the operation he spoke of a tingling in his feet, and on the next day there was a desire to urinate. The man passed a few drops voluntarily and said that he could tell when his feet were touched.

The subsequent history is as follows: Paralysis has been constant and complete. A spastic condition of the muscles of the legs has developed, which is more marked on the right side. The skin-reflexes generally are exaggerated, though the cremasteric reflex is about normal. Anesthesia has been and is complete from a line drawn around the body on a level with the crests of the ilia and extending down to two inches above the symphysis. The line of demarcation is sharp and has descended since the operation. Control of the bladder and rectum is gone. The patient thinks that at times he feels a desire to urinate, but this may not be so. He suffers no pain. Two small bedsores have formed over each trochanter, but are now becoming smaller. There is a small fistula in his back and the back is stiff. He can sit up, though he rarely does this, being more comfortable lying down. The general nutrition has been good all along and he has gained flesh.

In attempting the operation, I, of course, realized that the mortality-rate was high, yet Phelps has stated that the mortality-rate of the fracture from crushing or bending is the highest, and such cases are, therefore, less desirable for operation, as the cord, too, has been crushed.

The mortality of fracture of the spine is large. Agnew reports seventy-three cases treated at the Pennsylvania Hospital, of which forty-seven died in the house, seventeen were removed, and no doubt subsequently died, one was cured, and eight were unrecorded, so that probably only one case out of seventy-three recovered. Ashhurst has analyzed sixty-one cases in which operations were performed, giving a mortality of 73 per cent., and only three cases of fair results. He condemns the operation except for exceptional cases.

In cases that are not operated upon, Cooper and Séquard give the mortality as 99 per cent., and Erichsen has said that all cases are fatal, while Ashhurst gives the mortality at from 61 to 78 per cent., according to the seat of the injury. It would not be just to compare the results of operations for disease of the cord and those for fracture, performed either at the time of the injury or later. Many cases that do not die as the immediate result of the injury die later of myelitis and its consequences. This is due to the traumatism or hemorrhage of the cord. The injury of the cord may be caused by compression at the time, or by constant compression from the deformity, or from spicules of bone. To overcome this possible condition is the indication, and this can be better done by an operation than in any other way. Should a fragment of bone be pressing on the cord or into its substance, it can be removed, which removal would diminish the dangers of secondary inflammatory action. These facts I offer as the one reason for the operation.

The dura was not opened in my case, for I could not see how any possible good could come of it. Should the cord be injured, it was from compression and crushing, and for this nothing could be done.

There is yet another point to be met, and that is the time of operation. It is easy to see that every hour of delay after the patient attains a state to warrant an operation is so much added to the dangers of secondary inflammatory action; and so it seems to me that, if an operation be justifiable, it should be done as soon as there is recovery enough from shock to justify it. In many of the cases of which I have seen accounts, the operation has not been performed till late, and then it could not be of the same value as if performed early. The mere operation, while adding to the gravity of the case, is usually recovered from. It should be remembered, however, that even a late operation may favorably change the conditions.

Most favorable cases have been those in which only the laminæ have been injured, and Ashhurst recommends that only such cases should be operated on. These are the cases that, if let alone, would make a recovery, and if the operation be restricted to those cases, practically the indications for the operation are not met. I think, however, that it is better to operate on cases of injury to the laminæ than to take the chance of a spicule of bone in the cord.

In cases like the one reported, the best that could have been hoped for would have been a fibrous union between the bodies of the contiguous vertebræ, and even this would not have been enough to permit any very extensive use of himself by the patient. Yet judging from the standpoint of human life, this man is now alive and free from suffering, while, had he not been operated upon, considering the extent of the injuries, he no doubt would have died, though even now he is only a helpless cripple.

THE IDENTIFICATION OF THE LARGE AND OF THE SMALL INTESTINE.

By J CHALMERS DA COSTA,
OF PHILADELPHIA.
DEMONSTRATOR OF SURGERY IN JEFFERSON MEDICAL COLLEGE.

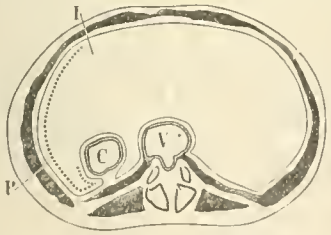
In abdominal operations it is frequently imperatively necessary that we recognize with certainty the large intestine or identify positively the small bowel. The size of the tube will not always help us in this recognition, as a small intestine may be enormously large because of distention, and a large intestine may be contracted to the size of a finger because of obstruction above.

The longitudinal muscular fibers of the large bowel are accentuated in three portions, and these accentuations constitute the three longitudinal bands which begin at the cecum, and terminate at the end of the sigmoid flexure of the colon. Each band is composed of a number of shorter bands, and the shortness of these constituent bands permits the sacculation of the large intestine. Longitudinal bands and sacculation are not met with in the small gut, and we have in their presence or absence a means of identification in many cases; but when the colon is much distended the bands cannot be seen, and the sacculation disappears. (Edmund Owen.) From the large intestine only spring the appendices epiploicae, small overgrowths of fat in pouches of peritoneum, but these appendices are sometimes not well marked, except upon the transverse colon, and when emaciation exists they may almost entirely disappear.

The relatively fixed position of the large intestine and the free mobility of the small bowel are important points of distinction. The foregoing statements indicate that it is not always easy to distinguish between colon and small gut, and that according to old rules it may often be necessary to make large incisions, to look as well as feel, and to extensively handle the bowels. Any scrap of knowledge which will shorten an abdominal operation, which will permit of as certain work through a smaller incision, and which will diminish handling of intra-peritoneal structures, must tend to increase the chances of recovery.

For these reasons I wish to suggest a method of bowel-identification, which rests upon the fact that each bowel has a posterior attachment, and that the origin of the attachment differs according to the bowel which it supports, that a single finger can detect the origin of the peritoneal support of any section of the bowel, and this origin being known, the portion of bowel which it supports is with certainty deducible.

In an exploratory operation, for instance, the finger comes in contact with the bowel; in order to determine whether it is a large or small bowel, note first if the structure is movable or firmly fixed; next pass the finger over the bowel, and let it find its way posteriorly. If we are dealing with a small bowel the finger will reach the origin of the mesentery between the left side of the second lumbar vertebra and the right sacro-iliac joint; if we are dealing with the large bowel, the finger will reach the origin of the meso-colon, or the point where the colon is fixed posteriorly and to the side.



In an operation we may wish to find at once the large bowel. In operating for appendicitis, after making the incision (I in illustration), carry the finger along the parietal layer of peritoneum (first outward, then backward, finally inward, as shown by the dotted line in the illustration); the first obstruction it meets is the colon. The head of the colon is found by passing the finger downward, and the appendix is readily detected, usually internally and posteriorly. Professor Ashton, of the Medico-Chirugical College, has kindly tried this plan in several cases of appendicitis, and he tells me it greatly simplifies the finding of the large bowel and the appendix.

In the operation of iliac colostomy the same plan can be pursued. The incision is made upon the left side, and the finger follows the parietal peritoneum outward, backward, and inward. The first obstruction it meets with is the descending meso-colon.

This method of differentiating between the large and small bowel is so simple that the writer hesitates to record it through the conviction that it must already be known; but having demonstrated it repeatedly in the sugical laboratory at Jefferson College, without having it claimed as old knowledge, and being unable to find it in text-books, it may seem proper to describe the plan, and to urge that it be tried by abdominal surgeons.

MEDICAL PROGRESS.

Changes in the Colostrum and Milk of Nursing Women induced by Disease.—As the outcome of an analytic study in a moderate number and range of cases, Ludwig (*Archiv für Gynäkologie*, B. xlvi, H. 2, p. 343) has found that the amount of fat contained in the milk of nursing women is considerably increased in cases of tuberculosis (when any secretion of milk takes place at all), while the remaining constituents undergo no noteworthy change. In case of albuminuria, particularly if the amount of albumin lost is large, and also if the amount of albumin is small if the nutrition is also impaired, the amount of proteids in the lacteal secretion is notably diminished and the amount of sugar is slightly diminished. In case of profound anemia following hemorrhage in the course of labor the lacteal secretion is deficient in solids, in fats, and in sugar. In case of marked pyrexia the amount of solids and of fats falls, while the amount of proteids and sugar is variable. The milk of syphilitic nursing women was found to be poor in solids, in fats, and in sugar, while the amount of proteids was variable.

Cystinuria in Four Members of One Family.—Pfeiffer (*Centralblatt für die Krankheiten der Harn- und Sexual-Organe*, Bd. v, H. 5, p. 187) has reported the case of a family in which the father and several paternal uncles were gouty, while all of the children, two daughters and two sons, presented cystinuria. This condition was observed in the eldest sister after the passage of a cystin calculus, following an attack of renal colic. She had long suffered with cystitis and pyelitis, but the cystinuria was not discovered until an examination of the calculus led to an investigation of the urine for its presence. Some time after the passage of the stone cystin could no longer be found in the urine. The urine of a younger sister and of two brothers also contained cystin, while that of the mother and of the father, as well as that of two children of the eldest daughter, did not.

For the Sterilization of Sponges, either new or soiled by use, Contejean (*Compt. rend. hebdom. des Séances de*

la Soc. de la Biologie, 1894, No. 11, p. 290) recommends the following mode of procedure: The sponges are first washed with soap and water, then immersed for some time (even for half an hour without harm) in a 1 to 5 solution of nitric acid, then washed in a 2 per cent. solution of sodium bicarbonate (first heated and then cooled), then immersed for an hour, and well stirred, in a 5 per cent. solution of carbolic acid heated to a temperature of 158°. The sponges may be kept in the carbolized solution, or they may be dried by heat. Before being used, any fluid that they contain should be expressed, and they should be placed for several hours in a saline solution, 7 parts to 1000.

The Relation between the Gastric Juice and Intestinal Putrefaction.—As the outcome of a special investigation, MESTER (*Zeitschrift f. klin. Medicin*, B. xxiv, H. 5, 6, p. 441) has found that under normal conditions intestinal putrefaction is induced as a result of the action of putrefactive microörganisms introduced into the digestive tract in large measure with the food, and in a degree inversely proportionate to the activity of the hydrochloric acid of the gastric juice. It is thus increased with a diminution in the hydrochloric acid, and this becomes evident when meat relatively free from putrefactive organisms is used as food; while, when the proportion of hydrochloric acid in the gastric juice is normal, similar conditions of the food are without influence upon intestinal putrefaction.

Gastroplication is the term employed by BRANDT (*Centralblatt für Chirurgie*, 1894, No. 16, p. 361) to indicate an operation for mechanically correcting abnormal dilatation of the stomach, especially when no organic cause for the condition can be found. The procedure consists in exposing the viscus and folding and suturing the peritoneal and muscular coats of the anterior and posterior walls of the stomach upon themselves. A case is reported in which the operation was successfully performed.

THERAPEUTIC NOTES.

Fatal Intoxication with Medicinal Doses of Creosote.—ZAWADZKI (*Centralblatt für innere Medicin*, 1894, No. 18, p. 401) has reported the case of a woman, forty-two years old, who for a few weeks had complained of a dry cough, with sharp pains in the right side of the chest, for relief from which creosote had been prescribed in doses of six drops thrice daily. Soon after having taken the third dose the woman felt pain and difficulty in swallowing, with hoarseness, and shortly abdominal pain, vomiting, diarrhea, and irritative cough were superadded. Weakness was a pronounced manifestation. Frothy saliva was constantly being ejected, and the breath had a distinct odor of creosote. There was in places a cloudiness of the epithelium upon the lips, the soft palate, and the pharynx. The soft palate was paretic, and, together with the root of the tongue and the posterior pharyngeal wall, anesthetic and analgesic. The vocal bands were paretic, the patellar reflexes normal, the entire left arm, the left hip, and the outer aspect of the leg, analgesic. Upon the right side of the chest posteriorly there was slight impairment of the pulmonary percussion-resonance, with roughness of the respiratory murmur and numerous moist and dry râles. The action of the heart was feeble, the pulse small and compressible. The urine contained a considerable quantity of albumin, together with tube-casts, but the presence of creosote could not be detected. Despite supporting treatment, collapse set in at the end of six days. Upon post-mortem examination two small oval ulcers with white bases, as if eroded, and with undermined margins, were found in the upper fourth of the esophagus; similar ulcers were also found at the pylorus. The mucous membrane of the stomach and duodenum was injected, reddened, and ecchymotic. The liver was cloudy and clay-colored on section. The kidneys were in a state of acute inflammation. There were numerous pleural adhesions, and the whole left lung and the lower lobe of the right lung, together with the brain and meninges, were hyperemic. The middle lobe of the right lung was in a state of interstitial hyperplasia. There was besides a verrucose endocarditis affecting the leaflets of the mitral valve. The spleen was cyanotic, and the endometrium was hypertrophied.

The Treatment of Syphilis by Hypodermatic Injections of Mercurials.—As the result of an elaborate collective investigation, WOLFF (*Therapeutic Gazette*, vol. xv, No. 5, p. 309) has determined that the treatment of syphilis by hypodermatic injections of mercurials is largely employed on the Continent of Europe, except in France. The best preparation is the corrosive chlorid, and next in order the mild chlorid, then the salicylate, the yellow oxid, the sozoiodolate and gray oil. Soluble preparations are to be preferred to insoluble ones. The mild chlorid seems to hold the first place as regards rapidity of action and permanence of effect. The duration of the treatment cannot be sharply defined; it should continue until all of the symptoms have disappeared. Untoward effects are uncommon, and especially so with the soluble preparations. Serious complications are to be avoided by the observance of proper care and cleanliness.

For Favus.—The Paris correspondent of the *Medical Press and Circular* is authority for the efficacy of the following treatment of favus. The hair is cut close around the affected parts of the scalp, which are then washed with ordinary soft soap. A compress saturated with the following mixture is applied three times daily:

R.—Thymol. . . . . ℥ss.
Chloroformi . . . . . f℥v.
Olei olivæ . . . . . f℥iij.—M.

As soon as the crusts covering the patches become detached the parts should be carefully epilated, and finally a solution of two parts of tincture of iodin and one of glycerin should be painted once a day over the denuded parts. The treatment extends over a period of a month or six weeks.

For Hemorrhoids.—

R.—Acid. carbolici . . . . ℥jss.
Acid. salicylici . . . . ℥ss.
Sodii biboratis . . . . ℥j.
Glycerini . . . . ad f℥j.—M.

S.—Inject slowly from 2 to 4 minims into the base of the hemorrhoid. *Practitioner.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will upon publication be liberally paid for, or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be provided without cost to the author.

Address the Editor: GEO. M. GOULD, M.D.,
1004 WALNUT STREET,
PHILADELPHIA.

Subscription Price, including Postage in North America.

PER ANNUM, IN ADVANCE . . . . . $4.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, JUNE 9, 1894.

RATIONAL MILK-CONTROL.

EFFORTS to regulate the milk-supply have been among the most prominent features of modern sanitary legislation. Scarcely any civilized country is without some regulation, although much variation exists as to the standard selected. Milk, being a natural product largely composed of water, is not of constant composition, and rigid control includes usually only the adoption of a minimum percentage of solids. The earlier efforts at analytic supervision are now known to have been seriously in error. The specific gravity alone is no guide, and Wanklyn has pointed out that many a good milk was ruthlessly seized in Paris under the operation of a system in which the lactometer was entirely relied on. Even the earlier methods of analysis, including that developed by Wanklyn himself, failed to give a correct figure for the ratio between the fatty and non-fatty solids, and led to injustice in the practical application of standards.

So rapidly, however, does knowledge, especially in chemistry, progress, that analysts have scarcely succeeded in placing milk-analysis upon an exact basis, when it is learned that its percentage-composition is relatively of far less moment than has been supposed. It is now apparent that milk is an active distributer of disease, not so much through the practices of skimming or watering (except as the latter process may introduce impure water), but through the specific organisms derived from the animal or from the surroundings of the dairy. The great importance of these dangers can scarcely be over-estimated. Milk being the only animal food generally eaten in the raw state, it is plain that unless collected under circumstances of extreme cleanliness, it will be most dangerous. The employment of new methods of diagnosis, especially the use of tuberculin, has shown that a large proportion of dairy cattle is subject to tuberculosis, and constantly distributing this disease, in addition to which we have the liability of conveyance of typhoid fever, diphtheria, scarlet fever, etc., from the persons associated with the dairy-work. In the face of such dangers, discussion as to whether the legal limits for the composition of milk should be twelve or thirteen per cent. of solids, and nine or nine and one-half per cent. of non-fatty solids, seems puerile. These limits still form the principal features upon which many boards of health rely, but it is obvious that as tuberculosis is quite as abundant, if indeed it is not more so in high-grade cattle, mere richness is no guarantee of wholesomeness in milk.

The sanitary regulation of milk-production, therefore, including supervision of the water-supply, health of farm-hands and families, condition of cattle, facilities for keeping, transporting, and distributing milk, is the method by which the community will be protected, and under such systems serious adulteration will not be possible. The routine analytic work of a city or State sanitary bureau will throw very little light on the dangerous adulterations of milk. To establish complete supervision will undoubtedly involve the appointment of a "swarm of office-holders," who may "harass the people and eat out their substance," yet such supervision ought to be secured.

The title of this article is suggested by a circular issued by a commission of physicians in Essex County, N. J., which seems to point out the road to proper supervision, without the drawbacks of official methods. This commission has entered into a contract with the owner of a dairy who agrees to permit rigid inspection of his property, animals, and work-people; to furnish samples as required for analysis; and to allow publication of all results. The commission has no pecuniary interest in the results, and it is naturally expected that physicians will encourage such a system. The circular at hand, dated

March 6, 1894, details two analyses and inspections made during the latter part of February.

There can be but little doubt of the advantage of this system over compulsory inspection by officials secured under our present political influences. By encouraging honesty and progressiveness on the part of dairy-farmers much more is accomplished than the protection of the milk itself; the example is fruitful, and will influence other features of trade and commerce. It is true of "that monster, Custom" that "to the use of actions fair and good, it likewise gives a frock livery that aptly is put on." High as are the proportions to which food-adulterations and other systematic dishonesties have risen, something may be accomplished in the way of reform by moral suasion, and by encouraging honesty by publicly rewarding it. It is to be hoped that the milk furnished under the conditions enumerated will, as it should, secure a little higher price, and this fact, if no other, may induce other farmers to seek admission to the supervision, until all important dairies near our large cities may by amicable agreement be prepared to furnish safe milk. It should not need argument to convince anyone that such a result will be far more satisfactory than compulsory control over unwilling and insincere proprietors.

Some incidental points in the circular deserve criticism. It is universally acknowledged that the practical purposes of milk-analysis are met by a determination of the total solids and fat; by subtraction of the latter figure from the former the so-called solids-not-fat are obtained which give the valuable clue to the presence of added water. Slight variations of sugar, proteids, and ash, although of scientific interest, have no known sanitary significance, and it is pedantic to include determinations of them in an analysis intended for general circulation. It is somewhat surprising to see the determinations carried out to the third decimal place when the processes of analysis are scarcely exact to this point. Moreover, in the two analyses given in the circular the figures of the individual items—fat, proteids, sugar, and ash—sum up to the exact figure for the total solids, a result that must be either merely a coincidence or indicates that some datum has been determined by arithmetic and not by actual experiment. If the latter is the case the fact ought to be indicated.

Control of the milk-supply, as far as the detection of watering and skimming is concerned, can be secured by simple and rapid methods, and the introduction of elaborate routine should be discouraged as involving unnecessary expense. The large business of the Aylesbury Dairy Company, of London, has been controlled in the most satisfactory manner for many years, the last report of the chemist showing that during 1893 over twenty-eight thousand samples of whole milk, and nearly two thousand samples of cream, buttermilk, and skimmed milk, were analyzed in the company's laboratory, in which but two chemists are engaged. The analyses were almost exclusively limited to determinations of two of the three data—fat, specific gravity, and total solids—it being possible from any two of these to calculate with close accuracy the third. In the numerous prosecutions for violation of laws regulating the sale of milk it has been the almost invariable custom to omit determinations of sugar and proteids. The determination of ash is easily made, and is often included when watering is suspected. In milks obviously of good quality, such as those exhibited in this circular, even the figure for the ash is redundant.

The importance of the foregoing criticisms lies in the fact that in endeavoring to extend the system of voluntary non-official dairy-inspection like this Essex County case, the question of expense will be one of the most serious obstacles, and everything should be done to simplify the routine. Processes of milk-analysis accurate to within one-tenth per cent., costing less than one cent per sample, requiring no high analytic skill, and but a few minutes, are known, and the results, fat and total solids, are the analytic data that the interests of public hygiene need. Questions of effects of feeding, breeding, season, etc., may be left for the experiment-stations or the private laboratory, in which the more extended analyses may be made.

SOCIETY PROCEEDINGS.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

(Continued from page 624.)

Third Triennial Meeting, held at Washington, D. C., May 29th, 30th, 31st, and June 1st.

THIRD DAY—MAY 31ST.

DR. WM. M. POLK, of New York, read a paper on "The Conservative Surgery of the Female Pelvic Organs." His deductions were based upon a study of 164 cases in which he had performed abdominal section for disease of the appendages. Of these, 64 were operated upon by the radical method and 100 by so-called con-

servative measures. By the term conservative was meant the retention of all tissues having a reasonable chance of adding to the local or general well-being of the individual. Conservative surgery is applicable to traumatisms, non-malignant disorders, and the early stages of infectious disorders of the female pelvic organs.

The advisability of conservative operations on the perineum, vagina, and cervix has long been recognized and accepted. In speaking of myomectomy, Dr. Polk took the ground that when the tumors have pedicles or distinct capsules, and their number is not too large, operations for their removal may be indicated. Ligation of the broad ligament has been suggested in order to check the growth and lessen the hemorrhage. This operation seems to be capable of filling a valuable place for these indications. It seems to be better than the operation of oöphorectomy, but as yet our knowledge is insufficient to enable a more definite statement to be made.

One of the most conservative operations is curetting, with the drainage and depletion to be obtained by packing. This is applicable in all forms of endometritis and metritis, whether acute or chronic. In acute or subacute inflammation after abortion or labor, it is of great service if done at once.

In affections of the appendages it may be that efficient depletion can be secured by the cavity of the uterus, and will do much toward effecting a cure. The results should be best in the early stages of salpingitis and oöphoritis, but the chronic cases are not beyond the influence of this procedure. If done properly it is harmless and renders the secondary operation safer. The more Dr. Polk has employed this method of treatment the better has he been pleased with it. Women are better mentally and physically for the maintenance of menstruation and ovulation. Until recently many conditions of the tubes and ovaries were considered adequate causes for their removal. Such is not now the case. The functions of menstruation and ovulation should be preserved when possible, without sacrificing the patient's health or life. In cases of destructive inflammation of the appendages the operation is best done after the subsidence of the acute inflammation. The tendency of these inflammations is in the direction of resolution. There are many cases of occluded adherent tube in which the ovaries are in good condition. The same statement applies to some cases of pyosalpinx and many cases of hemato-salpinx. Dr. Polk's proposition was to remove such tubes and leave such ovaries. The nearer the patient is to Nature's menopause the less is the necessity for such conservatism. In early life it is urgently necessary. Dr. Polk has operated in 45 cases in this way, and in their ability to work and enjoy life the women are in as good condition as any equal number of cases of oöphorectomy. Mentally they are far better.

In 36 cases Dr. Polk had resected ovaries the seat of simple cysts or of blood-cysts; in all but 5 of these the results were entirely satisfactory. In 2 cases there was fresh development, and in 3 suppuration in the cyst occurred as a result of infection from the catgut used. When the tubes have been simply adherent they are released and allowed to remain. Twelve such cases have done well, with the exception of 1, in which gonorrheal infection spoiled the work. When the abdominal opening of a tube is closed this is opened and the fimbriated ring stitched back. Dr. Polk reported 5 cases from his own practice in which women had become pregnant after operations of this character. The precise question is, however, not so much the possibility of pregnancy as it is the mental, moral, and physical influences resulting from allowing the ovary or a portion of it to remain.

In the evening DR. ALFRED L. LOOMIS delivered the President's Address, which was entitled "The Influence of Animal Experimentation on Medical Science." He stated that the specific problems with which medical science deals are questions of the relative influence of multiple forces on the production of given results. Only the deepest ignorance can fail to recognize that the forces concerned in the simplest change of inorganic nature are so numerous and their relations so complex that they defy recognition under uncontrollable conditions, while in the organic world the task is even more hopeless. Experimentation, therefore, in which one or more of the involved forces can be controlled, becomes an absolute necessity in all scientific investigation. However clear the mental analysis, however accurate the logical demonstration from cause to effect, it is possible by experiment alone to prove that no involved force has been overlooked. Is it not strange that medicine should be denied the right to follow those imperative methods of scientific research which are so unquestionably accorded to every other science? It is not a little surprising that men with an appreciation of the necessity of experimentation should for so long have preferred to be its subjects, and that even to-day so many refuse to yield the place to animals. For example, in widespread epidemics we note the effects of an infection on perhaps half a million of human beings, with a great sacrifice of human life. On the other hand we study in laboratories the cause of the epidemics with a comparatively small sacrifice of animal life.

In entering upon the consideration of this subject Dr. Loomis fearlessly laid down this proposition: Every distinct advance, every established principle, and every universally accepted law of medical science has been in the past and will be in the future the direct, if not the immediate, result of animal experimentation. He then passed in review some of the obvious and conclusive proofs of this proposition.

It is not too much to claim that during the latter half of the present century the results obtained from experiments on animals have done more than all the observations of the preceding centuries to raise medicine from conditions of vagueness to conditions of exactness. From the time of Aristotle, who proved that the blood, brain, and spinal narrow in animals have no sensation, down to the present day, animal experimentation has been practised by all investigators who have gained any definite knowledge of the more important phenomena of animal life.

Galen must be regarded as the pioneer in this line of investigation. By his experiments on living animals he showed that arteries contain blood, that the lungs passively follow the movements of the chest, and that the diaphragm, although the most important, is not the only muscle of respiration. Further, by section of the spinal cord and of the recurrent laryngeal nerve he demonstrated

the nervous control of the voice and explained the mechanics of respiration. He also advanced the knowledge of the functions and movements of the alimentary canal, and laid the foundation of our knowledge of the functions of the brain and spinal cord. The results of his experimental work are now as conclusive as when first made, and are the only part of his vast labors which have stood the test of modern investigation.

From Galen's time to Harvey's great discovery little experimental work was done, and during this time medicine ceased to advance. Harvey's demonstration of the circulation of the blood, in 1620, rests entirely on animal experimentation, as is shown by his writings.

The next series of important investigations on animals were applied by Galvani and Volta to the nervous system.

In 1664 Robert Hook, by inflating the lungs of animals by means of a bellows, demonstrated artificial respiration. The experiments of Boyle and of Priestley in the seventeenth century laid the foundation of our knowledge of the respiratory process.

The injection of fluids into the bloodvessels of animals was first done by Dr. Christopher Wren. In 1666 Richard Lower performed the first transfusion, and the following year Dr. Denis performed the same experiment on man.

In the middle of the eighteenth century Haller proved that all motion in the human body proceeds in great measure from the brain and spinal cord. He also demonstrated that irritation of the peripheral end of a severed nerve causes contraction in the muscle to which it is distributed. This was followed by the experiments of Sir Charles Bell. At the beginning of the present century Magendie demonstrated the difference between the anterior and posterior roots of the spinal cord. His experiments on animals, by the injection of various medicinal substances, enabled him to lay the foundation of the doctrine that remedies exert their action upon special structures and organs. In this line of work he was followed by Claude Bernard. It is perhaps a conservative statement that, excluding medicinal foods, 90 per cent. of all our medication is made definite and valuable by this principle alone. Magendie, Bernard, and Loget established by their experiments the doctrine of recurrent sensibility, and this was followed by the discovery of Marshall Hall of reflex action of the spinal cord. The doctrine of vasomotor action was practically demonstrated by Bernard's experiments.

John Hunter, in 1785, by his experiments on dogs, established the fact that injuries to healthy arteries are soon repaired, and that ulceration after ligature occurs only when the vessel is diseased. These experiments led him to apply ligatures for the cure of aneurism to healthy portions of the arteries. Hunter first learned by experiment on pigeons and young pigs that the growth of bone is from the periosteum.

As we witness some capital operation performed at the present day without pain, almost bloodless, followed by neither fever nor suppuration, we may ask how far these results are due to experimentation on animals. The effect of chloroform was discovered through experimentation on the ant. Simpson practised and perfected his use of chloroform on animals before he placed his first patient in a state of anesthesia. That other great alleviator of pain was first used on dogs.

These results are sufficient to exalt animal experimentation to the first place as a means of scientific advancement.

The first important step in the field of etiology, based on animal experimentation, was made in 1850, when it was proved that splenic fever could be communicated from animal to animal by inoculation, and the first hint of bacteriologic study was given by the discovery constantly in the blood of these animals of little thread-like bodies.

About the same time Virchow made his observations on trichinosis.

Villemin inaugurated an important era when he established the fact that tuberculosis was an infectious disease. The invaluable studies of Pasteur introduced us into a new world of knowledge. He not only obtained pure cultures of organisms, but also studied their life-history and placed bacteriologic science on a firm basis. The crowning glory of Pasteur's work came with the discovery of attenuation of bacterial toxic products. It is not possible to point to a work of richer or grander promise, yet it is a work that was possible only by experiments on living animals. The application of Pasteur's doctrine by Mr. Lister to the antiseptic treatment of wounds has been a full confirmation of this principle.

The discovery of the bacillus tuberculosis by Koch marks another brilliant epoch in medical science.

Within the past two decades animal experimentation has accomplished more in the field of cerebral localization than all the preceding centuries of carefully recorded cerebral symptoms studied in the light of post-mortem investigation. It has opened a new field of operations.

From this history, it seems evident that most, if not all, of the real advances in medicine have been made possible through experimentation. This review of what our profession has done is not a plea for mercy—it is a cause for pride. Until infinity repeals the edict which gave man power over all created things, the right to claim the services of the brute can never be denied him who devotes his life to the service of mankind. We glory in our experimental work because we know the tenderness of cruelty, the balm of pain, the life whose birth is only in the throes of death. From the ignorant we expect to receive only censure, but from those who in the valley of the shadow of death have learned to know what manner of men we are, I have faith to believe that the reply will come, "We have trusted you with the lives of our loved ones, we intrust to you God's dumb creatures."

Fourth Day—June 1st.

At the business meeting, Dr. Nevins B. Hyde presented on behalf of the American Dermatological Association the following resolution, which was adopted:

Whereas, The American Dermatological Association recognizes the importance of the undoubted existence of leprosy in North America; therefore,

Resolved, That the Congress of American Physicians and Surgeons be requested to memorialize the Congress of the United States of America with the view to the appointment of a commission of five to investigate the prevalence of leprosy in the United States of America and in the countries upon its borders, and to suggest means for the control of the disease.

DR. WILLIAM H. WELCH, of Baltimore, stated that a bill had been presented in Congress prohibiting experiments on animals in the District of Columbia, and he presented the following resolution, which was adopted:

Whereas, The attempt in other countries to regulate by legislation the practice of experimentation upon animals has proved most disastrous to the progress of medical science and art,

Resolved, That the Congress of American Physicians and Surgeons enters its most earnest protest against any legislation tending to interfere with the advancement of medicine by means of experimentation upon animals conducted by properly qualified persons.

DR. L. MCLANE TIFFANY, of Baltimore, offered the following resolution, which was adopted:

Whereas, The Army Appropriation Bill reduces the number of medical officers in the army by twenty-five, and also reduces the appropriation for the Library of the Surgeon-General's Office from $10,000 to $7000,

Resolved, That it is the opinion of this Congress that these proposed reductions are unwise and are contrary to the best interests not only of the Army, but of the medical profession of this country, and of all who depend upon them for skilled professional services, and that we respectfully request our Representatives and Senators to so amend this bill as to prevent the reductions above referred to.

The question of amendment of the By-law relating to the place of meeting was brought up and its consideration postponed until the next meeting, when it should be made the special order for the first day's session.

The Congress then proceeded to its scientific work. The first portion of the afternoon was under the direction of the American Laryngological Association, and the subject for consideration was the Surgery of the Accessory Sinuses of the Nose. The first paper was on "Diseased Conditions of the Ethmoidal Sinuses," by DR. F. H. BOSWORTH, of New York. He said that diseases of these sinuses differ from diseases of the other sinuses in the anatomic peculiarities and in their symptoms. In the other sinuses there is a single large cavity, while in the ethmoid there is a mass of small cells more or less completely separated from each other. In order to establish a radical cure it would be necessary to open each one of these cells. This is impossible, and therefore the separating walls must be broken down and a single cavity formed.

In affections of the other sinuses the principal symptom is the occurrence of a purulent discharge, while ethmoidal disease sets up a train of symptoms more or less neurotic in character, such as headache, intra-orbital pressure, sneezing, asthma, and interference with the action of the brain. Ethmoidal disease is more frequent than is commonly supposed. There are three varieties of disease of the ethmoid: the extra-cellular myxomatous, the intra-cellular myxomatous, and purulent ethmoiditis. These varieties are really simply successive stages of one and the same affection. As the disease progresses the mucous membrane may project into the nasal cavity in the form of small polypi. Another result may be a crowding out of the middle turbinated bone, from distention of the ethmoid cells. The final result is suppuration, and the pus may be discharged through the anterior or through the posterior cells.

Treatment in these conditions should be instituted early, if possible before the occurrence of suppuration. In acute ethmoiditis the ordinary measures employed in acute rhinitis are indicated. Of all measures the douche is to be regarded as the most valuable. One or two gallons of water, rendered saline and as hot as can be borne, should be passed through the nose twice daily. This is devoid of danger, provided the patency of the nostrils is determined beforehand and the water is passed in the narrower nostril so as to obviate any interference with its discharge.

In the chronic stage surgical treatment is demanded when other measures have failed. The object of the treatment is to relieve the intra-cellular pressure. To remove the projecting portions the snare answers the purpose best. In operating on the ethmoid cells a small burr attached to a dental engine is the best instrument. The operation usually requires several sittings, and care must be taken on account of the thin bone separating the cavity from the orbit and from the brain. The operation is not especially painful and can be done under the application of cocain.

Of 97 cases of ethmoid disease, 3 presented carcinoma and 1 sarcoma. Of the simple inflammatory cases, 15 in number, 9 were cured, 3 improved, and 3 disappeared. There were 29 cases of myxomatous degeneration, of which 12 were cured, 10 improved, and 7 were seen but once or twice. There were 22 cases of myxomatous change, with polypi; 9 were cured, 10 improved, and 3 disappeared. There were 27 suppurative cases; 8 were cured, 12 improved, and 7 disappeared. In nearly all of these cases radical measures were employed.

DR. J. H. BRYAN, of Washington, read a paper entitled "Surgery of the Maxillary Sinus." He said that of the surgical affections of the antrum empyema is the most important, and the principal question that has arisen in regard to its treatment has been as to the method of opening the cavity. The washing out of the cavity through the natural opening has been strongly advised. This is applicable to acute but not to chronic cases, and the results are uncertain. In the majority of cases an artificial opening is necessary. If there is a carious tooth present it should be extracted, and frequently in this way the cavity will be opened; if not, it will be necessary to establish a communication by a trocar or small trephine propelled by an engine. The opening should be large and a metallic drainage-tube introduced. If the anterior wall of the antrum shows signs of weakening the opening may be made at this point. If it is desired to enter the cavity from the nose it may be done through the inferior meatus by a spear-shaped knife, but it is better to use the trocar or drill. After the cavity has been opened it should be washed out with mild antiseptic solutions.

When the case is an obstinate one, the opening should be enlarged so that the cavity may be thoroughly explored with a probe, the little finger, or the endoscope. This will often show the presence of spots of ulceration, necrosis, supernumerary teeth, etc., as the cause of the trouble.

DR. J. N. MACKENZIE, of Baltimore, also called attention to the various methods of opening the antrum. Washing out through the natural opening is not applica-

ble to many cases, for it is often difficult to find the opening and this is so even after death. In order to obviate this difficulty, it has been proposed to remove the inferior turbinated bone, but this procedure does not seem justifiable in the majority of cases. It has also been proposed to make an artificial opening below the natural opening. This is rather difficult to accomplish, and the hemorrhage is sometimes great. The operation of entering the antrum through the canine fossa should only be performed in cases of growths, or when the wall of the antrum is so thin that it is an easy matter to pierce it, and when, if the surgeon does not make an opening, the antrum will discharge spontaneously. By far the best operation for gaining access to the antrum is that through the mouth, by the extraction of a tooth, whether sound or decayed, or by going through the alveolar process without the extraction of a tooth. Dr. Mackenzie considers this method far superior to any other. The opening thus made furnishes drainage from a dependent point, and when injections are made through the opening, most of the fluid escapes through the nose. The objections that have been urged against the operation are that it involves the loss of a tooth, perhaps sound, that food may enter through the tube, and that there is danger of microbes gaining entrance from the mouth. These objections are, however, without weight. There is only one contra-indication, and that is the presence of an edentulous alveolar process. In such a case the operation had better be done through the nose.

Dr. John O. Roe, of Rochester, read a paper on "The Surgery of the Maxillary Sinuses." He pointed out that the treatment of cases of disease of the maxillary sinuses is largely surgical, on account of the fact that they are largely out of reach of ordinary medicinal treatment. Most cases of ozena are, in all probability, due to discharge from some of the sinuses of the nose. In cases in which the discharge does not rapidly subside under treatment, a free opening should be made. If there is no history of long-standing disease, the treatment should be begun with injections through the natural passage. If the case is recent, the discharge persisting after an acute inflammation, this may bring about a healthy condition. When such treatment cannot be employed an artificial opening should be made. When the teeth are sound the opening can be made through the zygomatic region or through the meatus. If the disease does not rapidly subside, it is probable that there are conditions of the cavity which must be dealt with radically. Then a free opening should be made and the diseased conditions removed. The opening should be maintained until the disease is entirely cured. The following conclusions were presented:

The old idea of considering drainage and cleanliness as the treatment, regardless of the exciting cause, should be abandoned. In all cases in which the purulent discharge does not cease after a reasonable time, the cavity should be freely laid open, so that the exact pathologic condition can be determined. The opening should be maintained for inspection and treatment until the disease has been cured.

The second portion of the session was in charge of the American Neurological Association.

Dr. James J. Putnam, of Boston, read a paper entitled "The Influence of Infectious Processes on the Nervous System; Pathology and Etiology." He maintained that the relation of nervous diseases to infectious processes may be studied from the point of view of the bacteriologist or that of the neurologist. It was the latter that was taken up. The nervous system may suffer from local bacterial action; from the effects of toxic products; from the effects of a lowered vitality of the nervous system, making it prone to show signs of constitutional weakness or fall a prey to new causes of disease. The term "infectious" was, for convenience, used somewhat loosely to denote the action of specific viruses as well as that of specific organisms.

The infectious diseases that would be admitted by everyone to cause nervous affections are: tetanus, rabies, syphilis, tuberculosis, diphtheria, lepra, gonorrhea, typhoid fever, erysipelas, influenza, mumps; the acute exanthemata, the pyogenic organisms, the diplococcus lanceolatus, malaria, actinomycosis, may bring about the same result. The nervous affections that follow acute infectious diseases are not always due to the primary infection; sometimes they result from secondary infection; or they may be only an indirect result.

The diseases of the nervous system which are suspected, but not fully proved, to be of infectious origin, are especially beri-beri, poliomyelitis, Landry's disease, certain forms of myositis, neuritis, myelitis, some of the cerebral palsies of children, chorea, disseminated sclerosis, and other cerebral and spinal scleroses, amputation-neuritis, herpes zoster.

Finally, a number of affections follow in the wake of infectious processes, but these are hardly to be considered as indicating the action of specific viruses. Among these are the constitutional neuroses and psychoses; the adynamic cerebral affections; the results of edema or of arterio-sclerosis; various forms of sclerosis of the spinal cord, to which the nervous system is always prone, and which any one of various poisons will help to bring about; subacute forms of multiple neuritis of the ordinary type, such as arise from manifold causes.

A disease may be suspected to be of infectious origin when bacteria are found in the tissues; when the outbreaks occur in epidemics, or are related to season or locality; when it exhibits vascular and histologic changes characteristic of the infection; or specific toxicity of the blood and urine; or if it has become much less frequent since the introduction of antiseptics. The discovery of bacteria is by no means conclusive, as they are often only incidentally present. A disease should be suspected of not standing in a very close relation to infection if it is of a kind developing under other influences, and it is therefore important to study what are the morbid conditions which occur most easily as a consequence of various general strains, and as a result of heredity. The French school has done much in this direction. The arguments are strong in favor of the infectious origin of the different forms of acute (often hemorrhagic) myelo-neuritis or poly-myositis (including beri-beri, the epidemic disease of Northern fishermen, Landry's disease, and poliomyelitis). It can at least be said that they are due to some poison acting powerfully for short periods, and in the manner characteristic of bacterial toxins. Bacteria have been found in Landry's disease, but they are not yet accepted as specific. Chorea is probably of infectious origin (Pianese, Dana,

Berkley); bacteria have been found which may or may not be specific. Myelitis (acute focal or transverse) may be produced experimentally by injection of cultures. It also may follow gonorrhea, and may occur in a manner suggestive of other infectious causes. Amputation-neuritis is said to have become less common since the introduction of improved methods of asepsis. There is little to be said for the infectious origin of zoster.

The nervous affections that attend the infective diseases of known character are mainly the following: Acute multiple neuritis may follow almost any one of the infectious processes, but it is difficult to say just what relation it bears to them. The lesions observed have more of the vascular and interstitial character than is ordinarily met with in neuritis of inorganic origin; but they are, doubtless, often due to the products of metabolism. Sometimes, as in diphtheria of rapidly fatal course, no obvious lesions are produced, but modern research is continually widening our resources in this direction. The meningitis which follows the exanthemata is probably due to secondary infection. It cannot, however, be affirmed that the absence of bacteria indicates the absence of a specific local action. In diphtheria and other affections, the virus seems to be almost the equivalent of the organism in its power of exciting local reaction. The meningitis which complicates typhoid fever, pneumonia, perhaps influenza, is generally due to the primary infection, at least in part. Epidemic cerebro-spinal meningitis and sporadic forms are generally due to the diplococcus lanceolatus, the same germ which causes pneumonia; sometimes, also, to other organisms. Recent research has accentuated the importance of purulent and even simple catarrhal affections of the naso-pharynx and the ear as starting-points for meningeal affections. The specific organisms, liable under favorable conditions to cause meningitis, are often present in even the healthy pharynx.

Sometimes the infective agent seems to gain entrance through the intestinal tract.

If we exclude from consideration the cerebro-spinal membranes, which are a great breeding-place for many bacteria, we may say that the instances of local bacterial action upon the nervous system are few, while on the other hand the nervous system is especially prone to suffer from toxic agents circulating in the blood. These poisons are sometimes separable into several definite constituents, which vary as regards their volatility, their solubility in alcohol, their physiologic action. Several of them have a strong tendency to attack the vasomotor system in various ways, and the disturbance of the circulation thus produced is liable to prevent the normal vascular dilatation which is so necessary for the protection of the body against the invasion of pathogenic organisms. These poisons affect the nervous system in various characteristic ways, though it is not improbable that they are capable of acting as universal neurotic poisons. In tetanus the irritability of the spinal cord is heightened, as in strychnin-poisoning; in diphtheria the cardiac centers are sometimes profoundly involved, though gross lesions may be absent; in influenza the tendency of the poison is toward the brain more than in the case of some of the analogous diseases. Besides the psychoses, which are common, acute hemorrhagic encephalitis occurs.

As regards chronic poisoning and its results, we find disseminated sclerosis after various acute infectious diseases, and especially after malaria, but it is not probable that the lesions are due to the action of the specific virus of this antecedent malady.

The causes that contribute to increase the liability of the nervous system to suffer from the effects of infectious disease may be divided into (*a*) those that increase the liability to invasion of the body by pathogenic organisms; (*b*) those that lower the resistance of the nervous system.

In the latter class are hereditary weaknesses in special directions, the presence of other poisons in the nervous system, the effects of trauma, a poorly acting vasomotor system.

Debility of the nervous system may contribute to increase the liability of the body to invasion by impairing the vitality of the tissues, which should resist the germs of disease, besides impairing the efficiency of the vasomotor mechanism.

The most important lines of research for the future are in the direction of classifying the special liabilities on the part of the nervous system to disease, independently of infectious causes, the refinement of our methods of histologic research, the more widespread and thorough study of bacteriology, and of the means of determining the toxic condition of the blood and urine.

DR. CHARLES K. MILLS, of Philadelphia, read a paper entitled "Relation of Infectious Processes to Mental Disease," presenting the following conclusions:

Specific infection must be included among the causes of the mental symptoms, or disease which precedes, accompanies, or follows febrile and other infectious disorders.

Much negative evidence can be adduced to show that acute delirium or acute mania is due to toxemia. Such evidence is afforded by autopsies which reveal neither gross nor histologic lesions; in these cases the toxemia probably overwhelms the patient before the production of meningitis or other diseases with recognizable structural lesions.

Analogies with nervous affections that are known or believed to be of microbic origin, such as multiple neuritis, myelitis, and chorea, favor the view that insanities with similar or related phenomena and lesions are also microbic in origin.

The evidence afforded by careful bacteriologic investigation of cases of acute insanity is thus far more meager and shows that various microörganisms may induce the same or similar types of mental disease.

The mental disorders of pregnancy and the puerperal state are in a considerable proportion of cases toxemic, without reference primarily to childbirth, but it cannot be regarded as proved that a bacillus of either eclampsia or puerperal mania is the sole cause of one or the other of these affections.

DR. FRANCIS X. DERCUM, of Philadelphia, read a paper entitled "The Therapeutics of Infectious Processes of the Nervous System." He contended that a consideration of the treatment of infectious nervous processes involves not only the treatment after infection but also its prevention. From much that we know, we have reason to believe that the occurrence of infection is markedly influenced by the nervous system. The ability

to resist infection depends largely upon the maintenance of normal nervous tone. We have also learned that the nerve-cells undergo certain changes in the course of their functional activity, and these changes can only be interpreted as those of fatigue. The first problem is the prevention of undue waste of nervous substance from undue or excessive fatigue. The necessity for proper proportion of sleep and exercise and suitable food must be borne in mind as an important element in prophylaxis. The question arises:

Are there any means of special prophylaxis against this or that infectious disease? Here the answer is uncertain. The preventive inoculations of Pasteur, Behring, Tizzoni and Cattani suggest themselves, but at the same time doubts as to the advisability and the applicability of the methods arise.

Again, is there anything that can be done in the various infectious fevers, in general pyemia, to prevent nervous infection? When the nervous system is threatened by the existence in other structures of foci of infection, the indication to remove these sources of infection is clear.

In regard to treatment the general indication is to arrest or limit the infectious process and to bring about elimination of the morbid products. To meet the first indication is not as yet possible; but the field of chemistry, and of the biologic laboratory, may in the future yield great discoveries.

The attempt to combat infectious microbes by means of the toxins which they produce was then considered; but with the possible exception of tuberculosis and lepra, the symptoms produced by infectious microörganisms appear to be due not so much to the germ as to these very toxins.

With regard to tuberculosis of the nervous system, the use of the lymph of Koch has been shown to be not only useless but dangerous.

In the treatment of leprosy by the use of lymph, the failure appears to have been almost equally marked.

With regard to hydrophobia, the literature was reviewed at length, and the conclusion reached that it is vain to deny the truth of Pasteur's experimental researches on animals, while the evidence as regards human beings in specific instances is strong and convincing.

In reference to tetanus the condition is still more interesting. A full review of the literature of the subject was given, including the collected reports of thirty-four cases treated either by the powder of Tizzoni or by serum. Of these, twenty cases were successful; but in some of these cases other measures, such as amputation or early active treatment of the wound, were employed. There is no contra-indication to the employment of these antitoxins, as they appear to be in no way injurious.

The other means at our disposal for combating the infectious nervous processes resolve themselves into general remedies, drugs and surgical procedures. Cold has been applied with varying success. It is not improbable that baths of suitable temperature might prove of service in the treatment of infectious nervous diseases. Whether or not by this means the elimination of toxins would be favored is a matter that at present can only be conjectured.

With regard to drugs we meet little that is encouraging or gratifying. In leprosy especially much has been claimed for gurjun, oil of chaulmoogra. In chorea, which is probably infectious, Dr. H. C. Wood has proposed quinin as of considerable value. Antipyrin also has its advocates.

Surgical procedures enable us occasionally to accomplish definite and often brilliant results. This is especially true with regard to the evacuation of pus in positions formerly considered inaccessible, as in brain-abscess.

In conclusion a suggestion was offered in regard to the treatment of tetanus which it was thought might prove of value. It has been observed that the bacillus of tetanus while growing in thymus-infusion did not develop spores, and that animals injected with such cultures were highly immune to the cultures of tetanus-bacilli grown in other media. If thymus-juice possesses such remarkable properties, it should be tested with a view to its possible therapeutic effect. Its administration in a case of tetanus beneath the skin could certainly do no harm, and might do good, and it might also be administered by the mouth. If successful it would prove far more valuable than the antitoxin, because so readily procured.

This completed the scientific work of the Congress.

The President, Dr. Alfred L. Loomis, in adjourning the Congress, congratulated the members on the fact that the registration had been larger at this than at any other of the previous meetings. The attendance at the sessions of the various constituent Associations had also been larger, and the work of a high degree of merit. There had been a united feeling and action among the different Societies in support of the Congress, and the different Associations had become more closely united than ever before. He considered the Congress to be one of the most important medical bodies in this country, as it brings together skilled workers in all the departments of medicine and surgery, and encourages unity of thought and action among medical men. If there is one body more than another in this country that is to raise our profession from the position which it has occupied so long, it is such a body as the Congress.

AMERICAN SURGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at Washington, D. C., May 29, 30, and 31, and June 1, 1894.

(Continued from p. 617.)

THIRD DAY—MAY 31ST.

AT the Executive Session the following officers were elected:

President, Dr. F. S. Dennis, of New York. *Vice-Presidents*, Dr. J. R. Weist, of Richmond, Ind.; Dr. J. B. Roberts, of Philadelphia. *Secretary*, Dr. M. H. Richardson, of Boston. *Treasurer*, Dr. N. P. Dandridge, of Cincinnati. *Recorder*, Dr. De Forest Willard, of Philadelphia. *Member of Council*, Dr. T. F. Prewitt, of St. Louis.

The next meeting is to be held in New York City. Dr. Dudley P. Allen, of Cleveland, Ohio, was elected to membership.

The following were elected to Honorary Membership: Sir Spencer Wells, F.R.C.S., London, Eng.; Dr. William Macewen, Glasgow, Scotland; Dr. M. H. E. W. Schede, Hamburg, Germany; Prof. Ernst v. Bergmann, Berlin, Germany; Prof. Karl Thiersch, Leipzig, Germany;

Prof. Theodor Kocher, Berne, Switzerland; Prof. Jules E. Péan, Paris, France.

The discussion of the papers on "Renal and Ureteral Surgery," read on the preceding day, was now taken up.

DR. M. H. RICHARDSON, of Boston, emphasized the importance of examination of the urine prior to all operations. In regard to the method of performing nephrectomy, he dwelt upon the abdominal method, the incision being made in front laterally. This enables the operator to control bleeding, which is the chief source of danger in the operation. By this method the surgeon is able to determine the presence or absence of the other kidney. Dr. Richardson expressed the belief that by this method the mortality of nephrectomy would be greatly reduced, by so providing for hemorrhage that it could not be an element in the mortality.

DR. H. H. MUDD, of St. Louis, agreed with Dr. Tiffany that in traumatic lesions of the kidney, even gunshot and stab wounds, it is not always necessary to do nephrectomy. He had seen such cases recover. He had also met with a number of cases of extensive laceration of the kidney from contusion, in which there was no external evidence of such injury. In many of these cases recovery takes place without operation. When operation was needed, Dr. Mudd believed that partial nephrectomy was justifiable. If necessary, a secondary operation can be done. The removal at a primary operation of kidneys so injured is likely to be disastrous. In pyelo-nephritis and renal lithotomy the first operation should be tentative, consisting of incision and evacuation, the kidney being allowed to remain; a secondary operation being performed if necessary.

Dr. Mudd did not favor the abdominal incision for the removal of the kidney, on account of the risk of infecting the abdominal cavity in suppurative conditions of the kidney, and because the lumbar incision is usually sufficient and, if necessary, it can be extended and the abdomen opened.

DR. T. F. PREWITT, of St. Louis, related several cases of renal stone, laceration, etc., coming under his observation. One of these was in a man who had passed scales of stone by the urethra and in whom operation showed a stone in the pelvis of the kidney, with several small detached particles. Dr. Prewitt was unable to offer an explanation of this separation. With regard to diagnosis, he held that a large amount of pus with a small amount of mucus in the urine indicated that the trouble was in the kidney rather than in the bladder.

DR. W. S. FORBES, of Philadelphia, called attention to the tolerance of the kidney to the presence of stone. He related a case in which the autopsy revealed the presence of a stone in the pelvis of the kidney, and in which, during life, there were no indications of stone. The character of the stone was peculiar in that it was what is known as an indigo stone.

DR. CHARLES B. NANCREDE, of Ann Arbor, said that he had used the abdominal method of nephrectomy in four cases, but he did not favor it in suppurative conditions of the kidney. In order to avoid hemorrhage he had used an elastic ligature, gradually slipping it down and removing the kidney piecemeal until the pedicle is reached. In the treatment of the suppression of urine that may follow these operations, he recommended the use of nitroglycerin, which he had used with advantage.

DR. JOHN B. DEAVER, of Philadelphia, added his testimony in favor of the anterior incision in nephrectomy. He felt certain that with proper precautions the danger of infection of the peritoneal cavity could be avoided.

DR. STEPHEN H. WEEKS, of Portland, Me., reported the case of a man who developed an abscess in the groin after having had symptoms of renal colic some months before. On opening this abscess pus was discharged, and subsequently a small calculus was passed. No urine was discharged through the abscess at any time. The sinus has since almost healed.

DR. WILLIAM H. CARMALT, of New Haven, Conn., reported the case of a woman in which it was thought that nephrectomy might be required. On preliminary examination through an abdominal incision only one kidney could be discovered. The patient died three years later, and the autopsy showed that the second kidney was located in the pelvis.

DR. WILLIAM B. COLEY, of New York, read a paper entitled "The Treatment of Malignant Disease with the Toxins of Erysipelas." He related that in a previous paper he had reported ten cases treated by the injection of living cultures of erysipelas. The first case was one of inoperable, recurrent sarcoma of the tonsil. The injections were continued for some time without causing an attack of erysipelas, but finally a culture from a virulent case was used and reproduced the disease. The tumor ceased to enlarge, the general condition improved, and the patient is still living, three years after the beginning of the treatment.

Six of the ten cases presented sarcoma and four carcinoma. In only four was erysipelas produced. Those cases in which the disease was not induced seemed to be as much benefited as those in which it was, and this led to a trial of the toxic products instead of the living cultures. A combination of the toxin of the bacillus prodigiosus with that of the streptococcus of erysipelas was also employed and found to be more satisfactory than that of the latter alone. Since December, 1892, Dr. Coley has treated thirty-five cases of inoperable malignant disease by the injection of the toxins of these two organisms. Twenty-five were cases of sarcoma, seven of carcinoma, and three either sarcoma or carcinoma. Among the cases reported were the following: A case of sarcoma of the abdomen and pelvis, followed by recovery; a case of recurrent sarcoma of the back and groin, with entire disappearance of the tumor, and no recurrence fourteen months after cessation of the treatment; sarcoma of the iliac fossa, with partial disappearance of the tumor—the health of the patient being perfect; inoperable sarcoma of the abdominal wall, with entire disappearance under treatment; sarcoma of the leg recurring after amputation, with enlargement of the glands of the groin, with marked improvement, but still under treatment; enormous round-celled sarcoma of the neck and thyroid, with marked improvement; large, pulsating round-celled sarcoma of the ileum and buttock, with marked diminution in size.

In the eight cases of carcinoma treated there has been marked improvement in two, slight improvement in four, and no effect in two. In no case has the tumor disappeared.

Of the total number of cases treated there is reason to hope for a permanent cure in five. Nine cases showed

marked improvement, eight showed only slight and temporary improvement, while in two there was no apparent effect. One of these latter cases was an osteo-sarcoma of the sternum, in which only four injections had been given; the other was a sarcoma recurring after removal, and in which, owing to the condition of the patient, only small doses could be employed. The spindle-celled and mixed-celled sarcomata seemed to be the most susceptible to the action of the toxins, and periosteal sarcomata and osteo-sarcomata less susceptible.

An important element in the success is the character of the culture employed. Cultures from any but virulent cases have had but little effect. With regard to the manner in which the treatment acts, Dr. Coley was inclined to base the explanation on an acceptance of the micro-parasitic origin of malignant disease. It is only in this way that the effect of this mode of treatment can be explained.

The following conclusions were presented: 1. The curative action of erysipelas upon malignant tumors is an established fact. 2. This action is much more powerful in sarcoma than in carcinoma. 3. It is chiefly due to the toxin of the streptococcus of erysipelas, which may be isolated and used with safety. 4. It is greatly increased by the addition of the toxin of the bacillus prodigiosus. 5. To be of value the toxin should be obtained from virulent cultures and should be freshly prepared. 6. The results obtained from the use of toxins, without danger, are so nearly, if not quite, identical with those obtained from an attack of erysipelas that inoculation should never be resorted to.

Dr. Lewis S. Pilcher, of Brooklyn, read a paper entitled "Venous Tumor of the Diploë." The case reported differed from others which had been described in that the tumor did not communicate with the longitudinal sinus, but was essentially a large venous cavern into which numerous diploic veins opened. The patient was a girl, fifteen years old, who at the age of five years fell and struck the top of her head. Within a few days a small, soft swelling was noticed at the site of injury, without pain or tenderness, but gradually increasing in size. At the end of five years the swelling was incised and a small quantity of clotted blood evacuated, but the sac immediately refilled. It was repeatedly opened, with the same result. When the girl came under observation she presented a prominent tumor over the site of the anterior fontanel, about two and a half inches in its largest diameter. Over the convexity of this mass the skin was thin and without hair. In the right anterior quadrant of the base an elevated plate of bone could be felt. The tumor was soft and could be diminished very slightly in size. It was gradually enlarging. An operation for the relief of this condition was undertaken. It was found that in the anterior part of the base of the swelling the cranial bone was wanting and over a space of 2½ by 1½ cm. the dura mater was exposed. Certain venous channels of the diploë were seen to be opened and from these free bleeding took place. The overhanging edge of bone was cut away with bone-forceps, the base of the cavity was well curetted, and the cavity was packed with iodoform-gauze, and as far as possible the wound was sutured. The after-course of the case was uncomplicated.

Dr. J. W. Elliott, of Boston, read a paper entitled "Strangulation of Meckel's Diverticulum caused by Volvulus of the Ileum." He detailed the case of a man, thirty years old, who came under observation after having been sick for four days with vomiting, chills, and abdominal pain. The bowels had moved twice in the preceding forty-eight hours. The temperature was 103.6°, the pulse 160, the respiration 35. Under ether, a large, hard mass was felt in the middle of the abdomen. The case was regarded as one of appendicitis.

The abdomen was opened by a vertical incision two inches inside of the anterior superior iliac spine. A quantity of turbid fluid escaped. The appendix was found to be normal. The incision was extended, and the mass exposed. It sprang from the lower part of the convex surface of the ileum, and was tightly twisted at its point of attachment. Separating the adhesions, it was found to be attached to the under surface of the umbilicus, and it was then evident that it was Meckel's diverticulum in a strangulated and gangrenous condition. It was seven inches long and about the size of the ileum. The diverticulum was removed and the opening in the ileum closed. The ileum in this position was found twisted on itself, but the gut was not competely obstructed. This twist was evidently due to old adhesions extending into the mesentery. The patient, already septic at the time of operation, died of septic peritonitis on the second day.

Meckel's diverticulum is due to the persistence or incomplete obliteration of the vitelline duct. It is usually small, and has its principal interest in the fact that it not infrequently acts as a band, and causes intestinal obstruction. It may be the seat of retention-cysts, which may or may not communicate with the intestine. A cyst of this kind has been reported, of which the pedicle had become strangulated, causing gangrene of the mucous membrane, and setting up acute peritonitis. These two cases establish the fact that strangulation of Meckel's diverticulum is one of the causes of acute peritonitis. The diverticulum resembles the vermiform appendix, and the lesions of the two may easily be confounded clinically. A case of peritonitis following perforation of the diverticulum has been reported.

The symptoms of inflammation of the appendix and those of inflammation of Meckel's diverticulum are the same. In differential diagnosis the history of a discharge from the umbilicus would suggest the presence of a diverticulum, while a history of previous attacks of pain would be significant of either an inflamed appendix or an inflamed diverticulum. The presence of a tumor, or tenderness near the umbilicus, should favor the theory of an inflamed diverticulum. In the case here reported, the tumor was below and slightly to the right of the umbilicus.

The only treatment in such a case is prompt celiotomy, the pedicle being carefully stitched, as it often opens directly into the intestinal canal. The vessels should be carefully ligated, because the diverticulum is supplied by a branch of the mesenteric artery.

Fourth Day—June 1st.

Dr. J. McFadden Gaston, of Atlanta, read a paper on "Mooted Points as to Fractures of the Arm, with Notice of an Improved Splint," which is to appear in a future number of The News.

DR. W. S. FORBES, of Philadelphia, presented a communication entitled "The Removal of Stone in the Bladder; with the Presentation of a New Lithotrite." This also is to appear in a future number of THE NEWS.

DR. WILLIAM H. CARMALT, of New Haven, Conn., read a paper on "Extirpation of the Larynx." He reported a case in which extirpation of the larynx was done in such a way as to permanently close the opening into the mouth, so that there should be no communication with the lungs.

A man, forty-four years old, came under observation with severe attacks of dyspnea due to the presence of an ulcerated nodule in the larynx, which had been first discovered two years before. The dyspnea necessitated the performance of tracheotomy. The larynx was extirpated, the upper portion of the esophagus being stitched to the epiglottis. The man was able to swallow fluids on the second day, and made an uneventful recovery. He is now able to speak in a whispered voice.

DR JARVIS S. WIGHT, of Brooklyn, exhibited a number of instruments, including needle-forceps, self-threading needle, aneurism needle-forceps, and a new form of knife provided with a beak substituting the use of a grooved director.

The following papers were read by title: "The Effect of Erysipelatous Attacks on Tuberculosis," by DR. DE FOREST WILLARD, of Philadelphia; "Hernia," by DR. W. T. BULL, of New York; "Cases of Extra-uterine Pregnancy, with Remarks," by DR. M. H. RICHARDSON, of Boston; "Treatment of Urethral Vegetations by a Circular-cutting Curet," by DR. JOHN B. DEAVER, of Philadelphia; "Report of Surgical Cases," by DR. CHARLES B. PORTER, of Boston.

ASSOCIATION OF AMERICAN PHYSICIANS.

Ninth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from page 619.)

THIRD DAY—MAY 31ST.

DR. J. P. CROZER GRIFFITH, of Philadelphia, presented a paper on "Tetany in America." This disease, although common enough in Europe, is rare in this country. Several varieties of the disease have been described, as the chronic, the rheumatic, etc., but there are no well-defined lines of demarcation between these forms. The disease is characterized by tonic spasms, either continuous or paroxysmal, and usually symmetric, not accompanied by unconsciousness, and not dependent upon lesions of the cord or of the nerves, nor upon hysteria. Dr. Griffith reported a series of cases occurring in his own practice. Although cases have been recognized, the disease is exceedingly rare, at least in this country. Carpo-pedal spasm is a mild form of tetany. Dr. Griffith has been able to collect from the literature 72 cases of the disease. The occurrence of carpo-pedal spasm in association with laryngismus stridulus is very infrequent. Of the 72 cases collected, 34 were at the age of puberty, or older; 13 between puberty and two years of age; 25 under two years of age, and 20 of these less than one year of age. Pain in the affected parts, apparently due to the spasm, was present in 21 cases only. There were 17 cases of laryngismus stridulus. The chief remedies for the condition are the nerve-sedatives. But few cases have proved fatal, and death, when it occurred, was due to complications.

DR. W. GILMAN THOMPSON, of New York, reported a case of tetany occurring in a man thirty-five years old.

DR. STOCKTON, of Buffalo, reported a case with a somewhat obscure etiology, occurring in a child four years of age. The child presented carpo-pedal spasm, with some suppression of urine, which at the time was thought to be probably due to fibro-cystic degeneration of the kidney. The child made a good recovery, although still delicate. The kidney-disturbance was probably functional.

DR. ABRAHAM JACOBI, of New York, regarded laryngismus stridulus as of a quite frequent occurrence, and thought that the paucity of reports is due to the great frequency rather than to the great rarity of the disease. He regarded rachitis as probably the cause of the disorder.

DR. WILLIAM OSLER, of Baltimore, reported the case of a woman in which the disease recurred during six successive pregnancies.

DR. WHARTON SINKLER, of Philadelphia, read a paper on "Lead-palsy in Children." He stated that this condition is rare in young children, for the reason that they possess more active powers of elimination. The symptoms are both motor and sensory. The paroxysm in a child is as likely to affect the lower extremities as the upper. He reported eight cases gathered from the literature, and three cases occurring in his own practice. The pathology of lead-poisoning in children is generally thought to consist in alterations in the nerves. It is probable, however, that in many cases the symptoms are due to the direct action of the poison upon the muscles; in the chronic cases they may result from alterations in the horns of the cord.

DR. C. P. PUTNAM, of Boston, agreed with Dr. Sinkler in the statement that the legs are affected in children as well as the arms. He thought that the more marked involvement of the arms in adults is due to the greater use of those parts; in children the legs are used largely, and hence, probably, the greater frequency of leg-palsy in them.

DR. ABRAHAM JACOBI, of New York, has had two cases, in each of which the legs were involved as well as the arms.

DR. CHARLES L. DANA, of New York, read a paper entitled "A Study of the Temperature in Cerebral Apoplexy." Within the term apoplexy he included all cases of intra-cranial hemorrhage and all cases of softening due to embolism and thrombosis. As to the direct effect of an apoplexy upon the general bodily temperature there is on the first day a rise of from 1° to 2°, as shown by the rectum. In acute softening from embolism or thrombosis there is rarely any disturbance of temperature on the first day. Hence any elevation of temperature occurring on the first or second day of an apoplexy indicates cerebral hemorrhage. The fever is slight, the temperature reaching from 101° to 103°. In those cases in which there is a terminal rise to 106° or 107° a pneumonia, perhaps a gangrenous pneumonia, is probably the cause. Unilateral disturbances of temperature after an apoplectic stroke have been noted. In seven cases of acute cerebral softening and in three of cerebral

hemorrhage, in all of which autopsies were made, it was found that in the grave massive hemorrhages the affected side showed a higher temperature than the well side; in the cases of acute softening there was no difference of temperature noted. The sudden tearing of the brain by the hemorrhage causes more disturbance than the gradual process of softening. A preliminary fall of temperature in apoplexy is exceedingly rare. This may be explained by the fact that most of the cases are seen some hours after the event has occurred. The effect of the special localization of the clots or the softened areas upon the temperature-changes is interesting; and this brings up the question of the position of the thermic centers. Authorities differ in their belief as to the exact location of these thermic centers. The studies and researches of physiologists lead to the conclusion that injuries of the corpus striatum and pons cause a rise of temperature, while injuries of the cerebellum and white matter of the cerebrum do not cause such an elevation. Dr. Dana, however, doubted the accuracy of these results. He called attention to the fact that after linear craniectomy the temperature frequently shoots up to a high point, and this elevation is due probably to cortical injury. Also cases of injury of the corpus striatum have been followed by no rise of temperature. He believed that it cannot definitely be stated that the thermic centers are present in the brain, but it can be said that the temperature is likely to rise after lesions of the pons and after tearing wounds of the cortex of the brain. He urged the great value of further studies of temperature-changes following apoplectic seizures.

Dr. John H. Musser, of Philadelphia, read a paper on "The Mild Character and Diminished Prevalence of Syphilis and the Infrequency of Visceral Syphilis." He spoke of the difficulty of securing accurate statistics on such a subject. The most reliable sources of such statistics are the Army and Navy records of a large hospital. He believed that there is less syphilis in his own community at present than there was ten years ago. The cause of the diminished prevalence can only be a matter of speculation. The increase in the habits of cleanliness and the improvement in the methods of treatment of the infectious period of the disease are probably factors. The decline in the tertiary manifestations, while small, is still to be noted. Visceral syphilis is quite infrequent now as compared with the past.

Dr. Janeway, of New York, thought it would be a mistake to overlook syphilis as a preëminent factor in the production of disease. He finds it a frequent etiologic factor in the production of locomotor ataxia and in general paresis. It is also a strong etiologic factor in the development of aneurism.

Dr. H. M. Lyman, of Chicago, said that the tendency of syphilis is toward a diminution in the virulence of the primary and secondary manifestations rather than of the tertiary manifestations. A proof of the tendency of the disease to die out is shown by the history of the Pacific Islanders. A century ago, when first discovered, they were entirely free from syphilis, and yet they were undoubtedly direct descendants of the Asiatics, among whom the disease has ever been prevalent.

Dr. Frederick C. Shattuck, of Boston, read a paper entitled "The Frequency of Renal Disease as Shown by Albumin and Casts, especially in those past Middle Life." He stated that the chemic preceded the microscopic examination of the urine. The presence of casts in the urine always shows an involvement of the renal tissue. He did not propose to enter into the question as to whether or not albuminuria is physiologic, as would seem to be indicated by its great frequency. He considered the heat-test the most delicate of all tests for albumin. He has for a number of years been in the habit of examining the urine of patients, no matter what the disease for which they came. Excluding all cases of fever and those in which bile and sugar are present, or in which there is sufficient blood or pus to account for the albumin, as well as all cases of unquestionable nephritis, Dr. Shattuck stated that as a result of his studies he is not disturbed by the presence of albumin and casts in the urine of patients under fifty years of age as much as he was formerly. He was inclined to believe that renal albuminuria, while undoubtedly pathologic, is not of any more significance than a chronic pharyngitis. The frequency of albuminuria increases with advancing age.

Dr. T. M. Prudden, of New York, read a paper on "Experimental Phthisis in the Rabbit with Formation of Cavities." He stated that he believed that secondary infection of the lung by the streptococcus pyogenes after primary infection by the tubercle-bacillus has a decided effect in the production of the symptoms of pulmonary tuberculosis. He introduced into the lungs of rabbits already affected with tuberculosis cultures of the streptococcus pyogenes, and in a large number of such cases of mixed infection cavities formed in the lungs. While not wishing to draw any practical conclusions from his investigations, he laid stress upon the fact that it is possible to produce artificially, in the way indicated, cavities in the lungs of tuberculous animals.

In the absence of Dr. E. L. Trudeau, of Saranac Lake, his paper, entitled "A Report of the Ultimate Results Observed on Experimental Eye-tuberculosis by Tuberculin-treatment and Preventive Inoculation," was read by Dr. Loomis, of New York. It was pointed out that the tendency to relapse in the eye-condition after treatment with tuberculin is much less than before such treatment. The action of the injection of tuberculin is believed to be the same in effect as that of celiotomy upon tuberculous peritonitis. After the operation such reactive inflammation is set up as to overcome the original tuberculous inflammation. A relative degree of immunity may be secured in this way. The tuberculous process produced in the eye of an animal previously subjected to this protective treatment runs a course different from that produced in animals not so immunized, and may go on to an absolute cure.

"Cough Induced by Posture as a Symptom Nearly Diagnostic of Phthisis" was the title of a paper read by Dr. Norman Bridge. He dwelt on the fact that in pulmonary tuberculosis change in posture has a decided effect in increasing or decreasing the tendency to cough. Some patients may rest in comfort on one side and suffer greatly when lying upon the other side. As soon as the whole lung of one side is involved, resting on that side is attended with comfort. It was thought probable that a study of this subject may be of service in diagnosticating the situation and extent of a pulmonary tuberculosis.

FOURTH DAY—JUNE 1ST.

DR. VICTOR C. VAUGHAN, of Ann Arbor, presented a paper entitled "The Chemical Products of the Anaërobic Putrefaction of Pancreatic and Hepatic Tissues, and their Effects upon the Tests for Morphin." He stated that the products of putrefaction vary as the process takes place under aërobic or anaërobic conditions. Owing to lack of caution in this regard, the tests of Dragendorff are probably more or less inaccurate. Indol and skatol may yield the same chemic reactions as morphin, and responding thus to the same tests may give rise to errors in the conclusions in toxicologic investigations. Indol and skatol, and their derivatives, must, therefore, be excluded in all such investigations.

DR. H. M. LYMAN, of Chicago, read a paper on "Gastro-enteric Rheumatism." He said that rheumatic dyspepsia is just as much a nervous manifestation of gastric disease as rheumatic tonsillitis is a neurotic manifestation in the throat. Both are localizations of the rheumatic diathesis. Gastro-enteric rheumatism is a disease of advanced life. At times obesity, diabetes, and polyuria are associated with it. Some of the patients have had rheumatism in early life. It is a rheumatic affection of the nerves of the alimentary canal. The patients suffer some hours after meals, or when the stomach is empty. The pain is referred to the epigastrium or hypochondrium. At times pain is felt in the cardiac region. The character of the pain is very peculiar. It may be accompanied with tenderness in the epigastrium when pressure is exerted. Its intensity is not usually very great, though at times it may become so. It is a dull, persistent, widely-distributed distress. It is readily distinguished by the sufferer from pains having their origin in the abdominal walls. The disease shows a marked tendency to alternations with neuralgias elsewhere over the body; thus facial or brachial neuralgia and insomnia may be accompaniments. At times the pelvic nerves are affected, and the patient then suffers from rectal or vesical tenesmus. Nocturnal erections may occur. The attacks are more marked and more frequent during the wet seasons of the year. In the intervals between the paroxysms there may be perfect bodily comfort. At first the general health is not affected, but in course of time exhaustion and neurasthenia supervene, together with anemia, cachexia, and hypochondriasis. The disease must be distinguished from abdominal gout, peritonitis, abdominal rheumatism, chronic catarrhal gastritis, chronic hepatitis, chronic pancreatitis, carcinoma of the stomach and liver, ulcer of the stomach, and other abdominal conditions. The pathology of the disease is as unsatisfactory as that of rheumatism in general. It is probably to be found in a toxemia resulting from retarded oxidation accompanying certain conditions. Free perspiration will afford great relief, thus going to prove the existence of a toxic condition. In rheumatic gastritis the gastric juice contains a great excess of free hydrochloric acid, in contradistinction to the condition noted in gastric carcinoma. This is analogous to the presence in the muscles of free sarcolactic acid during an attack of ordinary muscular rheumatism. The treatment of rheumatic gastritis does not differ in any respect from that of other varieties of neuro-rheumatism. If the distress follows three or four hours after meals, a crust of bread, or a glass of water or milk, may arrest the painful sensation. The danger, however, is that dilatation of the stomach may result from such a course. Sodium salicylate, ten grains every three hours, is valuable in alleviating the condition. Salol also is of great benefit in the treatment. Chief among the remedies is olive-oil, which not only relieves the pain, but also controls the constipation that usually coëxists. Alteratives, such as mercury in small doses, potassium iodid, and tonics, are of service. Occasional mercurial purges should not be neglected, and occasional flushing of the bowels is very valuable. The diet must be regulated, and should be entirely vegetable if the patient is of plethoric habit. Mineral waters are of service. This regimen must, however, not be adhered to too rigidly. In elderly people slight alcoholic stimulation may be of service. Frequent warm baths are exceedingly grateful, especially when associated with massage. Mental and physical fatigue must be avoided.

DR. JOHN H. MUSSER, of Philadelphia, decried the multiplication of terms. He regarded this condition as a gastro-enteric form of lithemia, and this term, as indicating the general nature of the disease, should be employed in preference to gastro-enteric rheumatism.

DR. VICTOR C. VAUGHAN, of Ann Arbor, thought that there should be a discrimination made between pains due to the presence of an excess of uric acid and those due to other conditions. He would call the pain due to uric acid gouty. Gouty cases are to be recognized by an examination of the blood, with a determination of the number of polynuclear colorless cells present.

DR. DANA would restrict the term rheumatism to that particular class of cases in which there are articular manifestations, with a tendency to cardiac and pericardial complications, and would give new names to all of the other conditions resulting from the rheumatic diathesis.

DR. GEORGE DOCK, of Ann Arbor, reported a "Case of Osteomalacia." The disease occurred in a Pennsylvania woman, twenty-four years old, whose father probably had had syphilis, and her mother a large goiter, but otherwise was well. The patient married at seventeen, and gave birth to her first child two years later. Throughout the pregnancy she suffered from rheumatic pains. In the labor the placenta was adherent, and grave hemorrhage took place. Two years later a second child was born, and again the placenta was adherent and the hemorrhage alarming. The woman nursed both children. The second pregnancy was followed by a return of the rheumatic pains, and shortly after this softening of the bones began to be noticed. She had a fall some time later, fracturing her left thigh. There was a steady advance in the progress of the disease up to the time of her death, which resulted from some acute bronchial affection. Sexual desire was absolutely abolished, in contradistinction to the usual history of these cases. The urine never contained the slightest trace of lactic acid. Toward the close of life renal colic developed, and calculi and gravel were passed. The treatment consisted in the administration of a concentrated syrup of lime until the colic was increased. Phosphorus did no good at all on account of the gastric disturbance that it occasioned. The severe pain was controlled by the use of codein. At one time the patient was placed upon chloral, forty-five grains per diem, for one month, but

without any effect. After death all of the bones were found to be softened, with the exception of those of the head. The ribs could be cut through with a knife, as could also the bones of the pelvis. The superior outlet of the pelvis was of normal shape. The femora were composed of bony spicules imbedded in various kinds of bone-marrow. They also contained cysts at various points. The chief remedies in the disease are phosphorus in large doses, and castration. In this case castration was proposed, but declined.

The following papers were read by title: "A Case of Mitral Stenosis, with Great Hypertrophy of the Right Ventricle; Death from Hemoptysis," by Dr. A. McPhedran, of Toronto, and "A Case of Calculous Pyelitis, with Invasion by the Bacillus Lactis Aërogenes," by Dr. John H. Musser, of Philadelphia.

AMERICAN MEDICAL ASSOCIATION.

Forty-fifth Annual Meeting, held at San Francisco, Cal., June 5, 6, 7, and 8, 1894.

(By Telegraph.)

GENERAL SESSION.

FIRST DAY—JUNE 5TH.

The Forty-fifth Annual Meeting was called to order by President James F. Hibberd, of Richmond, Ind. There were present, besides, on the platform Dr. I. N. Love, of St. Louis, Second Vice-president; Dr. Wm. B. Atkinson, of Philadelphia, Permanent Secretary; Dr. H. B. Ellis, of Los Angeles, Assistant Secretary; Dr. J. L. Simmons, President of the California State Society; Dr. R. H. Plummer, Chairman of the Committee of Arrangements.

Prayer was offered by Rev. DR. ROBERT MCKENZIE.

In the absence of Governor Markham and Mayor Ellert, who were unavoidably detained, Supervisor J. G. JAMES extended a hearty welcome to the Association, with the freedom of the city.

DR. J. L. SIMMONS, of Sacramento, in behalf of the California Medical Society, also delivered an address of welcome.

DR. H. R. PLUMMER, Chairman of the Committee of Arrangements, announced instructions and information to delegates and visitors. He also presented to President Hibberd a gavel, whose handle was made of orange-wood, representing the State color, yellow, and the body of manzanita wood, which is peculiar to the Pacific slope; its sides were of gold, one inscribed A. M. A., S. F., 1894, and the other James F. Hibberd, President.

The physicians of Oregon, through the courtesy of Dr. W. G. Owens, sent one dozen gavels to be used in the various sections; the handles were of yew-wood, the body of myrtle. President James F. Hibberd prefaced an address (which will be found at p. 625 of this issue of THE NEWS) with the following remarks: "Some of the pleasantest surprises of my life are occurring at the close of my career. The sentiment which has prompted the gift of this gavel is more appreciated than the gift itself. I shall endeavor to use it discreetly and properly." On motion of DR. W. T. BISHOP, the address was referred to a committee of five for consideration. The committee was constituted by the appointment of I. N. Love, Acting President; Dr. W. T. Bishop, of Pennsylvania; Dr. Lyman Beecher Todd, of Kentucky; Dr. R. Beverly Cole, of San Francisco; Dr. Fred. W. Mann, of Michigan; Dr. J. P. Woodbridge, of Michigan.

DR. N. QUIMBY moved that a committee of five be appointed to especially consider the danger of reduction of the number of army surgeons. The committee was constituted of Dr. I. N. Quimby, of New Jersey; Dr. J. Copeland, of Alabama; Dr. J. B. Hamilton, of Illinois; Dr. E. E. Montgomery, of Pennsylvania; Dr. J. M. Duff, of Pittsburg.

On motion, Dr. Ed. C. Ingalls, of Chicago, was elected a member of the Association.

On motion, the delegates from the Pharmaceutical Association were also invited to take seats in the Convention.

Owing to the illness of the Treasurer, DR. R. J. DUNGLISON, the Treasurer's report was read by the Permanent Secretary.

DR. INGALLS presented the Treasurer's report in detail. It was indorsed by Dr. E. E. Montgomery and Dr. E. Fletcher Ingalls.

On motion of DR. HUME the report was received and filed.

The Secretary presented a report regarding the action of the various State Societies as to the revision of the Code. Twenty-one societies are opposed to the change. Nebraska, Vermont and Indiana are in favor of the change. Wisconsin and Florida laid the matter on the table. Three had not yet considered the question, and from eleven no reply had been received.

A brief recess was held, after which the election of the Nominating Committee was proceeded with.

The following resolution was offered by DR. L. D. BULKLEY:

WHEREAS, Each section should have three members on the Business Committee of the Association; and

WHEREAS a considerable number have signified their inability to be present this year;

Resolved, That the officers of the various sections be hereby instructed to appoint from the members in attendance alternates to act at this meeting for those who are unable to be present.

DR. R. J. DUNGLISON tendered his resignation as Treasurer.

The following resolution was offered:

WHEREAS, Dr. R. J. Dunglison has been for seventeen years a faithful, energetic Treasurer of this Association, without any compensation; therefore, be it

Resolved, That the hearty and unreserved thanks of this Association be cordially extended to him for his efficient and laborious duties on behalf of this Association, and a copy of this resolution be forwarded by the Secretary to Dr. Dunglison.

An amendment was offered by DR. MONTGOMERY to present to Dr. Dunglison $300 in appreciation of his services.

SECOND DAY—JUNE 6TH.

The Association was called to order by President Hibberd at noon.

The report of the Committee of Arrangements was presented.

The following resolution was offered by DR. QUIMBY, of New Jersey, and was adopted:

Resolved, That the American Medical Association urge upon Congress the advisability of preserving and promoting the efficiency of the Army Medical Department.

Resolved, That any reduction in the present membership of the Army Medical Department or of its appropriation would be prejudicial to the interests of the army and of the country; and be it further

Resolved, That the Secretary be instructed to thus inform Congress by telegraph.

The Address on Medicine was delivered by DR. C. H. HUGHES, of St. Louis, who chose for his subject "The Nervous System in Disease and the Practice of Medicine from a Neurological Standpoint." He said that in this age of preëminent progress in every department of human research the medical profession is to be congratulated on the onward march Medicine has made and is yet making toward the mitigation of human misery and the mastery of disease. As Hippocrates drove the devotees of superstition from the Temple of Hygeia, and taught the people that offended gods could neither bring, nor propitiated gods dispel, disease, and as Andreas Vesalius defied the popular prejudice and ecclesiastic power of his day, at the risk of his life, to make his first human dissection, so his professional descendants of today continue breaking down barriers of ignorance, of prejudice and superstition in the way of man's happiness and prosperity, unlocking the secrets of Nature's arcanum and setting the captive mind and organism free from the enthralment of disease. Substitutive inoculations, for establishing tolerance and immunity to other diseases, are spreading the rescuing power of the medical profession. Pulmonary tuberculosis, with its 165,000 annual victims in this country alone, will soon be a thing of the past, through wisely applied antisepsis. Electroscopic and other explorations now penetrate the dark and otherwise hidden places of the human body, making them a glow of light to the diagnostician. But little, if any, of the human anatomy is absolutely beyond reach of medical science or relief. The abdominal cavity is no longer a *terra incognita* to the resources of surgery, thanks to Lister, of Edinburgh; McDowell, of Kentucky; Battey, of Georgia; Lane, Gross, Agnew and others. The once-hidden recesses of the brain are now penetrated with impunity, saving lives and minds formerly doomed to destruction, thanks to Fritsch and Hitzig, of Germany; Ferrier and Horsley, of England, and Bartholow, of America, the last having been the first physician in the world to explore and prove the truth of cerebral localization by demonstrations on the living human brain.

Dr. Hughes then took up for consideration the complications of influenza, and more particularly the nervous and psychic aspects and sequelæ of the disease. The pneumonia of influenza, it was pointed out, is suggestive of that which results from section of the vagi, and may be ascribed to a toxic influence exerted upon the medullary centers. The therapeutic indications to be deduced from this conception of the disease are the enforcement of rest and the adoption of reconstructive measures. Chloral was recommended as the best antiseptic, hypnotic, and calmative, even in the delirious stage of the disease. In this condition ammonium bromid may be usefully added. For the pain the analgesics derived from coal-tar products and the sweat-producing opium-combinations were recommended, together with the elimination of all circulatory influences exerting a disturbing and depressing influence upon the nervous centers, *e.g.*, the rheumatic or the venereal poison.

Dyspepsia was next considered from the point of view of its cerebral origin. It was maintained that the disorder is more common in those who do intellectual work rather than in those that eat largely and indiscriminately. The relation was said to exist principally through the neural connections of the brain and the stomach. This is illustrated in the association of migraine and nausea and of gastric disturbances and vertigo.

The brain influences the stomach and the stomach influences the brain, but the power of the former over the latter is far greater than that of the latter over the former in chronic conditions.

In conceding this influence of the nervous system over the digestive processes, we need not ignore any fact of chemico-biologic research, or shut out any of the light thrown on the subject by the investigations elucidating the functions of the stomach.

The liver, the kidneys, the bladder, and the bowels, are similarly influenced by emotion, and the lymphatic system is likewise under nervous control, like the arterioles, by the vasomotors.

A center in the medulla also influences, through the chorda tympani nerve and probably the sympathetic, the salivary secretion. A center there also influences the action of the kidneys. The chorda tympani contains secretory and vaso-dilator fibers, the sympathetic, vaso-secretory and vaso-dilator. Salivary secretion is induced reflexly by mastication and the irritation of the presence of food in the mouth and stomach and by the vivid remembrance of certain foods whose eating has made an agreeable impression, and by emotion.

The vagus and the vasomotors influence, or govern, circulation, respiration, and digestion.

The dominion of the nervous system over the spleen is also conceded by the physiology of the day.

Physiologists now maintain that its metabolism is controlled directly by the nervous system.

Hysteria illustrates from the standpoint of clinical observation how suddenly and how extensively nearly all the organs of the body may be profoundly disordered in function by morbid impressions through the nervous system.

There is a suggestive practical lesson in this "neuromimesis," or mimic neurosis, as to the relation of the nervous system to diseases in general.

Dr. Hughes further dwelt upon the tropho-neuroses, the question of physiologic rhythm and its practical bearing upon the management and treatment of the sick, the importance of the early recognition of neurasthenia, the relations of neural overstrain to the development of carcinoma and pulmonary tuberculosis. He also considered the advances made in neuro-dermatology, the relation of certain affections of the heart to cerebral influence, the relation between hemophilia and the vasomotor system, the dependence of the bodily temperature and fever upon conditions of the nervous system, the relations between the nervous system and the liver. He referred to the possibility of leukemia being a neurotrophic blood-disease, and called attention to the fact that rattlesnake-poison first acts with deadly nervous

shock. Finally, attention was directed to the treatment of inebriety.

Dr. Didama, of New York, moved that a vote of thanks be extended to Dr. Hughes for his address. Carried.

A resolution was offered by Dr. Marcy, of Boston, recommending the appointment of State Examining Boards. Carried.

The report of the *Journal* was adopted as the sentiment of the American Medical Association.

Adjourned, to meet on Thursday, for special consideration of the Constitution and revision of the Code.

(To be concluded.)

NEWS ITEMS.

The Cholera in Europe.—It is reported by cable that cholera has broken out in Upper Silesia, Prussia, and also in the city of Stettin.

Despatches from the East Prussian frontier give alarming news of the spread of the disease. In Mislowitz the hospital has been filled with cholera-patients, and huts are building for those who cannot gain admission. At Schilno, near Thorn, there are three cases of cholera. The Vistula has been declared infected throughout the district near Thorn, and bathing in it has been prohibited.

There is a decided falling off of the epidemic of cholera in Eastern Galicia, the last report showing only four cases and two deaths, the total to date being thirty-nine cases and seventeen deaths. In the Galician towns of Skala and Sikierzynce, both near the Austro-Russian frontier, in which cholera now prevails, the drinking-water used by the people comes from a polluted river; there are no wells or springs. The situation along the Russian frontier may be regarded as dangerous owing to the number of centers of infection.

In Constantinople the condition of the epidemic varies greatly from week to week, but on the whole may be considered as greatly ameliorated. It is believed that the dissemination of cholera in Turkey is chiefly due to transport-ships conveying Turkish troops from point to point.

The accounts of the epidemic at Lisbon are very conflicting. It is certain, however, that an epidemic, at first believed to be simply one of diarrhea, appeared early in April. Later it was announced that the comma-bacillus had been found, and as this occurred at a time when there was an average of seventy cases daily, quite a panic ensued. The epidemic has now somewhat abated, and it is officially denied that the disease was Asiatic cholera.

In Spain sporadic cases of cholera have been reported, but not officially confirmed.

In France cases of cholera continue to occur in the departments of Finistere and Morbihan.

No cases of cholera have been reported in Italy. The quarantine regions of this country have been increased and several new stations established.

The Outcome of a Suit for Malpractice.—In 1888 Dr. C. D. Palmer, of Cincinnati, in performing a perineal operation upon a woman, broke his needle. Careful search failed to find one of the fragments, either in the soft parts or on the floor. The patient was not doing well under the anesthetic, so that further search was deemed unwise and the operation was brought to a finish. A few days afterward the doctor was thrown from his buggy in a runaway accident and received severe injuries about the head, remaining unconscious or semi-unconscious for about a month, and being utterly unable to attend to his business for a year. In the meantime the patient fell into the hands of another physician who operated again and found the needle. A suit for $10,000 for malpractice was brought against Dr. Palmer, but decided in his favor May 26th.

The State Board of Medical Examiners will conduct its first examinations of applicants for license to practise medicine in Pennsylvania on June 11, 12, and 13, 1894, at Philadelphia (at the School of Applied Art, Broad and Vine Streets) and Pittsburg (in the Council Chamber, Municipal Hall). It is announced that those granted licenses by the New York Board of Medical Examiners will receive the certificate of the Pennsylvania Board without examination.

Dr. Emory Lanphear, the editor of the *Kansas City Medical Index*, has resigned the chair of Operative Surgery and Clinical Surgery in the Kansas City Medical College and has removed to St. Louis, to assume the chair of Surgery in the St. Louis College of Physicians and Surgeons.

The Medical Society of New Jersey will hold its one hundred and twenty-eighth annual meeting at Lake Hopatcong, June 26 and 27, 1894. An interesting program has been arranged.

The New Hampshire Medical Society will hold its one hundred and third anniversary meeting on June 18 and 19, 1894, at Concord. An interesting program has been arranged.

Prof. Vincenz Czerny, of Heidelberg, has been designated as the successor of Virchow in the direction of the first surgical clinic of the University of Vienna.

Books and Pamphlets Received.

Albuminuria without Manifest Organic Renal Lesion. By Waldron B. Vanderpoel, M.D. Reprinted from the Medical Record, 1893.

Quiz Compends, No. 4. A Compend of Human Physiology especially adapted for the Use of Medical Students. By Albert P. Brubaker, A.M., M.D. Seventh edition, revised and enlarged, with new illustrations and a Table of Physiological Constants. Philadelphia: P. Blakiston, Son & Co., 1893.

REPORT ON HYDROPHOBIA.[1]

BY CHARLES W. DULLES, M.D.,
OF PHILADELPHIA.

IN June, 1888, I made my last report to this Society, in pursuance of the resolution adopted at Williamsport, in 1886, asking me to continue my studies on hydrophobia and to report to the Society from time to time. During the six years which have just elapsed I have continued to collate cases of so-called hydrophobia and to study them, with a view to the report which I now make.

The period of time covered by my present report is six years, from June 1, 1888, to nearly June 1, 1894. I have collated for these six years seventy-eight cases which had any claim to be regarded as instances of hydrophobia. A considerable number of these are, in my opinion, utterly incredible and wholly spurious. Admitting them all as true hydrophobia, we have for the United States an average of thirteen cases per annum, or about one case to four and a half million of inhabitants per annum. This is about the same proportion as I found in my last report.

The geographical distribution of the cases was as follows: 62 (about 80 per cent.) in the section of country from Maine to Georgia—14 of these being in the New England States; 43 (55 per cent. of the whole number) in New York, New Jersey, and Pennsylvania; and 5 altogether in Maryland, South Carolina, and Georgia. Only 16 cases (20 per cent.) occurred in the country west of the Allegheny Mountains.

This distribution I attribute to the influence of the newspapers published in New York and Philadelphia, which have at times, especially those in New York, given too much space to descriptions of the horrors of so-called hydrophobia, and to the exploitation of the Pasteur Institute established in New York. Twenty-four cases occurred in New York City and places in Long Island and New Jersey which may be considered as environs of New York—like Jersey City, Newark, Elizabeth, etc.

[1] Read before the Medical Society of the State of Pennsylvania, May 16, 1894.

The table of 78 cases accompanying this report will be published in the Transactions of the Pennsylvania State Medical Society and the Transactions of the College of Physicians of Philadelphia for 1894.

In studying the cases that have come under my notice in the last six years I have been impressed by their bearing upon the views expressed in some books and papers on the subject as to the age at which hydrophobia occurs, and the relation of the length of the period of incubation to the age of the patient and the situation of the bite.

In regard to age, I find that this varied from what was called "a baby" to what was called "old."

Of the 78 victims, 18 were under ten years old; 16 were between ten and sixteen years old; 8 were between seventeen and thirty-one years old; 34 were between thirty-five and fifty-seven years old; 1 was said to be "old," and the age of one has not been ascertained.

TABLE OF AGES.

Little children.	From 10–16 years.	From 17–31 years.	From 35–57 years.	Old.	Not stated.
Baby, 1	11 y'rs, 5	19 y'rs, 2	35 y'rs, 2	1	1
3 years, 2	12 " 4	22 " 3	Adult, 23		
4 " 3	13 " 3	27 " 1	40 y'rs, 1		
5 " 3	14 " 1	28 " 1	43 " 1		
6 " 4	15 " 2	31 " 1	45 " 1		
7 " 2	16 " 1		48 " 2		
8 " 2			50 " 2		
9 " 1			53 " 1		
			57 " 1		
Total, 18	Total, 16	Total, 8	Total, 34	1	1

Of these victims of so-called hydrophobia, the only ones too young to have distinct notions in regard to this disease were the "baby" (No. 59), about whom I have no evidence that the case was one of hydrophobia except a newspaper headline; a child of three years (No. 27) that was bitten by a dog that was living and well six months later, when the child died; another child of three years (No. 44), about which I have only a brief newspaper item, saying the disease was pronounced hydrophobia; a child four years old (No. 10) that died in convulsions six weeks after having been bitten by a dog of which nothing was known, and attended by a physician whose name I cannot find in any medical directory; a child four years old (No. 35) that died in Philadelphia after having been bitten by a pet dog with which he was playing and about which there is not a particle of evidence that it was rabid (a case that the coroner refused to admit as hydrophobia); and another child four years old (No. 68), bitten by a dog on whose sore foot he had

trodden, and the owner of which scouted the idea that it was rabid. All the rest were of an age at which most persons have very distinct notions about and fear of hydrophobia.

In regard to the relation of the period of incubation to the age of the patient and the situation of the bite, the statistics of the United States for the last six years are, I think, very instructive. They indicate precisely what is found upon studying the thousands of cases reported in books and medical journals which I have investigated, namely: That the facts do not in the least support the theory that bites near the center of the nervous system are more dangerous or more likely to be followed by a brief period of incubation than those inflicted on more remote parts. In our statistics we find a child four years old bitten on the face, with an incubation-period of nearly five months, and a man thirty-five years old bitten on the hand, with an incubation-period of only four weeks. We have also a four-year old child bitten on the finger, with an incubation-period of three weeks, and an adult bitten on the leg, with an incubation-period exactly the same. Taking all the cases together, we find that after bites on the face the incubation-period was less than the time-honored quota of six weeks in only a third of the cases, while the same is true of a full fourth of the cases of bites on the hand and wrist. These facts correspond to what other statistics show. Nobody can predict the length of the period of incubation, even approximately, from a knowledge of the seat of the bite or from a knowledge of the age of the patient. Assertions to the contrary are either pure assumptions or are founded upon averages, which are false and misleading.

Table of Situation of Bite, Age of Patient, and Period of Incubation.

50 "	40 "	Cat-bite.
53 "	8 "	
Old	13 "	Total, 24

The foregoing table gives the details of the cases I have collected in the last six years in regard to the situation of the bite, age of the patient, and the period of incubation.

The number of cases of hydrophobia that occur in this country is happily small. It would doubtless be smaller still but for the exploitation of the Pasteur Institute, conducted by Gibier, in New York, and of its feeble imitator, conducted by Lagorio, in Chicago. These institutions, and the newspapers that in times past have published sensational accounts of cases of so-called hydrophobia, have in a mild way reproduced some of the conditions which make France the hotbed of hydrophobia, as well as of hystero-epilepsy. But the psychological make-up of Americans is less favorable to the development of the germs of hydrophobia or those of hystero-epilepsy than that of the French, and consequently there is less of both here than there is in France. There the history of the last six years differs but little from that which I described to you in my last report. As then, so now, the number of deaths in France is greater than it was before Pasteur, just ten years ago (in May, 1884), boasted to a newspaper reporter: "Whoever gets bitten by a mad dog has only to submit to my three little inoculations, and he need not have the slightest fear of hydrophobia." The year before he made that boast there were four deaths from hydrophobia in Paris (the Department of the Seine); the year after, when he had practised his preventive method for six months, the deaths from hydrophobia leaped at once from four to twenty-two. In 1886 the number fell to three again in Paris; but I have a list of twenty-three persons that died after treatment by Pasteur himself in that year. In 1887 the deaths in Paris rose to nine, in 1888 to nineteen. These oscillations indicate that Pasteur's method is no more preventive of hydrophobia than is the method which he declared in 1884 would eradicate rabies in dogs. On the contrary, Pasteur's method has undoubtedly increased the number of deaths from hydrophobia. I have indicated what has taken place in France, and can assure you that there has been no diminution in the number of deaths from hydrophobia in any part of the world since Pasteur's infallible cures were inaugurated; and at the same time there has been added to these a large number of deaths due to inoculation of the virus of what ought to be called "Pasteur's disease." Just how many these have been no man can say. The statistics are confusing. Those from friendly sources contain remarkable discrepancies. Pasteur's own statistics, published in the *Annales de l'Institut Pasteur* for March of this year, admit seventy-two deaths in seven and one-half years after treatment in Paris. My own show a much larger

number, while I find that Dujardin-Beaumetz, a most enthusiastic supporter of Pasteur, reported to the Académie de Médecine on June 21, 1892, ninety-eight cases in only six years, which is just twenty-six cases more than Pasteur himself reported for eight years. One way in which such curious figures appear may be seen when we examine Pasteur's detailed report for 1893, in which we find that ten actual deaths are set down as four, because two of the ten unfortunates succumbed in less than fifteen days, three developed their fatal disease while receiving the inoculations, and one did not stay to have the treatment completed. The same manipulation may be found in the reports for other years.

In view of these facts, and of others which I cannot detain you with, it is astonishing to see how medical writers quote approvingly the claim that the Pasteur method has reduced the mortality from hydrophobia from 15 or 16 per cent. of those bitten by rabid animals to a fraction of 1 per cent., especially as this claim of Pasteur and his disciples, besides being in the face of the fact that more people die now from this disease and Pasteur's disease than used to die from hydrophobia, rests upon the stupendous fallacy that Pasteur has saved from death by hydrophobia during the last eight years nearly 15,000 persons, who are in the report spoken of as "cured," of whom about nine-tenths were Frenchmen, say about 1500 a year. Of this number he is supposed to have "cured" about 1400 Frenchmen in the year 1893—more persons than have died from hydrophobia in the United States in a century.

But for the frequent use of the word "cure" by Pasteur and his disciples, it would be better to assume that his claim to have saved life covers only 15 or 16 per cent. of the figures given here.

One of the perils of the science of medicine at the present time is the credulity which some writers show for statements published from experimental laboratories and the contempt which they manifest for sources of knowledge that conflict with laboratory-theories. One might suppose that prolonged study of what has been written in regard to a subject from a clinical, an experimental, and a philosophical standpoint would warrant a conscientious and fairly intelligent investigator in believing that he knew something about it; but my experience shows that this will not protect one against the scorn of some who spend more time in producing artificial diseases in test-tubes and guinea-pigs than they do in curing natural diseases in human beings.

On this occasion you may be spared the labor of trying to follow figures to establish what I say. You know that I have said such things as this often before, and that they have been published and spread abroad where their credibility might be impeached if they were incorrect, and their fallacy exposed if they were fallacious.[1] But nothing of this kind has happened. Thus far no man has cared to proceed to a deliberate and detailed review of the arguments by which I have at various times endeavored to present to others the views in regard to hydrophobia which I hold, and which are held by a large number of intelligent men.

With this I conclude what I have to say on this occasion. I speak earnestly, because I feel deeply, and I believe what I have said to be of great importance to humanity. With less earnestness I should long ago have given up a course which has had abundant pains and few rewards.

CHRONIC APPENDICITIS.[2]

BY JOHN B. DEAVER, M.D.,
OF PHILADELPHIA.

I PURPOSE considering chronic appendicitis under two heads, namely, relapsing and recurrent, and under these headings I will class all varieties of appendicitis that are not acute. There are cases, however, which strictly speaking are border-line cases. The subacute inflammations of the appendix that follow acute attacks and that have responded to treatment represent this class, but clinically these varieties are most advantageously included under the head of chronic appendicitis.

A patient who has had an attack of acute appendicitis with the characteristic colicky pains, vomiting, and localized tenderness, which has responded to rational treatment, with subsidence of all acute symptoms excepting tenderness in the right iliac fossa, is left in a subacute condition. If this subacute condition is followed within a short space of time by another acute attack, it is an example of the relapsing variety. The recurrent variety is that in which there is an interval of quiescence. In this there is an absence of the symptoms of acute appendicitis. This type is characterized by the evidences of chronic inflammation. Palpation will disclose the presence of an enlarged and inflamed organ, which is more or less tender, according to whether pus be present or not. The mass is more easily made out if there are marked and extensive adhesions, and there will be a decided tumor if the appendix be enveloped in adherent omentum. In a recent article by Dr. Edebohls, published in the *American Journal of the Medical Sciences*, he de-

Assoc., Aug. 6, 1884. Comments on Pasteur's Method of Treating Hydrophobia, Medical Record, New York, Feb. 13, 1886. Case of So-called Hydrophobia, with Remarks, etc., Lancet, London, May 1, 1886.

[2] Read before the Forty-fourth Annual Session of the Medical Society of the State of Pennsylvania, May 15, 1894.

scribes a method of palpating the normal appendix in women as follows:

After completion of the ordinary bimanual examination of the pelvic organs, the woman is drawn upward upon the table to the extent of a foot or so, her feet still remaining where they were placed for the vaginal examination. This is done mainly for the purpose of unfolding the flexure of the thigh upon the abdomen and to render the right inguinal region more accessible to the palpating hand. One hand only, applied externally, is required for the practice of palpation of the vermiform appendix. No assistance can be rendered by a finger introduced into the vagina, and very little assistance, and that only occasionally, by a finger introduced into the rectum.

The examiner, standing at the patient's right, begins the search for the appendix by applying two, three, or four fingers of his right hand, palmar surface downward, almost flatly upon the abdomen, in a straight line from the umbilicus to the anterior superior spine of the right ilium; he notices successively the character of the various structures as they come beneath and escape from the fingers passing over them. *In doing this the pressure exerted must be deep enough to recognize distinctly, along the whole route traversed by the examining fingers, the resistant surfaces of the posterior abdominal wall and of the pelvic brim.* Only in this way can we positively feel the normal or the but slightly enlarged appendix; pressure short of this must necessarily fail.

By this method I have been able to palpate an appendix which was but slightly enlarged. There are associated with the presence of the enlarged appendix evidences of intestinal indigestion, discomfort, or pain increased by exertion and referred particularly to the right iliac fossa, mucous diarrhea alternating with constipation, and digestive irregularities. There is indisposition and general debility. When tuberculosis enters into the causation there is decided emaciation. Neurasthenia is often an associated condition. Exercise and undigested food, by increasing peristalsis and thus pulling upon the adhesions, frequently cause exacerbations of pain. Fever is of importance only when it is of the hectic type.

The diagnosis of chronic appendicitis is not always easy. There are many affections that may be localized in the right iliac fossa which are not easily differentiated from chronic forms of appendiceal inflammation. Carcinoma of the intestine, while occurring most frequently in the rectum, does occur also in the sigmoid flexure and in the cecum. The tumor of carcinoma is, however, persistent, while in chronic appendicitis the tumor will at times be marked and at other times hardly perceptible and will sometimes even be absent. In carcinoma there will be mucous and bloody diarrhea, associated with occasional attacks of obstruction. These symptoms, accompanied by decided and progressive emaciation and cachexia, and persistent pain and the absence of marked tenderness, will be the main points in making the differential diagnosis. Exploration may be necessary to establish a diagnosis.

In the presence of an enlarged appendix, with rigidity and a moderate degree of circumscribed tenderness in the right iliac fossa, occurring in a patient who presents a decidedly anemic appearance, and who gives a family history of two or more members of the immediate family having died of pulmonary tuberculous, it is difficult to draw the lines of distinction between tuberculous inflammation of the cecum and possible involvement of the appendix and chronic appendicitis. Primary tuberculosis of the intestine is more common in children than in adults, and when occurring in the latter is ushered in with colicky pains, irregular diarrhea, and slight fever. In this class of cases examination of the chest, sputa, and dejecta is negative. In a few cases there may be hemorrhage from the bowels. The abdomen in tuberculous disease is apt to present a scaphoid appearance, while in chronic appendicitis there is fulness.

Tuberculous peritonitis may be confounded with chronic appendicitis. The abdomen in the former condition is usually moderately distended, though not uniformily so, but may be concave with the walls tense and unyielding. Palpation of the abdomen in tuberculous peritonitis may reveal the presence of masses either of thickened omentum or of enlarged mesenteric glands. When these masses are located in the right iliac fossa they may be mistaken for a chronically enlarged appendix, although the fact that there is more than one mass present will exclude the appendix. Pain may or may not be present, and when present it is usually diffused.

The diagnosis between chronic appendicitis and fecal impaction can be dismissed with the statement that a collection of dry feces in the cecum in obstinate constipation is so extremely rare that it is not a factor in the differential diagnosis. I have never met with a cecum distended with feces at operation, and therefore I believe the sausage-tumor described by some recent writers as being present in the right iliac fossa, existed not in the belly of the patient, but in the mind of the writer. Furthermore this statement is corroborated by all operators of experience.

From chronic intussusception, the differential diagnosis will rest upon the fact that this occurs most frequently in children; that there is present a doughy, irregular ovoid mass, associated with spasmodic attacks of abdominal pain and tenesmus, which occur at irregular intervals and are accompanied by a discharge of blood and mucus from the rectum. Digital examination of the rectum may detect the invaginated gut.

From floating kidney, chronic appendicitis may be differentiated by the presence of a movable tumor, blood in the urine, a depression in the loin cor-

responding to the site of the kidney, and possibly symptoms of uremia.

From psoas abscess and iliac abscess, chronic appendicitis can be diagnosticated by the history of the slow onset, little or no fever, generally accompanied by evidence of bone-disease, and the absence of pain, tenderness, and bowel-symptoms.

Neuralgia of the right iliac fossa may be mistaken for chronic appendicitis, but the intermittent character of the pain, which is relieved rather than increased by pressure, should establish the diagnosis.

From chronic salpingitis or ovaritis the diagnosis is readily made by a vaginal examination coupled with the history.

The treatment of chronic appendicitis resolves itself, in my judgment, into that of the removal of the appendix. In my experience the mortality has been *nil*, as will be observed by the thirty cases reported. In closing this paper I would call attention to the three important facts to which I attribute my success in the treatment of chronic appendicitis: First, the careful preparation of the patient before the operation; second, the thoroughness and rapidity of the technique; and third, the absolute exclusion of opium in any form in the after-treatment.

NATIONAL CONTROL OF LEPROSY.[1]

BY WALTER WYMAN, M.D.,
SUPERVISING SURGEON-GENERAL U. S. MARINE-HOSPITAL SERVICE.

In the few minutes allotted to me I propose to discuss the relations of the National Government to the subject of the control of leprosy.

In October, 1889, the American Public Health Association, at its meeting in Brooklyn, passed a

[1] Delivered before the Congress of American Physicians and Surgeons, Washington, D. C., May 30, 1894, under direction of the American Dermatological Association.

resolution calling upon the Marine-Hospital Service and the State Board of Health of Florida, and all quarantine-commissioners of ports having intercourse with Cuban ports, to exercise the same vigilance with regard to leprosy that is already observed in the case of yellow fever during what is known as the quarantine-period. In accordance with this request, a circular was issued by the Surgeon-General of the Marine-Hospital Service, approved by the Secretary of the Treasury and the President, December 23, 1889, forbidding entry of any vessel to any port of the United States without a certificate from the proper officer that no case of leprosy was found on board said vessel, or in case one had been found, that it had been removed from the vessel and detained at the quarantine-station ; with a further provision permitting the departure of the detained leper on outgoing vessels bound to the foreign country from which the leper last sailed.

The new Quarantine Regulations of the Treasury, promulgated April 26, 1894, provide as follows :

"Vessels arriving at quarantine with leprosy on board shall not be granted pratique until the leper with his or her baggage has been removed from the vessel to the quarantine-station.

"No case of leprosy will be landed.

"If the leper is an alien passenger, and the vessel is from a foreign port, action will be taken as provided by the immigration laws and regulations of the United States.

"If the leper is an alien, and a member of the crew, and the vessel is from a foreign port, said leper shall be detained at the quarantine at the veesel's expense until taken aboard by the same vessel when outward bound."

Furthermore, the immigration-law of the United States, providing for the medical inspection of immigrants, forbids the landing of immigrants afflicted with a loathsome or contagious disease, thus furnishing an additional protection against the importation of cases of leprosy. These laws and regulations have, in a measure at least, been effective. I am informed by the Sanitary Inspector stationed at Havana that several persons afflicted with leprosy desiring to immigrate to Florida have been debarred from so doing by reason of these restrictions.

National control of leprosy *within* the United States has been frequently advocated, particularly by State and municipal boards of health, when finding such cases upon their hands and desirous of being relieved of their care. The arguments for such control, of course, are based upon the presumption of the contagiousness of the disease (even though moderately contagious) and also upon the claim that where no segregation of cases, or no supervision of cases not colonized is enforced, the disease gradually increases in prevalence, and that where segregation or colonization has been enforced the disease has been made to disappear.

One reason alleged for a national establishment is the fact that in some States the disease is of so rare occurrence that the erection of a special hospital or place of confinment for lepers is scarcely justified, and it is desirable, therefore, that there should be established an asylum to which any of the States might send these unusual but highly objectionable patients. It is further urged that by reason of the difficulty of properly caring for lepers, and because of the uneasiness and excitement that would prevail in cities or localities should the presence of a leper be announced, the health-authorities themselves are tempted to conceal the cases from the knowledge of the public. Thus, if there is anything in the doctrine of contagiousness whatever, the local authorities themselves may directly aid in the extension of the disease. If a national asylum were provided there would be no motive for concealment. Granted that the danger of contagion is small ; granted that, in the language of another, a case of leprosy within a family should be regarded with less concern in its relation to the health of the remaining members than a case of tuberculosis ; granted that the disease spreads chiefly among the lower classes, nevertheless in the movement which is now only near the starting-point, but which promises to be a controlling movement, and which will mark the close of the present century and the beginning of the next, so far as medical science is concerned, as distinctly as any other evidence of progress in the healing art (I refer to the settled resolution to exterminate every contagious disease), it would appear to be incumbent on the profession to leave nothing undone to exterminate this, together with other communicable diseases.

Now, with regard to national control, there are two considerations involved. *First :* Does the *right* of national control exist? *Second :* If it does, how may that right be best exercised?

Concerning the first consideration, I find a difference of opinion among eminent men with whom I have conversed, based upon their different views regarding the Constitution of the United States.

A strict constructionist will inform you that the United States Government can only legislate in accordance with powers expressly delegated by the Constitution, and that the general-welfare clause of the Constitution applies as a qualifying clause to the specified prerogatives—that the latter are only granted when necessary for the general welfare.

The States, however, may make any laws which are not forbidden by the Constitution of the United States. This view would discourage the attempt to establish a national leper-hospital by the General

Government, but it is claimed that the end might be met by one State establishing a hospital and being willing to receive into it the lepers consigned from other States, their expenses being paid by the latter, as has been done in a number of instances with regard to jails and penitentiaries.

Those who take a different view of the Constitution assert that it is quite within the province of Congress to appropriate a sufficient sum to establish a national leper-hospital, though the necessity for it must be plainly shown. They call attention to laws already passed to which objections similar to those mentioned above were urged.

An outline of a bill for this purpose might be stated as follows:

An Act appropriating a sufficient sum to establish a national leper-hospital, and authorizing the national officer in charge thereof to receive, or to proceed and take possession of, a leprosy-patient upon the consent of the proper authority of the State. There should be a corresponding act passed by the Legislature of the State, conferring power upon some official—preferably the Governor, with the advice of the State Board of Health—to *respond* to such a requisition. It should be made the duty of the Government officer in charge of the institution, upon hearing of the presence of a leprosy patient, to request such authorities of the State as have been designated for that purpose by the Legislature, to turn over said patient to said officer, for the purpose of being transferred to said hospital; and the Congressional act should also provide that the officer in charge of the institution should make such regulations for the treatment and confinement of the patient as the nature of the case demands.

It will be observed that an act of this nature would still practically leave the determination of the disposition of the patients within a State to the States itself, and leave to the discretion of the Governor and the State Board of Health whether in a given instance the leper should be segregated. The necessity of this discretion is evident from the fact that special circumstances might so surround a given patient as to make it cruel or unnecessary to remove him. At the same time it would provide for the proper removal and proper care of those who are not surrounded by such circumstances. To the objection that some States might fail to thus legislate or avail themselves of the privilege of a national institution, it may be urged that in this event the law of February 15, 1893, which permits the making of regulations to prevent the spread of contagious diseases from one State to another, could be brought into exercise to prevent lepers leaving such a State. It is believed that this State would in time have a physical demonstration of the necessity of taking advantage of the national institution or of making equal provision itself.

This is a brief outline, which it might be necessary to modify.

To determine whether such a bill would pass, it would be necessary to introduce it, but, as preliminary to its passage, its necessity would have to be demonstrated to Congress. For this purpose, and that Congress may be assured that the medical profession and sanitary officers had not acted upon insufficient premise, it is suggested that a leprosy-commission should be appointed, of three or five members, to make report upon the prevalence of leprosy in the United States and the necessity and proper method of its control.

A preliminary bill might be introduced empowering the President to appoint such a commission; and, as the success of the bill would be enhanced if it called for no additional appropriation, there might be included a provision setting aside a portion of what is known as the "Epidemic Fund," to meet the expenses of this commission.

Whether a national leper-hospital would be the result of this action or not, a commission of this character would cause a sense of relief to the people of the United States, whatever its conclusions, either affirmative or negative, as to such establishment.

As for myself, I believe that leprosy should be under national control.

REPORT ON IRRIGATION OF THE URETHRA AND BLADDER WITHOUT A CATHETER.[1]

BY GEORGE EMERSON BREWER, M.D.,
OF NEW YORK.

SOME three years ago my attention was directed to a report of some experiments by H. Felike, of Buda-Pesth, published in the *Internationale Centralblatt für die Physiologie und Pathologie Harn- und Sexual-Organe*, which demonstrated that, whereas, under ordinary circumstances, fluids cannot be forced beyond the compressor urethræ muscle, by means of the ordinary urethral syringe, the resistance of this muscle can be readily overcome when subjected to the pressure of a column of water of from one to three meters in height. His method was as follows:

The patient, immediately after a complete emptying of the bladder, was placed in the horizontal position on a table or bed. The blunt nozzle of a fountain-syringe was introduced just within the external urethral orifice, and the meatus gently compressed against it by the thumb and forefinger. The reservoir was then raised to a height of two meters, and the patient instructed to take one or two deep inspirations, allowing the air to rapidly escape by complete muscular relaxation. In a few moments the subject of the experiment would experience a desire to urinate, when it would usually be found that the bladder had been completely

[1] Read by title before the American Association of Genito-Urinary Surgeons at Washington, D. C., June 1, 1894.

filled without the slightest discomfort to the patient and often without his knowledge.

The idea of irrigating the bladder in this manner, although new to me at that time, was by no means a recent discovery, for upon looking over the literature of the subject, it was found that Dr. C. B. Crossfield had published in the *New London Medical Journal*, in 1792, a report of some similar experiments, in which he succeeded in irrigating the bladder from the meatus by means of continuous pressure furnished by an ordinary bulb-syringe; and in 1876, Dr. Hunter McGuire reported successful bladder-irrigation in the same manner. Being impressed with the advantages which this method of vesical irrigation offered over the ordinary procedure by means of a double-current or single-current catheter introduced into the bladder, I determined to give it a trial.

The first patient was a middle-aged man who had suffered for twenty-five years from symptoms of chronic prostatitis and posterior urethritis, with the frequent occurrence of an acute bladder-infection, during which he suffered intensely. For these attacks he had frequently been treated by bladder-irrigation, the catheter being introduced in the usual manner. This, while it seemed to have a favorable effect upon the cystitis, was always so painful as to cause acute suffering for a considerable period after the operation, and was often productive of so much irritation in the deep urethra as to render its continued use impracticable. It was during one of these acute attacks that he first came under my observation, and his urgent request for me to avoid, if possible, or at least postpone the introduction of any instrument into the bladder, led to a trial of the method described. The result was strikingly satisfactory, for the man not only recovered far more rapidly than was usual from such attacks, but he was able to accomplish this result without the dreaded pain which always attended the introduction of a catheter. In this case, after the first two or three washings, the patient was able to irrigate his own bladder without the slightest difficulty, and, on several occasions since this attack, has been able to abort a return of the symptoms by an early resort to this simple procedure.

A number of other experiments were subsequently made with a view to testing the value of this method in patients suffering with various diseases of the urethra and bladder in which irrigation was indicated, and, although the results have not, in every instance, been as satisfactory as in the case cited, it may be said that the irrigations were accomplished with much less discomfort to the patient than is usual when the catheter is employed. The only disadvantages which were observed were in cases exhibiting an unusual amount of tonicity of the sphincter muscle, and in these the first few attempts were attended with considerable delay before the fluid would pass into the bladder. In only one case under my observation has it been impossible to accomplish this result.

It is, however, in the treatment of chronic urethritis that this method seems to be most useful. In certain obstinate cases of gleet, especially when there is an involvement of both the anterior and posterior portions of the urethra, the daily irrigation of the entire canal is often attended with the most satisfactory results. The method most generally employed to accomplish this is perhaps that of Prof. Ultzmann, which consists in the introduction into the deep urethra of a short silver catheter, in the beak of which are several longitudinal slits. This, when in position, is so situated that the longitudinal openings are posterior to the compressor urethræ muscle. Several ounces of a medicated solution are then injected by means of a large, hard-rubber syringe. The fluid, after thoroughly washing the posterior portion of the canal, passes into the bladder, and is later expelled by the voluntary efforts of the patient after the withdrawal of the catheter. This insures a double irrigation of the posterior and a single washing of the anterior portion of the urethra.

As one of the many methods of treating this most annoying condition, I have often employed the method of Prof. Ultzmann, and frequently with happy results. The objection has been raised by several who have made use of this plan of treatment, that the metallic instrument often produces by its presence in the deep urethra well-marked irritation, giving rise to frequent and painful micturition, with vesical tenesmus. Not infrequently also when spasm of the cut-off muscle is present, the mucous membrane is lacerated by the sharp edges of the longitudinal openings, occasioning considerable hemorrhage.

Although recognizing the marked advantage which urethral, and especially posterior urethral irrigation offers over all other methods of treatment in certain cases of this kind, I had practically abandoned its use, owing to the objections stated. As irrigation without a catheter seemed to possess all the advantages of the Ultzmann procedure, and to avoid the chief objections attending its use, a trial of this plan was made in several cases, of which the following is an example:

B. F., thirty-four years of age, was referred to me by the medical examiner of one of our large insurance-companies, to find, and, if possible, remove the source of a small amount of pus which was habitually present in his urine. There had been a history of several attacks of gonorrhea during the past twelve years, with a more or less continuous gleet. An examination revealed a penis of three and a half inches in circumference; urethra free to 34 from bulb to meatus. The urine contained a faint trace of

albumin. In the first specimen passed there were found *Tripper-fäden* and a few pus-cells; in the second specimen a small amount of free pus. Endoscopic examination revealed the presence of congested areas and glandular involvement in the bulbous region, with marked hyperemia of the deeper portion of the canal. The patient had been treated by internal urethrotomy, sounds, and injections for many months, with some improvement. An irrigation was made by means of the Ultzmann catheter, with as much gentleness and care as possible. Considerable hemorrhage resulted, and the pain and tenesmus which followed necessitated the patient's going to bed. A day or two later the urethra was irrigated without a catheter, in the manner described, with a 1 : 5000 solution of nitrate of silver, without the slightest discomfort. This was continued daily for a week or more, when the patient was obliged to suspend treatment for a considerable period of time, owing to an enforced absence from home. On his return the irrigations were resumed, with a gradual increase in the strength of the solution, and with marked improvement. It may be added that on two occasions attempts had been made to make applications to the deep urethra through an endoscopic tube, both of which produced extreme irritation. The patient is now nearly well. The pus has disappeared from the second specimen of urine, and only a few *Tripper-fäden* remain in the first.

The foregoing case is reported, not as an example of a cure by this method, for the case is still under treatment, but simply because it illustrates the fact that a sensitive urethra can be irrigated in this manner without irritation.

As to the advantages which this method of urethral and bladder irrigation offers over those usually employed, and which are accomplished by means of the introduction of instruments, it may be said, in general, that there is less danger of septic infection, and far less danger of violence to the parts, and for these reasons it may with greater safety be intrusted to the patient in such cases in which prolonged treatment is necessary.

CRAMMING IN OUR MEDICAL SCHOOLS.[1]

BY OSCAR H. ALLIS, M.D.,
SURGEON TO THE PRESBYTERIAN HOSPITAL.

A FEW years ago the ease with which a medical diploma could be obtained led to the passage of a law in many of the States that necessitated a three years' attendance upon a graded course of medical lectures. The effect of this has been the multiplication of professional chairs. In addition to the seven original professorships there are now a much greater number of honorary professorships.

With the increase in the length of the term and an increase in the teaching staff, there has grown up a remarkable change in the mode of instruction, and this is especially observable in the effort to make the course as practical as possible. The student now has much laboratory-work, class-demonstrations, bedside ward-training, and daily special and general clinics; and yet with all this there never was a greater rush for post-graduate opportunities in the shape of hospital-appointments than now. For a time the faculties of our colleges took no hand in these scrimmages; but they soon learned that it was no small honor to the college to be represented in our best hospitals, and hence, during the final year of college-work, students that expect to apply for hospital-appointments are subjected to special training, and a professional quiz is regularly instituted with a view to give special opportunities to those desiring them.

Prior to the present year the diploma of any of our chartered medical schools was the only requirement by law for the general practice of one's profession in Pennsylvania; but the present State law makes a diploma only a passport to the Board of State Medical Examiners.

And what has been the result of the great increase of professional chairs, the rivalry for hospital-appointments, and the creation of a State Board of Medical Examiners? The answer is only too apparent, viz., to increase the hardships of the medical student. Hard and unsatisfactory as it was when he could get his degree in two years, it is doubly hard and far more oppressive under the extended course. He hears conflicting theories in the lecture-room, and sees the results of conflicting treatment in the daily clinics. He is expected to pass an examination upon oral demonstrations, oral class-instruction, oral lectures and clinics from a score of specialists, and must depend wholly upon notes, meager and almost too hastily taken to be deciphered, with no time or strength to rewrite or correct them. A day, a single week at longest, is enough to convince the ablest student that he will have no time to read, take notes, think, digest, or remember, and that he must hire someone to do all this for him. Hence has sprung up indispensable accessories to the class-room, viz., the quiz-masters. Sharp, shrewd, wonderfully well-posted men! Men who know the foibles, the vanities, the eccentricities of instructors, and who are masters of the minutest detail of every subject—walking encyclopedias, with patience and forbearance suited to their callings. Quiz-masters have existed for a century, but never before were they absolutely essential throughout a whole course to the best and ablest students. It is not necessary to go into the details of their work. I simply say to those who took their degrees fifteen or twenty years ago, that they can have no idea of the quiz-system of to-day. I will pass over the

[1] Read before the Medical Society of Pennsylvania at the forty-fourth annual session, May 15, 1894.

quizzing throughout the session, and only allude to a single branch. Each student knows a week or so before his final examination when he is to "come up," and for this he is taken under special training. For nine mortal hours, with refreshments to prevent interruptions, into the small hours of the morning the entire special branch is reviewed. Then a rest of one night and a second review for an equal length of time. Incredible as this may seem, I may add to its incredibility by saying that the student after all this will often sit up all night and study to the last moment before the final ordeal of examination. And this is only for one branch; and the same work must be repeated before each final examination. If he fails on a single branch, he is re-quizzed and comes up a second time. All of this for his diploma; then special quizzing for hospital-appointments; and finally, the last and most feared of all, the State Board!

Let us now glance for a moment at the student of law. In some of our schools he has but a single lecture a day, and is at liberty to spend the remainder with a preceptor or in an office. In some schools he has three lectures a day for five days a week. About equal to this are the three daily lectures of the theological student. In the high school, academies, and literary colleges, three recitations a day form the maximum requirement. Compare this with the minimum work of the medical student, who spends between sixty and seventy hours a week in actual, indispensable work. Of all students, the medical student is the only one who has no Sabbath.

And now, what of the final result? Does the law-student fail to get his diploma? Does the theological student fail? Either may fail, but only when extremely lazy, or under grave charges of misdemeanor. It is, indeed, rare that the entire class is not graduated. Very different is the result in our medical schools. In these 10 per cent. at least of every graduating class fail to get their degree; 10 per cent., after paying for three courses of medical instruction, three years' maintenance, and three years' loss of time.

Why, it may be asked, do so many fail?

One fruitful cause of failure is the utter unfitness of the student for his work. This should be ascertained at the preliminary examinations, which in medical schools are notoriously farcical. Think of "throwing" a man at his final examination because he cannot spell or write grammatically! What earthly likelihood is there that a student will pass the severest possible examinations on a score of scientific subjects when his early advantages are too meager and too imperfect to gain him entrance to the high school?

A second reason for failure is that the professor knows little or nothing of the student before he appears before him for his final examinations. This is not so in our literary colleges. In these it is the daily, weekly, monthly, class-room work that tells, and while I have no authority for stating it, I venture the remark that any student at the highest literary college in the land might fail in the final examinations of each year, and yet receive the diploma of the college upon his honest, faithful, conscientious class-room work, and what is more, his classmates would applaud the action.

Finally, students fail from sheer exhaustion. The long hours of work, often in foul and ill-ventilated rooms; the long tension of mind, unrelieved by the slightest relaxation; the magnitude of his work, with increasing perplexities every year, and the constantly menacing horror, that after all he may fail of getting his diploma, rob him of sleep and render him almost imbecile at the moment when his faculties should be freshest and brightest. Many a man fails that two months before would have passed the ordeal triumphantly.

If the law of the State demands a four years' course of instruction at a medical school, if the law demands a diploma as the only possible passport to the Board of Medical Examiners, it seems only fair that some more legislation is needed to give the student that justice which heretofore has never been meted out to him.

At the first alumni meeting of the Jefferson Medical College, after Dr. Keen had been made professor of surgery, he narrated a conversation he had with a young man that had failed in his final examinations: "I told him that I felt guilty; that I felt that I had money that belonged to him." I presided at that meeting, and as Professor Keen sat down I said: "That is the best speech that I ever heard at an alumni meeting." There is a suggestion in this that I would commend to those who make the laws of our State. If the law compels a young man to study four years, it ought to give him some guarantee that he will be fairly dealt with. Were our medical schools compelled to refund one-half the expenses of the student who fails to get his diploma, if the schools were obliged to refund all moneys expended on lectures, the graduating class would not be reduced in numbers, but the 10 per cent. that fail at their final examinations would have some redress. Many of these would be checked at their preliminary examinations, while the deserving would get more consideration. But this is not all. Were medical schools held to a strict accountability for their courses of instruction they would soon come to a comparison of their methods with the methods of other educational institutions, and the result would be less quantity but better quality, few failures and better men.

STONE IN THE BLADDER—CHOICE OF OPERATION.[1]

BY WILLIAM H. HINGSTON, M.D., LL.D., D.CH.,
PROFESSOR OF CLINICAL SURGERY, MONTREAL SCHOOL OF MEDICINE; SURGEON TO HOTEL-DIEU, MONTREAL.

As will be readily understood from the limited nature of the subject of this paper, dealing as it does with a small section of a large question, it will necessarily be short. So much has been written within the last few years upon stone in the bladder, and the best means of disposing of it, that little remains to be said. Yet is it within the province of the hospital-surgeon to modify somewhat, for himself at least, the rules for general guidance?

The surgeon most practically familiar with the subject of stone in the bladder occasionally meets this difficulty: Not what is the best operation to be performed in cases of stone in the bladder generally, but what is the safest and best operation to be performed in *this* particular instance? Every case has its own individuality, and these are cases to which the general principles or precepts enunciated by surgical writers can with difficulty be applied. The question of age commonly comes first, and *quoad* that element, the relative advantages of lithotrity and some forms of lithotomy have been practically settled. In both directions the limits in point of age have been greatly extended by the lithotritist, and very *young children* and very *old men* are now being subjected to the crushing operation.

Contraction of the urethra, in any part of its course, is no longer an obstacle to, but a delay merely in the use of the lithotrite.

The condition of the bladder is now no longer taken so much into consideration as formerly. The rule once laid down, that unless the patient can retain his urine a certain period, say a couple of hours, he should not be subjected to lithotrity, no longer holds. My most satisfactory cases have sometimes been those in which the patient could not retain his urine five minutes, and in some instances the sufferer was obliged to wear a caoutchouc bag, into which the water trickled drop by drop.

Whatever the quality of the urine may be, there is no hindrance on that account to the crushing operation. The claim formerly put forward for the superiority of perineal lithotomy, and revived in recent years in favor of the suprapubic method in cases of renal complications, does not appear to me in either instance to be well founded. I venture to say, in general terms, that in diseased bladder, in diseased kidney, and in cases of unhealthy urine arising from either, the lithotrite is as safe an instrument as the lithotomist's knife. Nor should an attempt at the removal of a calculus by either method be delayed pending an effort—usually fruitless—to improve any of those conditions.

The limits as to the size of the stone treated by lithotrity are becoming greater and greater as instruments are becoming more and more perfected.

The hardness of the stone does not now seem to be an inseparable obstacle to an attempt at its reduction. As "coming events cast their shadows before," it is not impossible that at this meeting a Philadelphia surgeon may so instruct us to measure the force of resistance of the calculus on the one hand, and the crushing power of the lithotrite on the other, as to establish the limits within which the crushing of a calculus may be carried with safety.

But while the sphere of lithotrity is steadily extending, and that of lithotomy is becoming more and more circumscribed, there are from time to time, and, in all probability, always will be cases in which cutting must necessarily be resorted to; and then comes the question: Which of the many cutting operations should be selected? (I may here observe, parenthetically, that all cutting operations being equally practicable in any given case, the lateral method, to my mind, still possesses greater advantages and fewer disadvantages than any other. But the lateral method is not always practicable.) When an enlarged prostate or a tumor so interferes with the manipulation of the lithotrite as to make it impossible not only to seize the stone, but also to establish its size, it appears to me to be more prudent to act as if the stone were of large caliber, too large, indeed, to be removed with ease or safety by the lateral operation, and to resort at once to the suprapubic method. Although, as elsewhere noted, I have removed by this method stones of much larger size than is deemed advisable by many to undertake by the lateral method, I am free to admit that in stone over a certain size, and in stones whose size cannot be clearly made out, the suprapubic method is the better.

Having said this much, I venture to express, in a few words, a few general principles or aphorisms, most of which have already been accepted by surgeons, and to offer an additional one for your acceptance. 1. Lithotrize—and by lithotrity I mean that more perfect method, which was foreshadowed by Mercier in France, and brought to its highest perfection in America—lithotrize in all cases of adults in whom the stone is neither too large nor too hard for the lithotrite. 2. Lithotrize when the urethra is, or can be made, sufficiently capacious for the crushing instrument. 3. Lithotrize in children, however young, when the urethra permits the passage of a crushing instrument. 4. In

[1] Read at the meeting of the American Association of Genito-urinary Surgeons, held at Washington, D. C., May 30, 1894.

very young children the cutting operation is preferable. The precise age at which lithotrity is possible must vary with the caliber of the canal, which in young children varies greatly in its capaciousness and in its capacity. When the urethra in the child is not and cannot be made fit to receive the lithotrite, the cutting operation to be chosen is the lateral method. 5. In cases of stone in the aged, when enlarged prostate not only prevents the stone being seized, but its dimensions being ascertained, one should act as if the calculus were of large size and incapable of reduction, and proceed to operate by the suprapubic method. I must confess that I have been forced to this conclusion by the consideration of two somewhat untoward cases of recent date, in which, prevented by an enlarged prostate from grasping the calculus, I adopted the lateral method, and found it impossible in both cases to complete the operation without reducing the volume of the stone before extraction—a procedure which it is always advisable to avoid when possible. In both these cases the suprapubic method would have been better. The consideration of these cases has led me to reconsider certain rules I ventured several years ago to lay down, to influence surgeons in the choice of operation, and it is the view then expressed I should wish, with your consent, to modify.

Surgical interference in cases of calculus in the female remains the same. The method employed years ago by Erichsen, Thompson, and others, has since been followed, and stones of large size are removable generally *per vias naturales*, after dilatation. In exceptionally large calculi the lithotrite commonly suffices; and rarely, indeed, is the surgeon obliged to resort to the knife in the case of females.

NEW DEVICE.

AN IMPROVED FRACTURE-BOX

For the Repair of Injuries of the Lower Extremities Requiring Extension and Counter-extension.

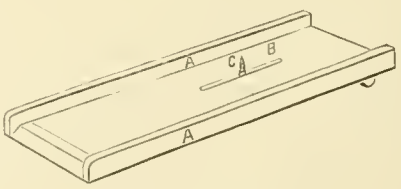
By JOHN B. BROOKE, M.D.,
of Reading, Pa.

There is, perhaps, no more successful method of treating fractures of the lower extremities in their continuity than by the ever-ready sand-bag, pulley and weight, which have largely supplanted the more pretentious measures adopted years ago, including the various appliances for extension and counter-extension from the axilla and perineal appliances, which were always more or less painful, difficult of adjustment, particularly in compound injuries, and always tedious to be borne for any great length of time. Whilst, however, this apparatus answers the purpose for which it is employed, and generally effects most admirable results, it is nevertheless, by its size and weight, inconvenient to handle, requires frequent adjustment, and, in hot weather, adds greatly to the warmth and discomfort of the patient, necessarily increasing nervous irritability and restlessness, and, as a consequence, protracting the recovery. Besides, to make the treatment effective, the sand-bags on the inside and outside of the limb must be firmly adjusted and strapped to it above and below the knee. Holding it thus in a vise as it were, extension is made along the leg, but not always with success, for no one who has had much experience with this form of dressing can fail to recall many instances in which it was almost impossible to keep the foot from deflecting to one side or the other. To this objection, too, must be added that of increasing greatly the weight of the extremity by the attachment to it of the bags, and necessarily requiring increased weight to effect the desired extension. This excessive weight, besides producing abrasions of the instep and heel, with the attendant pain and soreness, adds, also, to the strain upon the adhesive strips, creating irritation beneath them. There is a still further objection. By the combined weight of the sand-bags and limb, the bed, unless a very hard one, will, immediately under them, become so much pressed down into a hole, if you please, that it will act as an obstacle to the sliding forward of the leg and the consequent separation of the fragments.

To do away with the objections to the use of the sand-bags in whole or in part, I present to the profession an improved fracture-box, which I devised some months ago whilst treating an intra-capsular fracture of the femur. It has been in very successful use since then. It presents the following advantages over the sand-bag treatment: It is, under all circumstances, easily adjusted to the injured limb; it is not hot and confining; there is less pain and uneasiness in extension in consequence of less than one-half the weight being required by its use for a given amount of traction; injuries are readily examined, and above all, the surgeon has perfect control of the position of the limb.

In the construction of the box little skill is required, the only care demanded being in the proper selection of well-seasoned wood, particularly for the piece on which the box proper rests and rolls. Unless this is of the best material it will warp, and prevent the easy to-and-fro motion of the box, upon which the success of the whole apparatus depends. I may add that the bed upon which the patient rests should be of hair, and the bedstead at least one foot longer than those usually made for hospital use. With these precautions the fracture-box will always be firm, and the traction upon the limb at the best.

Fig. 1.

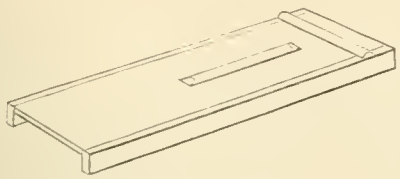


Upper aspect of track.

This improved fracture-box consists essentially of two parts. The first, as shown by Figs. 1 and 2, is nothing but a flat board, 8 x 22 inches, and a half-inch thick, guarded on the long sides by a strip one-quarter inch

thick by one inch broad (A, Fig. 1), to keep the box properly in place and to allow it to move freely on its base. This latter is perforated in its center by a slot, B, six

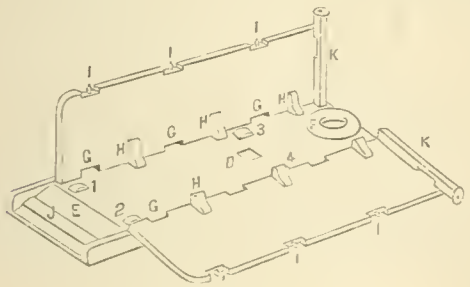
FIG. 2.



Inferior aspect of track.

inches long, and wide enough to admit of an inch screw (C, Fig. 1), which, entering a little block of lignum vitæ (D, Fig. 3), confines the box loosely to the base. This latter, at its back end, is slightly bevelled, to afford greater ease to the limb. The box proper (Fig. 3) con-

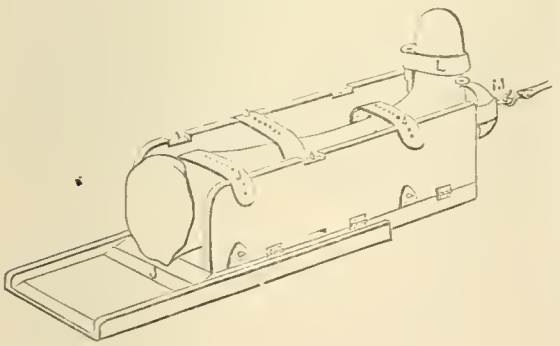
FIG. 3.



View of fracture-box, open.

sists of three pieces, viz., a bottom board one-half an inch thick, and large enough to run easily within the sides of the base. This is also bevelled, as seen at E (Fig. 3), in continuation of the base, and is perforated by four openings for rollers, 1, 2, 3, 4. The front end

FIG. 4.



View of fracture-box, extended.

has a circular opening two inches in diameter, which is covered rather loosely by a piece of chamois leather, and surrounded by a hair cushion, F, of the same material, to receive the heel and thus enable it to move the box when the weight is applied to the leg. The sides of the box are 5 by 19 inches, hinged to the bottom board and notched at the base, as at G, G, G, to admit of the passing of the straps to confine the limb. As these sides sustain the whole inward pressure of the straps, there are small blocks (H, H, H, Fig. 3), firmly glued to them to antagonize this force. At the top of the sides, and on a line with the lower notches, are similar ones to keep the straps in position and to receive the turned pins, I, I, I, made of steel or brass, which hold the straps and thus do away with the use of hooks or buckles. To avoid the pinching of the skin when the box is drawn back, a doubled strap of chamois leather is placed on the bevelled edge (J, Figs. 3 and 4). The posts, K, K, firmly fastened to the front of the sides of the box, are topped by pieces of copper—pennies answer an excellent purpose—turning eccentrically about a screw, so that the guiding strap of the foot (L, Fig. 4), may be removed at will without opening the buckle.

The straps are of soft leather, perforated at one end by one hole the size of the pins, and at the other by a number to admit of proper adjustment. Over each of these a pad slides so that pressure upon the limb can be applied when desired.

The play of the box is six inches, as indicated by the length of the slot in the base. In conclusion, I may add that the free ends of the traction plaster-strips pass around a segment of a ball 2 by 3 inches, the eyed screw, to receive the hook of the extension cord (M, Fig. 4), passing through the plasters, and into the ball, thus confining them the more firmly.

MEDICAL PROGRESS.

A "Human" Ostrich.—EVE (*British Medical Journal*, No. 1740, p. 963) has reported the case of a man, forty-three years old, who came under observation presenting symptoms of intestinal obstruction and peritonitis. The condition was so grave that local anesthesia was induced by means of cocain and the abdomen opened. The cavity was found to contain a large quantity of fluid feces, while the intestines were injected and in places matted together by recent lymph. In the ileum a perforation was found containing a piece of tin about an inch square, and a short distance beyond was a second perforation from which protruded a metallic hook bent upon itself, and which was with difficulty removed. Attached to the hook was a strip of leather extending for some distance into the bowel, but which could not be freed. A short distance below this an intussusception had formed. Several feet beyond the perforations the bowel was found to be attached in the right flank, where it was distended and closely packed with some hard substances feeling like coins. The condition of the patient failing, the two perforations were united by an incision, and the opening attached to the incision in the abdominal wall. Despite active stimulation death ensued, and upon post-mortem examination the ileum beyond the artificial anus was found stuffed for a distance of eighteen inches with foreign bodies variously mixed with strips of paper and including pieces of cork, tin-foil, coins, an iron ring, clay pipe-stems, a bullet, a rubber ring, pieces of leather, and some other things. The stomach and esophagus, as well as the large intestine, were in good condition. Upon inquiry after the operation it was learned that the man was, as a means

of livelihood, in the habit of swallowing coins, pieces of tin, paper, cork, swivels, watch-chains, keys, tacks, nails, rubber, purses, and sundry other articles, many of which were safely passed per rectum.

Typhoid Fever complicated by Diphtheria; Tracheotomy; Recovery.—GAYTON (*Lancet*, No. 3688, p. 1131) has reported the case of a boy, eight years old, who for five days had been complaining of pain in the abdomen and head, and presented a temperature of 104°. The abdomen was distended, but not tender, and there were no spots. The tongue was dry and fissured; a few râles only were to be heard over the lungs. The temperature kept high and was of a distinctly remittent type. Spots first appeared on the eighth day. The bowels throughout were rather confined. On the eighteenth day a harsh cough and hoarseness were observed, and a day later there was marked stridor. The patient was now placed in a steam tent and hot poultices applied to the throat. Two days later the lower ribs were slightly retracted. The fauces were inflamed, but no membrane could be seen. As the breathing and retraction became rapidly worse, tracheotomy was performed. No membrane was encountered, but the dyspnea was greatly relieved. The urine contained a trace of albumin. A day afterward some membrane was removed by feathering, and later a large cast of the trachea came away, the wound being exceedingly septic and presenting a foul-smelling discharge. A large mass and several smaller pieces of membrane were removed during the next few days. Thereafter the wound was cleaner, and as the trachea presented a natural pink color the tube was temporarily, and on the following day permanently, removed. A week later the albuminuria had disappeared and uninterrupted improvement ensued.

A New Clamp for Repairing Intestinal Injuries.—At a recent meeting of the Chicago Medical Society, LARKIN (*Chicago Medical Recorder*, vol. vi, No. 5, p. 337) demonstrated a clamp with which he claimed that he could securely close a stab-wound or bullet-wound of the intestine in fifteen seconds. The instrument is made of brass, though it may be made of any other metal or of hard rubber. It consists of two semicircular jaws that act upon two hinges. When it is open and ready for use its form is nearly circular; when closed and in position its jaws come together, and the several sharp, needle-pointed teeth in either jaw fit into corresponding holes countersunk into the opposite side. The jaws are held together by means of a steel spike that is accurately notched to receive a sharp spring on either side. This ratchet is for the purpose of locking the jaws at any point corresponding to the thickness of the gut operated upon. Practically, no experience is needed for the application of the clamp; no needles are required; no knife is used; no extra wound is made, and no false passages are created.

THERAPEUTIC NOTES.

Strychnin poisoning, with Acute Nephritis and Ascending Motor Paralysis.—PERRY (*Birmingham Medical Review*, vol. xxxv, No. 189, p. 293) has reported the case of a strongly-built man, twenty-five years old, who attempted to commit suicide by taking vermin-poison. When seen, general spasms were occurring every few minutes, and, although not violent in nature, were excited by touching the patient or by movement on his part. The stomach was washed out, and tannic acid introduced by means of a stomach-tube and a subcutaneous injection of ten grains of chloral was given. Within five hours after taking the poison the spasms had passed off, and the patient was able to swallow within four hours after coming under observation. On the following day the urine was withdrawn by means of a catheter, and was found to contain albumin and blood, and hyaline and blood casts. There was also aching pain and slight tenderness in the lumbar region. Vomiting occurred after the taking of food, and persisted for four days, until death took place. Hiccough was also present from the second day, and persisted intermittently until death. On the fourth day the patient complained of complete loss of power in the lower extremities, and of much loss of power in the upper extremities, which he had first observed the night before. Successively the extremities, as well as the intercostal muscles, became completely paralyzed. The knee-jerks and the superficial plantar reflexes were lost; the abdominal and epigastric reflexes were preserved. The pupils were equal, and reacted to light and in accommodation. The general condition of the patient steadily became worse, and the dyspnea more pronounced, and death took place amid the symptoms of asphyxia. Consciousness was preserved throughout. Shortly before death a return of movement was observed in the upper intercostal muscles. Upon post-mortem examination the kidneys were found in a condition of acute inflammation. No lesion was found in the spinal cord.

To Prevent Prolapse of the Iris in Simple Extraction of the Lens SMITH (*Archives of Ophthalmology*, vol. xxiii, Nos. 1, 2, p. 85) has, in sixteen cases, given a hypodermatic injection of one-quarter grain of morphin, after the toilet of the lens and the instillation of a one-grain solution of eserin into the conjunctival sac. After a few minutes the patients are put to bed, and there kept for from twenty-four to forty-eight hours. Eight hours after the first injection a second one is given, and on the following morning a third. The pupil is thus kept contracted for from thirty-six to forty-eight hours or more. For the discomfort that ordinarily follows the operation there is substituted tranquillity, while cough is additionally subdued, and involuntary traction of the recti or orbicularis muscles is avoided.

For Asthma.—

℞.—Chloroformi . . . . . f℥j.
Ætheris . . . . . f℥jss.
Syr. acaciæ . . . . . f℥j.
Tinct. cardamom. co. . . . f℥j.—M.

S.—A teaspoonful every half-hour until relief is obtained. *L'Union Méd.; Med. Press and Circular.*

For Tic Douloureux.—

℞.—Ammonii chloridi . . . . gr. xx.
Butyl-chloral hydratis . . . gr. v.
Glycerini . . . . . ♏x.
Aquæ chloroformi . . ad f℥ss.—M.

S.—Repeat three times at intervals of two hours.

SATURDAY, JUNE 16, 1894.

WHO SHALL DECIDE WHEN LAWYERS DISAGREE?

By a recent decision of the Supreme Court of Pennsylvania a notorious political bully, who had been tried and convicted of killing a man at the polls in this city, and who was serving his term in the Penitentiary, was released from confinement and granted a new trial because, in the opinion of that august tribunal, the trial-judge and the district-attorney in the lower court had committed grave error in the conduct of the case. It seems that the trial judge, apparently at the instigation of the district-attorney, had refused to admit vital evidence as to the *res gestæ*, among which were the testimony of the police-surgeon and the dying declaration of the murdered man.

To the scientist, whose methods aim at precision by the due weight of all evidence, this technical error in the case of a prisoner on trial for his liberty and reputation appears to be radical and deplorable. In his arraignment (for such it is) of the lower court, the learned judge emphasizes the fact, although he does not state it in words, that the officials of our courts can fail to agree upon the simplest details of a street fracas, the determination of which does not require scientific precision or learned attainments, and which yet turns the scale, held in the hands of a justice too often, alas, both blind and ignorant, against the fate of a prisoner.

To the medical expert this episode points a moral and supplies an argument. He is accustomed to hear in the courts, without cessation, the claim that expert testimony is weakened by the contradictory opinions of the experts themselves. This claim is reverberated through the public press, and affects injuriously the credit of experts in public opinion. Too often the claim is allowed to go unchallenged; in fact, there exists a feeling in the medical profession (which is conspicuous above all other professions for hunting out and correcting its own errors) that there is an element of truth in it, and that it is unfortunate and ought to be remedied. But we do not hesitate to say that usually the claim is grossly exaggerated, and that the true answer to it lies in the fact that the fault is with the courts and their methods, because, as in the case of the political criminal just liberated on a quibble, they fail to apply an intelligent test to determine the quality of the testimony submitted to them. If they are not competent to decide upon the merits of the evidence of a ward-fight (in which a man is merely killed in open daylight by a knife-stab), how can they decide upon the merits of testimony based upon accurate scientific knowledge of some of the most profound questions in mental pathology? If they require the correction of the Supreme Court in the matter of a police-surgeon's testimony, how much more must they need it in the matter of that of an expert alienist? If they deserve the castigation of a reversed judgment because they decline to listen to the dying utterances of a murdered man, how much more must they deserve it for refusing to listen to the ravings of an insane one?

When WEBBER, the delusional lunatic, who killed a South Street jeweller in this city, had been convicted on the testimony of a police-officer and a police-magistrate, who said that they believed him to be sane, in the face of the testimony of experts that he was radically insane, a judge of the Supreme Court of the State, who is now Chief Justice, wrote an opinion that the lower court had erred, and based it largely upon the fact that the expert testimony had practically been ignored. After seven years WEBBER lies in jail unhung to-day, but under condemnation of death, as though the law shrunk from recognizing the truth about him, and yet dreaded to hang him!

The case of Prendergast, the Chicago assassin, is an extraordinary example of the uncertainties and waverings of the legal powers. According to the best expert testimony, as we now have it, Prendergast is an undoubted and hopeless delusional lunatic, who committed his crime under the influence of a characteristically insane delusion. Under the extraordinary pressure of the newspapers, which are always remarkably unintelligent and prejudiced on the subject of criminal insanity, and amidst loud popular applause, which sounded like the brutal demonstration in an old Roman amphitheater, the assassin of the mayor was convicted and condemned. We might have supposed then that all but the last act of the tragedy had been played. But already we witness the spectacle of one judge undoing what another judge had done, and of one honest lawyer for the prosecution withdrawing from the case because, in his conscience or in his stomach, he had had enough of prosecuting a lunatic. What remains to be done in the case the medical world must wait to see, but probably no expert can be found so rash as to cast a prognosis of the fate of either the lower court or the prisoner.

But while it is most difficult to obtain in our courts a fair recognition of psychiatry, or a unanimity of judgment on the subject of insanity, it is remarkable how promptly both courts and lawyers resort to the defence of insanity when it is convenient and popular to do so. The most glaring abuse of the defence of insanity ever witnessed in this country was perpetrated not by experts, but by a court. It was in the case of young Nutt, who was tried in this State for killing in cold blood the seducer of his sister and the slayer of his father. There was not a scintilla of honest evidence of insanity in the assassin, but the public and the court were with the prisoner—and no other defence could be concocted. He was acquitted.

This readiness to accept the flimsiest evidence of insanity is shown strikingly sometimes when property, not life, is concerned. The old English law was more solicitous about property than about life, and our courts and juries, which have received its traditions, are often credulous to the last degree about the mental incapacity of the owner of an estate. A jury that would probably reject the highest expert testimony on the alleged insanity of a delusional criminal will promptly declare *non compos*, in the face of expert testimony to the contrary, an old woman who gives away part of her estate to the churches. This has happened recently in this city before a commissioner *de lunatico inquirendo*. The object of the inquiry was the mental capacity of a woman over seventy years old, who showed no mental changes except the slight loss of memory incident to old age. She had no lineal heirs, but because she chose to give during her lifetime some of her money to benevolent objects instead of to a brother and sister, who had no claim whatever upon it, the jury decided that she was incapacitated.

If it be true, as Blackstone has said, that gentlemen of the faculty of physic can derive no profit from the study of law, the converse is not so apparent; for it is clear that lawyers, who disagree about the elementary rules of evidence, and who disregard the teachings of science, could derive from the study of pathology an exactness in the determination of the value of proof that might save them sometimes from mortifying encounters with the Supreme Court.

EDITORIAL COMMENTS.

Attending Physicians and Consultation-fees.—An esteemed correspondent recently inquired:

"In consultations, is not the attending physician entitled to a consultation-fee in addition to his ordinary visiting-fee?"

We answered, "Yes."

Our correspondent writes again, stating that some differ with us in opinion, and requesting a more elaborate exposition of the matter. We fail to see how there can be any room for difference of opinion, so far as concerns the *right* of the attending physician to additional compensation for additional service. The expediency of the charge is a matter for consideration in each individual case, and both business-sense and more generous sentiment may, in some cases, induce the physician to forego his right. As a rule, however, physicians are much more likely to err on the side of undercharge than overcharge. The whole visiting-fee system is ridiculous, and no other body of professional men would submit to it. The physician should charge, as does the lawyer or the architect, in proportion to the importance of the case, the skill possessed and required, and the time, labor, and anxiety involved. Surgeons, at least the tip-top ones in city and country, do this for operative work, and physicians should do the same in medical cases. A fee that may be large for the treatment of a case of simple diarrhea may be ridiculously small for a grave case of typhoid fever or pneumonia. A single visit by a man who is able to diagnosticate a case—let us say, of concealed aortic aneurism—is worth more than hundreds of visits by a man who mistakes the case—let us say, for laryngitis. The man who removes a diseased uterus has not rendered any greater service than the man who restores to

function a diseased lung, and the latter should be equally well paid.

However, so long as the idiotic custom of charging by visit exists, physicians are entitled to the full payment such a custom permits. A true consultation is undertaken for the benefit of the patient. As the term implies, it is the meeting of two (or more) physicians for mutual interchange of opinion. Both the attending physician and the one summoned to his assistance, are therefore *consultants*, although technically, the term may be restricted to the latter. They may be, often are, of equal ability and authority. Sometimes the attending physician is the superior. The attending physician gives more time to the consultation than does the consulting physician; for he remains after the latter has left the house. Like the consulting physician, he comes at a fixed hour, and when a question of convenience arises as to the hour, he is the one to suffer any inconvenience that may be necessitated. He assumes the greater responsibility, for in case of irreconcilable difference of opinion, it is his opinion that must prevail if he remains in attendance. He is, therefore, justly entitled to a consulting-fee, because he consults and because this consultation involves additional time and trouble upon his part.

The Training of Nurses for the Care of the Insane.—By a fortuitous circumstance the opportunity was given DR. WEIR MITCHELL to supplement his words of sharp criticism and valuable counsel addressed to the American Medico-Psychological Association with others of kindly advice to the graduating class of the Training-school for Nurses of the Philadelphia Hospital. He pointed out among other things the demand for nurses specially trained for the care of the insane, and insisted upon the necessity for a thorough general training antecedent to the special training. Both are not ordinarily to be had in one institution, but the opportunity peculiarly exists at the Philadelphia Hospital by reason of the association of the insane department with the general hospital, both being under common control, and particularly on account of the existence of a splendid, well-directed, and well-disciplined training-school. It was recommended that for the education of nurses for the care of the insane at the Philadelphia Hospital one year be spent in the general hospital and two years in the insane department. The expense attendant upon such a course would be more than made good by the services rendered, and, besides, the community would be provided with skilled assistance valuable beyond estimation. It is not enough that such a nurse be merely decorated with a special uniform. She should possess, besides, a degree of intelligence rather above than below the average, for she would be expected to observe accurately, to record carefully, and to administer faithfully; and she would have to be familiar with the nomenclature both of disease and of therapeutics. She should be able to learn when to oppose, when to yield, when to deny, when to accede, when to contradict, when to agree, how to distract attention, and how to break morbid habits, and the value of replacing vicious mentation by physical action. She must be thoroughly familiar with the technique of special therapeutic measures, such as baths, feeding, the subjugation of the unruly, the cheering of the depressed. A sharp distinction is to be drawn between the attendant and the nurse. It must thus be perfectly clear that an excellent opportunity for good exists at the Philadelphia Hospital that seems hitherto to have been too much neglected, and that should not be lost. A school of training for nurses for the care of the insane would be at once a benefit and an economy.

Recovery from Toxic Doses of Opium and its Derivatives.—So variable are the results that follow the ingestion of bodies of recognized toxic activity that much caution must be exercised in assigning the place of an antidote to any other body that appears so to act. There are obvious difficulties in determining what shall be considered a toxic dose. This will necessarily vary with many conditions, both individual and general, such as idiosyncrasy, tolerance or habituation, age, sex, the condition of the stomach, the facility of absorption, the state of the circulation and respiration, the secretions and excretions, and the general health. While much interest attaches to the recent observations that seem to indicate that potassium permanganate acts as an antidote to opium and its derivatives, it may be well to withhold a final opinion in this relation until a growing experience shall have confirmed or demonstrated the error of such a conclusion. Recovery from enormous doses of opiates does sometimes occur under other treatment. Such a case is recorded in the *Lancet* for March 17, 1894, p. 668, by Dr. Percy Pope, who was called to treat a servant girl, nineteen years old, who had, with suicidal intent, taken hypodermatically an amount of morphin estimated at twelve grains, and in whom recovery was brought about by active treatment. When seen, a few minutes after having taken the poison, the girl was stuporous and drowsy, and the iris was so profoundly contracted that the pupils were not discernible. The conjunctival reflex was absent for some twelve hours, and the eyes appeared glassy and dull. The treatment consisted in the administration of atropin, of which 4 grains were given in the course of twelve hours, in doses of gr. $\frac{1}{20}$ at short intervals, without inducing any change in the pupils; the employment of galvanism, the application of wet towels, the injection of cold coffee, forced exercise, and artificial respiration. Symptoms of improvement manifested themselves in the course of twelve hours, but thirty-six hours elapsed before all dangerous symptoms had been dissipated.

The Difference between Copyrights on Books and Patents on Instruments.—Our respected friend, DR. LEARTUS CONNOR, takes issue in the *Journal of the American Medical Association* for June 2d with the contention of THE NEWS that there is a radical difference between the copyrighting of books and the patenting of instruments. He contends that both instruments and books equally instruct, and that their producers should therefore be equally rewarded and protected. Dr. Connor, however, evidently overlooks the fact that anyone may utilize the information contained in a copyrighted book, and even impart it to others, or go still further and incorporate it into a book of his own preparation; while none can use the patented instrument or utilize the ideas that enter into its construction without purchasing the consent of the patentee. Further, the patentee of

an instrument can arbitrarily make its price of sale so high as virtually to prohibit its use by others; or he might, if he chose, even not offer it for sale at all, for the purpose of retaining the privilege of its exclusive use, as did the Chamberlens with the obstetric forceps. The possibilities of evil from such opportunities must be perfectly obvious. The writer of a copyrighted book unreservedly *sells* his ideas, while the inventor of a patented instrument only *loans* his conditionally. The true parallel is not between a patented instrument and a copyrighted book, but between a patented instrument and a patented or copyrighted medicine. We have always understood Dr. Connor to oppose the latter.

The Spelling of Chemic Terms.—For the information of numerous correspondents and of others who may feel an interest in the subject, we reproduce a few of the rules for the spelling and pronunciation of chemic terms, adopted in 1891 by the American Association for the Advancement of Science, as a result of labors extending over a period of four years. The final *e* is dropped from words heretofore terminating in *ide* and the syllable is pronounced *īd* (as chlorid, iodid, hydrid, oxid). The final *e* is also omitted from the names of all elements and compounds that formerly terminated in *ine*, except doubly unsaturated hydrocarbons, and the syllable is pronounced *ĭn* (as chlorin, iodin, bromin, amin, anilin, quinin, morphin, caffein, cocain). *F* is used instead of *ph* in the spelling of sulphur and its derivatives (as sulfur, sulfite, sulfuric). *Aluminum* is preferred to *aluminium*; the dipthong is not used in *cesium*. The termination *ol*, in the case of specific chemic compounds, is used exclusively for alcohols, and when so used is never followed by a final *e* (as glycol, phenol, cresol, thymol).

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Eighth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from p. 620.)

THIRD DAY—MAY 31ST.

THE Secretary read for DR. EDMUND E. KING, of Toronto, Canada, who was absent, a paper on "Excision of the Initial Lesion," in which the ground was taken that excision of the chancre, if done sufficiently early, will abort syphilis. This opinion was based upon cases personally observed. In some of these, two years had elapsed without the appearance of any secondary symptoms. The belief was further expressed that if the secondary symptoms have appeared, excision of the chancre will still moderate their severity. The following conclusions were reached: 1. Early excision of the chancre—that is, within a few hours after its appearance—will abort the disease. 2. Excision of unhealed chancres will moderate the subsequent secondary manifestations. 3. It is the cleanest, least painful, and most scientific method of treating the lesion.

DR. EDWARD MARTIN, of Philadelphia, read a paper on "Epithelioma of the Penis." Regarding the etiology, phimosis is almost universally acknowledged. Traumatism is also an occasional factor. Until quite recently direct infection has been denied. Evidence is accumulating, however, that tends to call for a modification of this view. Syphilis is occasionally cited as a cause, but the etiologic relation is very problematic.

Operation in the earlier stages gives every prospect of permanent cure. Later, when the disease has involved the lymphatic glands of the inguinal region, or has so infiltrated the organ that the involved tissue cannot be entirely eradicated, operation still adds to the comfort of the patient, and prolongs life. Lymphatic enlargement may be either metastatic or inflammatory; in the latter case it will subside after operation.

It is advised that in every case, a microscopic examination should be made, to definitely settle the diagnosis and to determine whether or not all diseased tissue has been removed. If complete removal of the cavernous bodies is performed, the testicles should also be extirpated. The inguinal lymphatics should always be removed, whether enlarged or not. The two features emphasized, and which were new, are the possibility of the direct contagiousness of epithelioma, and the recommendation to remove the inguinal glands.

DR. R. W. TAYLOR, of New York City, read a paper on "Seminal Vesiculitis," in which he maintained that the disease is usually due to gonorrheal infection. The early symptoms of inflammation of the seminal vesicles are very similar to those of inflammation of the deep urethra. The patient feels a dull, throbbing pain deep in the pelvis; pus and blood may or may not appear in the urine. In cases of acute deep urethritis these are always present. Rectal examination will insure a recognition of the condition if present. The vesicles can be felt and will be found painful on pressure. Frequent noctural emissions, with or without erection, and emissions upon the least provocation constitute a marked symptom in many cases.

Resolution may take place, or the inflammation may terminate in abscess-formation. This, if unrelieved, may extend in different directions and may rupture into the rectum, the bladder, or the peritoneum. Cases have also been reported in which the abscess has reached a very large size without rupture. In one instance, ten pints of fluid were withdrawn. Seminal vesiculitis frequently complicates epididymitis, and in cases of the latter condition, if the symptoms do not subside in the usual time, involvement of the seminal vesicles may be suspected and should call for digital exploration.

In tuberculous disease of the vesicles, the symptoms are all of moderate character. There will be found swelling and infiltration of the organs, to be detected through the perineum and by rectal examination.

In the diagnosis, the most valuable information will be obtained by palpation with the finger in the rectum. The bladder should be full at the time of the examination; the vesicles are to be felt beyond and on either side of the prostate. The normal vesicles should be familiar to the touch of the surgeon; any departure from health will then be readily discernible.

The treatment should be such as is suitable to phlegmasic processes generally. Several leeches may be applied to the perineum, and cold water injected into the rectum, or the bowel may be packed with ice if agreeable to the patient. Opium will usually be required. If an abscess forms, an incision may be made in the peri-

neum, over the most prominent part of the swelling, or the pus may be aspirated; or in acute abscess, the incision may be made through the anterior rectal wall, as recommended by Dr. Gouley. Dr. Fuller recommends, in mild cases, emptying the cavity by "milking or stripping" the vesicle with the finger in the rectum. Dr. Taylor contends, however, that the vesicles cannot be satisfactorily emptied by any process of stripping.

In the discussion, DR. MARTIN referred to the difficulty of palpating the healthy seminal vesicles. In the treatment of chronic cases, great perseverance is necessary, as by any method of treatment improvement is exceedingly slow. He uses rectal irrigations of water as hot as can be borne. DR. BANGS and DR. HAYDEN concurred in the difficulty experienced in detecting the healthy vesicles. DR. WEIR, of New York, described the method of opening abscesses of the vesicles from the perineum, and of removing the glands in cases of tuberculous involvement.

DR. JOHN P. BRYSON, of St. Louis, read a paper on "The Question of Surgical Interference in Tuberculous Kidney." Of one hundred and seventy-four cases of tuberculous disease of the genito-urinary organs, which he had observed, the kidney was involved in but eighteen instances. In some of the cases of renal disease, the evidence was first manifested in the lower urinary tract. Dr. Bryson takes a conservative position in the surgery of the kidney. In abscess or in stone of the kidney, the surgeon's plain duty is to remove the offending material. But to open and drain a tuberculous focus or other disease that is apt to become generalized is not considered a justifiable procedure.

In the discussion, DR. BANGS said that his experience had led him to great conservatism in genito-urinary tuberculosis. In involvement of the bladder, mild palliative treatment is unquestionably the best. Much may be hoped for from sending the patient to a proper climate, and from a rigid attention to hygiene.

DR. EDWARD L. KEYES, of New York, expressed his impression that in uro-genital tuberculosis more medical treatment and less surgical treatment is required. Similar opinions were expressed by DRS. BELFIELD, BELL, and CHISMORE.

In closing, DR. BRYSON stated that in his experience he had not observed albumin or casts in cases of renal tuberculosis, and he should regard the presence of these in the urine as evidence against tuberculosis.

DR. F. TILDEN BROWN, of New York City, presented a "Brief Report of a Case of Cystitis and Pyelo-nephritis due to the Colon-bacillus, requiring Nephrectomy." A man, aged forty-two years, was treated for cystitis following the introduction of a steel bougie of large caliber. He had a relapse on the next instrumentation. Some time later he began to present symptoms of pyelo-nephritis: lumbar swelling, pus in the urine, chills, etc. Nephrectomy was performed. Cultures made from the removed kidney and from the urine drawn at different times by a sterilized catheter, invariably yielded pure cultures of the colon-bacilli.

FOURTH DAY—JUNE 1ST.

DR. ROBERT W. TAYLOR, of New York City, described a case of "Mixed Malignant Tumor of the Testicle."

The patient, twenty-seven years old, had had a chancre and gonorrhea, and had also been struck on the affected gland. On admission to Bellevue Hospital the tumor was as large as two fists, having doubled in size in two months. It had been perfectly smooth, but had recently become fungating upon the posterior surface. Microscopic examination showed the growth to be composed of cartilaginous, adenomatous, carcinomatous and sarcomatous tissue, and to be cystic in portions. The case is interesting on account of the age of the patient and the rapidity of growth.

In the discussion DR. BRYSON called attention to the observation of Jacobson, that tumors, which in other portions of the body are called benign, always become malignant when they attack the testicle. Dr. Bryson has also observed that, in administering the salts of iodin in cases of malignant disease, there is an increased tendency to hemorrhage. DRS. BRYSON, KEYES and BELL do not advise removal of the inguinal glands if the tunica vaginalis has not been broken through.

DR. JAMES BELL, of Montreal, Canada, reported "Two Cases of Syphilis having a Bearing on the Question of the Period during which the Disease is Communicable." The first of these was in a man who contracted a characteristic chancre, and was under careful anti-syphilitic treatment for two years and four months. The symptoms disappeared, and throughout the treatment progressed satisfactorily.

At the end of two years and six months the man married. He indulged freely in wine and indigestible food at the wedding. A few weeks later the patient's wife showed evidences of syphilis, which disappeared on anti-syphilitic treatment. On discontinuing treatment the symptoms returned, iritis being the most prominent. These again disappeared under treatment.

The second case was that of a man who contracted a chancre on the eve of marriage. The wife ceased menstruating after the marriage, and soon morning vomiting appeared. She was given anti-syphilitic treatment and has never shown any symptoms of syphilis. The child was born at full term, and though nine months have elapsed, its health remains perfect, and no evidence of inherited syphilis has appeared.

In discussing these cases, DR. TAYLOR called attention to the necessity of taking into consideration the possibility of an extra-genital chancre. Further, while cases of pertinacity of the infective principle are on record, Dr. Taylor is led to doubt the facts as stated in some of the cases. It is well-known that the blood is the least virulent of the various tissues of the body.

DRS. KEYES and BANGS expressed the conviction that a person affected with syphilis should not receive the consent of his physician to marry until three full years had elapsed, and then only provided that he shall have been under careful treatment and observation during this time. DR. TAYLOR said he would be inclined, in some cases, to give permission at the end of two years.

For Singultus, FESSLER (*Wien. Aerztl. Central.-Anz.*, 1893; *Memorabilien*, xxxviii, 3, 189) recommends the induction of vomiting by irritation of the palate and vault of the pharynx. The essential element is the contraction of the abdominal muscles and of the stomach.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Sixteenth Annual Session, held at Washington, D. C., May 30, 31, and June 1, 1894.

(Continued from p. 622.)

SECOND DAY—MAY 31ST.

DR. THOMAS R. FRENCH, of Brooklyn, read a paper entitled "Observations on Some of the Results of Cutting Operations on the Nasal Septum." He confined his remarks to two conditions, perforations and membranous adhesions. Our present methods of correcting septal deformities are not always successful. He asked: Are there not, then, conditions under which perforation of the cartilaginous septum can be made a perfectly justifiable procedure? He believes that with proper after-treatment such a perforation can be made without injury and with great relief when a breathway through the obstruction cannot otherwise be obtained. He excepts, however, a perforation made near the introitus of the nares, particularly in a septum bent obliquely across at both openings.

In regard to adhesions, he called attention to a cause heretofore overlooked, viz.: cut surfaces on the septum will become adherent to scar-tissue on the opposing turbinates from the previous use of the galvano-cautery. Hence before operating on the septum one should always inquire carefully into the patient's previous history as to operations inside the nose; and when both parts, septum and bone, require treatment, the septum should be attacked first. When for any reason it is necessary to operate on the turbinate first, preference should be given to the use of acids or the snare.

Doubtless, adhesions often result from saws with unprotected ends, and the unskilful use of trephines or forceps in narrow nostrils. In the use of the saw, one should begin by cutting upward, and finish by cutting downward, and whichever way one begins, the section should be finished by cutting in the opposite direction. In this way one can remove a maximum amount of tissue with a minimum danger of injury to the outer wall.

In the discussion, DR. F. H. BOSWORTH, of New York, admitted that perforations would result at times with every procedure, but they are harmless if in an antero-posterior direction, so that the incoming air does not directly impinge upon some projecting angle or edge. DR. JOHN O. ROE, of Rochester, N. Y., expressed his belief that in children only is there any danger of falling in of the nose from an accidental perforation. With his own septal forceps this accident is prevented by a screw in the handle, so as to prevent too close approximation of the cutting edges. The intact membrane on the sound side would act as a splint till healing occurred. DR. C. M. SHIELDS, of Richmond, Va., maintained that the septal thickening in these cases is a provision of Nature to prevent further bending. If it be removed, Nature reproduces it. He prefers the knife to all forms of punches, as the latter comminute the tissue. DR. W. E. CASSELBERRY, of Chicago, could not accept Dr. French's view as to adhesions resulting only when two raw surfaces are opposed. Naso-pharyngeal tumors often adhere to adjacent surfaces as a result of continuous pressure. Hemorrhage could come from the septum as well as from injured turbinated bones. DR. J. W. GLEITSMAN, of New York, said that failure to relieve symptoms after septal operations may result from the fact that the turbinated bones might be enlarged posteriorly. DR. W. PEYRE PORCHER, of Charleston, S. C., contended that iodoform-gauze is the best material for intranasal packing. He had seen sharp bleeding from the breaking up of adhesions. The paper was also discussed by DRS. M. J. ASCH, of New York; W. H. DALY, of Pittsburg; S. W. LANGMAID, of Boston, and M. R. BROWN, of Chicago. Special stress was laid by all on the fact that operations on the septum should not be undertaken unless one could be sure that the after-treatment would be effectually carried out.

DR. W. H. DALY, of Pittsburg, read a paper entitled "A Plea for Early Operation in Diseases of the Antrum of Highmore," which was based upon twenty-seven cases treated since 1882. He advocated exploratory incision (if necessary) for diagnostic purposes. As the proper site for operating, he preferred the point just above the second bicuspid tooth, where the wall of the antrum has a certain resiliency. The cheek will cover over the aperture, though particles of food will at times gain access to the antrum. A drill with a conical burr-head is the best perforator. Care should be taken to break up all the partitions in the antrum. An excellent irrigator is provided by a nozzle of proper length and shape fastened to an ordinary Davidson syringe. It is possible, however, to teach the patients to irrigate by instructing them to fill the mouth with water, and then, by a sort of bucco-lingual compression, force the fluid up through the opening. After flooding the sinus the fluid would escape through the natural opening into the nose. The opening made by operation should be of about the size of a small goose-quill. Constitutional symptoms may develop after operation. Dr. Daly had frequently noticed pain over the eye as an early symptom of disease of the antrum.

DR. A. W. DE ROALDES, of New Orleans, regarded irrigation through the natural opening as quite practicable. The operative opening should be large. DR. BROWN found the preferable site for operation between the roots of the teeth. In this way a part of the alveolus is perforated, and the floor of the antrum is opened into. A prolonged retention of the tube keeps up the discharge. Irrigation through the natural opening is possible, but not feasible. DR. J. H. BRYAN, of Washington, pleaded for conservatism in the surgery of the antrum. An exploratory opening could be made through either the inferior or the middle meatus. Only the mildest possible antiseptic should be employed. DR. SHIELDS also had found that discharges frequently ceased after the tube was removed. The opening would always close unless the patient had specific disease. DR. CASSELBERRY believed that the antrum is rarely diseased alone. Other sinuses are affected at the same time. They suppurate, and so prolong the discharge from the maxillary sinus. Pain over the eye is probably due to coexistent ethmoid disease.

DR. A. W. DE ROALDES, of New Orleans, read a paper entitled "A Case of Compound Follicular Odontoma invading the Antrum and Corresponding Nasal Fossa; with a New Apparatus for Anesthesia in Operations about the Mouth." A healthy boy, nine years old, presented a fibrous growth at the site of the central incisor tooth of

the right upper jaw. There was also an osseous tumor covering a considerable portion of the palatal bone back of the missing canine teeth, and extending posteriorly alongside the internal plate of the alveolus to near the tuberosity of the maxilla. Both growths were removed. A year later the osseous tumor had returned. A second removal was practised. Soon afterward carious bone was found at the site of operation, and the antrum was exposed. When first seen by Dr. de Roaldes, a hard, bony tumor was found occupying the right cheek, depressing the palatal vault and encroaching on the right nasal fossa. It was fused with the alveolar border exactly at a point corresponding with the missing canine tooth. A diagnosis of osteoma, but possibly odontoma, was made. By a modified Vollet's operation, the whole alveolar border was removed, from nose to tuberosity, and from alveolar border to orbital floor, and the main mass of eburnated bone chiselled out from a place corresponding to the canine fossa. On its surface were tufts of hard, adherent tissue; of these a large number of smaller ones (fifty or more, some tooth-shaped) were gouged out in all directions. After thorough curetting, the cavity was packed and bandaged. Recovery was rapid. Three months later the cavity was two-thirds filled with new, healthy tissue, and a photograph shows no external deformity. Microscopic examination showed the tumor to consist of an hypertrophied tooth-capsule which had ossified sporadically in places, thus producing a large number of denticles, which probably had been originally bound together by periosteum, the denticles being imbedded in the fibro-vascular structures, like plums in a pudding. These denticles consisted entirely of cementum, and the origin of the neoplasm was connected with the unerupted canine tooth. Dr. de Roaldes summarized the salient features of the case as follows:

1. The rare character of the tumor.
2. Its uncommon origin in an unerupted canine tooth.
3. Its location in the right upper maxilla.
4. Its coexistence at one time with a fibrous growth, probably a fibrous odontoma. Odontomata are frequently taken for exostoses, fibromata, etc.
5. The diagnosis is difficult when the mass is imbedded as this one was. A history of the teeth-eruption in each pattent will assist.
6. It is not always necessary to remove the entire maxilla in such cases.

Dr. de Roaldes also exhibited Souchon's apparatus for anesthesia in such cases.

DR. C. M. SHIELDS, of Richmond, Va., reported a case of "Foreign Body in the Larynx." A farmer, while hurriedly walking through some bushes, suddenly felt that he had drawn something into his mouth, being breathless, breathing with his mouth open. He immediately experienced considerable difficulty in respiration. On examination it was found that a burr was lying in the anterior commissure of the glottis, just at the lower level of the vocal bands. Its long axis was antero-posterior, and it was firmly fixed by the closure of the glottis on its sharp points, as it had been grasped just as it was passing through. The removal of the burr was somewhat difficult, on account of the extreme irritability of the throat. Cocain was freely sprayed, but various forceps failed to remove the offending mass, because of the inability to place the blades between the burr and the tisues. Similar failure resulted from the use of a wire loop passed through a curved canula, as the rapidly contracting vocal bands flattened out the wire; so also with cotton twisted on a curved probe, and a curved blunt curet passed below the burr. Tracheotomy was now regarded as inevitable, but finally a Schroetter's tube-forceps succeeded in withdrawing the foreign body.

DR. CHARLES H. KNIGHT, of New York, reported "Three Cases of Laryngeal Neoplasm."

In the first case a diffuse subglottic myxoma was present. This was partially removed through the mouth by Mackenzie's forceps. Tracheotomy was performed under cocain, and radical extirpation of the growth effected through the wound. Recovery ensued without a single bad symptom, and there was no recurrence.

The second case was one of papilloma of the larynx. This was removed with Mackenzie's and the Schroetter-Türck forceps. Galvano-cauterization was applied to the base of a growth attached beneath the right vocal band. Voice was restored within three weeks, although complete aphonia had existed for eight months.

The third case presented multiple papillomata of the larynx, which were removed with Mackenzie's forceps. The growths recurred at the end of a year. A second removal was undertaken, and was followed by a second recurrence, and a third removal five years later.

DR. ARTHUR A. BLISS, of Philadelphia, reported "Two Cases of Malignant Tumor of the Larynx."

The first was a case of squamous epithelioma of the larynx, and occurred in a man forty-six years old, who presented hoarseness, dyspnea, and enlarged glands, the history dating back two years. Owing to a refusal to submit to a radical operation, tracheotomy was advised. Laryngeal examination with the mirror in the pharynx showed the left arytenoid cartilage and vocal band to be so swollen that the band could not be seen. The other band was pushed to the opposite side. There was no odynphagia. The heart-sounds suggested atheroma, and there was considerable albumin in the urine, but no casts. The trachea was opened through the upper two rings. Severe spasm of the glottis resulted in the primary anesthesia with ether, and this was referred possibly to an accumulation of mucus in the air-passages. Death took place suddenly one month later, from angina pectoris. The autopsy revealed thickening of the pericardium, fatty heart, and greatly damaged kidneys.

The second case was one of small round-celled sarcoma of the larynx in a man fifty-three years old, with symptoms resembling those in the first case. The pharynx was normal. The epiglottis was a fungating mass. The right arytenoid was swollen and edematous. A swelling existed in the supra-hyoid region, but there was none over the thyroid. A radical operation was refused, and a high tracheotomy was performed. Death resulted in one year, from exhaustion.

DR. HENRY L. SWAIN, of New Haven, read a paper entitled "A Case of Laryngectomy by a New Method.' The patient was a German, forty-two years old, with an epithelioma of one vocal band, which had followed upon a simple fibroma, the existence of which had been known for a year previously. The malignant mass grew unti it filled the entire larynx. Tracheotomy was performed under cocain, and thirteen days later the larynx was removed. An incision was made from the hyoid bone to

the sternum, and also a low tracheal opening through which a sponge Trendelenburg canula was introduced. Cross-incisions were made from the top of the wound to the sterno-mastoid muscle on each side. The larynx was thus laid bare, and, bleeding being checked, a bistoury was inserted behind the junction of the larynx with the trachea. The trachea then being liberated by a cut with a strong blade, the larynx was hooked up, and dissection begun from below upward. The anterior esophageal wall was closely hugged until the arytenoids were reached. Then the direction of the dissection was changed so as to preserve a part of the arytenoid mucous membrane and of the ary-epiglottic folds. The next step was to cut across the epiglottis, to free the larynx, and check all bleeding. The epiglottis was then sutured to the anterior wall of the esophagus, thus entirely closing the cavity of the pharynx and cutting off all connection with the wound in the neck. Later, the latter was sewed up tightly, except a part of the first median incision, into which the upper rings of the trachea were brought, so that the latter was directed upward and forward. The wound was dressed with a plain dry dressing. No tube was left in the trachea. The operation occupied nearly three hours, and recovery from the ether was perfect. Healing was uninterrupted save for a stitch-abscess above and back of the trachea, which quickly closed up. On the second day the temperature was 101°, and then went down again to normal, without recrudescence. The internal wound at the base of the epiglottis healed by first intention, and the patient swallowed sterilized water from the outset. At the end of a week he could swallow fluid food, and at the end of a second week full hospital-diet. Both wounds were in a healthy condition. At first the man could make no audible sound; later he was able to "hiss" a little, and the sibilant consonants could be heard; now brief sentences and single words can be distinctly understood, even with the back turned, so as to exclude lip-reading. The voice is a whispering one, but is steadily gaining in strength. At the present time he is wearing a tube in his trachea most of the time, and is working at his trade as a carpenter.

Third Day—June 1st.

Dr. W. C. Glasgow, of St. Louis, read a paper on "Exudative Pharyngitis." He reported the case of a robust child, ten months old, that, following exposure to cold, complained of pain in the ear. Two days later, coryza with high fever ensued, the temperature being very irregular and not unlike that of a septic process. From the nose poured out mucus, which excoriated the skin wherever it touched. The excoriations soon became covered with a whitish pellicle. Corresponding lesions soon appeared on the tonsils, uvula, soft palate, and pharynx, but not in the nose. The patches were whitish and elevated, and left no bleeding surface after removal. They looked like blisters containing solid albumin. Prolonged aphonia and urgent dyspnea were prominent symptoms. Some fluid returned through the nose when attempts at swallowing were made. The cutaneous lesions differed from those on the mucous membranes only in having raised edges. There were no enlarged glands. The secretion was strongly alkaline. Therapeutically, reliance was placed upon sodium salicylate and phenol, with brandy internally and hydrogen dioxid externally. The skin was dressed with aristol. The mucous contained streptococci, but no bacilli of Loeffler.

A paper on "Singers' Nodes" was presented by Dr. F. I. Knight, of Boston. He described the lesions as little nodules, as large as a millet-seed, on one or both vocal bands at about the junction of the middle and anterior thirds. They are caused by over-strain of the voice or by error in vocal method. The diffuse variety of this same histologic formation is called chorditis tuberosa, also trachoma of the bands. The single nodules are circumscribed hypertrophies of the epithelium and of the submucous tissues. They contain no glands. As to treatment, the main reliance must be placed on rest and mild astringents. By these means Dr. Knight's cases had been so far improved that he did not feel like risking the possibly bad effects of cutting operations. Still Rice's guillotine might be allowed if simpler methods had failed.

Dr. J. W. Gleitsman, of New York, had been satisfied with the galvano-cautery in these instances. Chromic acid and trichloracetic acid are also useful.

Dr. S. W. Langmaid, of Boston, said that physically we have here to do with a definite, circumscribed tumor. He had seen six or eight cases, in one of which the nodule was further back than is usually the case. They occur most commonly in women, and unless there is too great inflammation of the bands themselves, do well. The nodule is not vascular. Error in vocal methods is not so often the exciting cause as vocal over-strain. Singers whose artistic powers are most acceptable to a critical public may have these nodes, which do not therefore, immediately at least, impair the voice. After treatment an impaired voice may never regain its former qualities, though it may answer for the dramatic stage. Surgical treatment would not necessarily injure the voice unless great violence was done to the edges of the bands. Curetting might suffice.

To an inquiry by Dr. Porcher, if these nodes ever became papillomata, Dr. Knight replied in the negative.

Dr. Murray had seen four cases, one in a child of seven, who sang considerably. He had known a perfect cure to result from the solid silver stick and steam-inhalations.

Dr. J. N. Mackenzie had treated one case of the tuberous variety with lactic acid in concentrated solution.

Dr. T. R. French emphasized the necessity of long-continued local treatment and the good results therefrom. One of his patients had been seen three times a week for over two years and a half, and had made a brilliant recovery. He regarded surgical measures as contra-indicated. He did not believe that the condition had any connection with tuberculosis, and with this view all present coincided.

Dr. W. K. Simpson, of New York, agreed as to excessive use of the voice being the causative factor rather than error in vocal method. These nodules may come from laryngitis or from hemorrhage into the bands. In one of his cases a linear hemorrhage on the inferior aspect of the band, and invisible in ordinary phonation, came into view in the median line when the higher notes were reached.

Dr. Delavan remarked that these nodules sometimes appear quickly in acute laryngitis, but he knew of no

relation between laryngitis and the chronic variety under discussion. As to tuberculosis, the two conditions may, of course, coexist without there being any causative relation between them.

Dr. A. W. Watson, of Philadelphia, reported a "Case of Sarcoma of the Tonsil." It occurred in a woman, fifty-three years old, who felt well until seized with severe sore-throat, probably a quinsy, followed by a discharge of a little pus, but without relief. Sharp pain continued, radiating to the ear. The left tonsil was moderately swollen, and the anterior pillar adherent thereto. The surrounding tissues were not infiltrated. One small gland at the angle of the jaw was enlarged; odynphagia was marked. Medicines gave no relief, and an incision revealed no pus. A part of the tonsil removed for examination showed the latter to have been invaded by a round-celled sarcoma. Removal was effected under cocain six weeks later, with short successive strokes of the galvano-cautery knife. The pillar was also removed at the same operation, the tonsil being lifted up by a vulsellum. Three weeks later, the glandular enlargement had disappeared; swallowing was easy, and the pain in the ear was nearly gone. The peculiar features of the case were the sudden onset, with the presence of so much pain and dysphagia, in view of the lack of infiltration of surrounding structures.

Dr. J. W. Gleitsman, of New York, read a paper entitled "Importance of an Early Diagnosis of Malignant Tumors of the Throat."

He said that at the present time there are three methods of procedure which promise a cure in a certain number of cases, excluding those in which the disease is so far advanced that only a tracheotomy can be done and the patient allowed to die easily, or risk his life by attempts at removal.

The first is the endo-laryngeal method. If the patient comes under observation early enough, this method should be practised oftener than it is.

Second. A possibility of relief is offered by the method of injecting into the malignant mass the cocci or toxins of erysipelas obtained by the cold method. Reference was made also to the use of methyl-blue, which had given better results when the substance had been taken internally than when it had been applied locally.

The third division includes the general subject of surgical removal. From the standpoint of operative surgery the larynx and pharynx could be regarded as analogous to the breast and uterus. Leading surgeons agree that by far too large a number of cases of malignant disease come into their hands too late for an operation. When seen an operation is either impossible or else extremely hazardous. Excepting trauma and sepsis, delay in operation is the most potent factor in determining bad results in surgery. Early diagnosis is often difficult, but when once made no delay is to be tolerated. Each case must be decided on its own merits as to whether a simple tracheotomy or a partial or complete laryngectomy should be done. Pieniazek, a Russian, has had thirty-seven cases of laryngo-fissure, with the head hanging downward, with only two deaths, one from diphtheria and one from tuberculosis. Gleitsman has seen thirteen cases in his own practice. The pharynx was involved in six; four presented carcinomata of various parts, and two tonsillar sarcomata. Of the former, one was operated on three months ago, and feels well now; the others are dead. Of the second two, one was inoperable, and the other lived two years after removal without recurrence, and died by suicide. The larynx was involved seven times—in six with carcinoma (all dead) and in one with alveolar sarcoma. The latter case is living without known recurrence. Laryngo-fissure, with removal of the diseased tissue, was done; unilateral and total laryngectomy were each done twice, and tracheotomy was done once. Death resulted twice speedily from shock, and twice from pneumonia on the second and third days respectively. One had a recurrence after six months, and died from exhaustion. One of the two total laryngectomies did well for six months, but died of an intercurrent appendicitis.

The last two papers were discussed together.

Dr. Wright regarded it as extremely difficult to make an early diagnosis in cases of malignant disease of the throat. Even the microscope is sometimes uncertain until the clinical course of the case removes all doubt. Skepticism was expressed as to the value of the streptococcus of erysipelas and its toxins.

Dr. Langmaid alluded to the method of removal of malignant tonsils from the outside as practised by Cheever, of Boston.

Dr. Casselberry thought it folly to place any reliance on an endolaryngeal operation as soon as malignancy was once determined.

Dr. W. Peyre Porcher, of Charleston, read a paper on "Neurasthenic Throats, with Illustrative Cases." Special stress was laid on the intimate relations between the heart and the lungs. Lesions in one of these organs are likely to excite symptoms in the other. Among the most common symptoms of neurasthenic throats are aphonia, reflex cough, and a spastic state of the muscles of the larynx. Some of these cases seem to be the point of departure for tuberculous invasion.

Dr. E. Fletcher Ingals, of Chicago, communicated clinical reports on the following conditions:

1. Cyst of the larynx. A man, thirty-three years old, had complained of sore-throat for two years, with cough for seven months, and considerable soreness, especially for two months. When seen, the annoying symptoms were hoarseness and a continuous burning pain in the throat. The general health, pulse, and temperature were all normal. He raised about a half-ounce of muco-pus daily, as he had a superficial laryngo-tracheo-bronchial catarrh, but no true pulmonary lesions. A large swelling was found in the larynx, situated on the left ventricular band and ary-epiglottic fold. It was about 1.5 cm. long and 1 cm. in its lateral diameter. Its surface was smooth and covered with congested mucous membrane. Resolvents did not reduce its size. Puncture gave exit to a little semi-transparent, grayish fluid, causing some diminution in the size of the mass. The peculiar feeling imparted to the puncturing needle was that of passing through a cortical portion into a cavity. A diagnosis of cyst was therefore made.

Injections of lactic acid in 30 per cent. solution were at first made at intervals of several days. Later it was decided to resort to injections of carbolic acid. Eight injections were accordingly made at intervals of about a week. From 15 to 20 minims of a 10 per cent. solution of the acid in glycerin and water were used,

with the result of causing nearly the entire disappearance of the tumor. No recurrence had taken place three months later.

The walls of the cyst were so thick that any cutting, crushing, or tearing operation was out of the question. To remove it by operation would, on account of its deep-seated location, have necessitated a removal of considerable of one side of the larynx.

2. Pharyngeal mycosis. Dr. Ingals detailed the histories of twelve cases of this affection. In 58 per cent. of the cases the patients had suffered more or less for years from sore-throat, and in 66 per cent. this had been particularly noticeable from four to six weeks immediately preceding the discovery of the mycosis. Three patients were dyspeptic, but in fully one-half of all of the cases the state of the general health was excellent.

In regard to treatment, Dr. Ingals believes that spontaneous cures are not impossible. Two of his own cases bore out this view. His favorite therapeutic measure is the galvano-cautery at a bright-red heat. Two or three patches are treated at each sitting, and the pain from one séance is allowed to subside before the treatment is repeated. He burns off the surface-mass first, and then plunges the electrode into the subjacent tissues for about one-eighth of an inch. In every instance in his experience under this treatment, a cure has resulted and no recurrence has been reported.

Dr. H. L. Wagner, of San Fransisco, presented a communication entitled "A Contribution to the Study of the Etiology of Rheumatic Affections of the Body due to Tonsillar Diseases." He described the tonsils as an inlet into the system, guarded by the white blood-cells. The latter protects the body from various germs. If the vitality of the cells is lowered, or if a diseased tonsil prevents their migration, the soil may be prepared for the growth of infectious microörganisms. As sequelæ of the diseases thus produced we may have various paralyses (as after diphtheria) and articulo-rheumatic affections (as after lacunar tonsillitis). The question arises: Are the latter produced by the migration of staphylococci, pneumoma-cocci, etc., from the tonsil into the system, or do these organisms remain in their original habitat, sending forth their ptomaïns? Dr. Wagner's researches go to support the former of these propositions. The joints generally affected are those of the ary-cartilages in the larynx, the knee-joints of shoemakers and dealers, owing to the constant kneeling posture, the wrist-joints of violinists and bookkeepers. In the two cases with knee-joint trouble the synovial exudate was removed, and the same organisms found as in the diseased tonsils. In nearly all cases the same germ was found in the urine. The family and the personal history of all these patients showed no rheumatism previous to the tonsillar attacks.

Dr. Harrison Allen, of Philadelphia, demonstrated some skulls of cretins, showing the peculiarities of the condition as affecting the size of the nasal chamber. In all, the hard palate was shortened, the inferior nasal meatus deepened, and in one instance the maxillary sinus was greatly enlarged. Dr. Allen expressed the belief that cretinism is more common in America than is generally supposed.

At the final executive session Dr. John O. Roe was elected President for the ensuing year. Rochester, N. Y., was chosen as the place of meeting, and the time left to the selection of the Council.

AMERICAN MEDICAL ASSOCIATION.

Forty-fifth Annual Meeting, held at San Francisco, Cal., June 5, 6, 7, and 8, 1894.

(By Telegraph.)

General Session.

The question of revision of the Code of Ethics gave rise to a protracted discussion, which terminated in an indefinite postponement of any action upon the subject.

The following were elected the officers for the ensuing year: Dr. Donald McLean, of Detroit, President; Dr. Starling Loving, of Ohio, First Vice-President; Dr. Wm. Watson, of Iowa, Second Vice-President; Dr. W. B. Rogers, of Tennessee, Third Vice-President; Dr. F. S. Bascom, of Utah, Fourth Vice-President; Dr. S. P. Newman, of Illinois, Treasurer; Dr. W. B. Atkinson, of Pennsylvania, Permanent Secretary; Dr. G. H. Rohé, of Maryland, Assistant Secretary. The next meeting will be held at Baltimore, Md., May 7, 8, 9, 10, 1895. Dr. Julian J. Chisholm, of Baltimore, was elected Chairman of the Committee of Arrangements. The Board of Trustees was constituted as follows: Dr. Jos. Eastman, of Indiana; Dr. J. T. Priestly, of Iowa; Dr. J. E. Woodbridge, of Ohio; for unexpired term, Dr. D. W. Graham, of Illinois; for full term, Dr. J. W. Graham, of Colorado, vice Dr. D. C. Patterson, deceased. The Judicial Council: Dr. D. W. Crause, of Iowa; Dr. R. C. Moore, of Nebraska; Dr. T. D. Crothers, of Connecticut; Dr. G. B. Gillespie, of Tennessee; Dr. W. T. Bishop, of Pennsylvania; Dr. C. H. Hughes, of Missouri; Dr. J. J. Heiberger, of District of Columbia; Dr. H. Brown, of Kentucky, for unexpired term. Dr. W. E. Quine, of Illinois, was appointed to deliver the Address on Medicine; Dr. C. A. Wheaton, of Minnesota, to deliver the Address on Surgery; Dr. H. D. Halton, of Vermont, to deliver the Address on State Medicine. Dr. Jerome Cochran was made Chairman of the Committee on Nominations.

Section on Practice of Medicine.

First Day—June 5th.

In the absence of Dr. H. A. Hare, of Philadelphia, the chair was taken by Dr. E. H. Kellogg, of Milwaukee, Wis.

In the absence of Dr. W. H. Washburn, of Milwaukee (the regular Secretary of the Section), Dr. Allen Pierson, of Spencer, Indiana, was appointed Secretary *pro tem.*

Dr. J. H. Wythe, of Oakland, Cal., presented a paper entitled "The Structure of Blood-corpuscles and its Relations to Practical Medicine." He said that from the earliest times physicians had recognized the importance of studying the blood, but owing to inadequate means, it was only within the past ten or fifteen years that a systematic study could be undertaken.

He pointed out that the blood is not simply an aggregation of corpuscular elements, but that the plasma is capable of exerting a powerful influence upon the economy, *e.g.*, by its bactericidal powers. This power was ascribed to the solvent action of the serum. Changes in the specific gravity, as well as in the acidity and

alkalescence of the blood should be noted. These often point to diseased conditions, and are due probably to the absorption of certain toxins, ptomaïns or leukomaïns, etc. As a result of observations of varied changes in the red blood-corpuscles, Dr. Wythe concludes that the changes have a definite relation to diseased conditions. Considering the various functions performed by the blood, it is not strange that it is constituted of a variety of structures.

Reference was made to eighteen cases of beri-beri in which the red blood-corpuscles were found in various stages of disintegration. Upon the basis of this observation, iron, quinin, and a generous diet were advised, with the result that every case improved.

DR. WM. WATT KERR, of San Francisco, read a paper entitled "Digitalis in the Treatment of Pneumonia." He briefly outlined the three principal classes of teaching as regards the use of digitalis in pneumonia. Those of the first class regard it as a specific; those of the second say that it has little or no effect; while those of the third believe its use inadmissible on theoretic grounds, objecting that the congestion and consolidation of the lungs offer a great resistance to the pulmonary venous flow, thus overcrowding the right heart, and that by using digitalis there is danger of inducing cardiac paralysis.

Depressed cardiac action in pneumonia is due 1, to absorption of toxins and products of tissue-waste; 2, to the pyrexia; 3, to obstruction of the circulation through the lungs. Dr. Kerr has never found digitalis produce any but good results when the indications pointed to its use. There are two conditions contra-indicating its use: 1, when pneumonia occurs in patients with fatty or degenerated heart; 2, when the patient is extremely plethoric. In these cases he uses nitroglycerin to overcome arterial tension. Digitalis is beneficial in certain cases of pneumonia, but it was not claimed that it is a specific. So long as the heart is doing its work well it should be left to itself and the course of treatment be directed to the other morbid conditions, but as soon as there is evidence of cardiac weakness, ♏xv of digitalis should be given every three hours till the pulse shows evidence of its effect; then the dose should be reduced sufficiently to hold the heart steady. When a patient comes under observation after the heart is overburdened, the best line of treatment is bloodletting and digitalis. Tincture of aconite and tincture of veratrum viride do more harm than good. Digitalis frequently fails in the treatment of pneumonia because its action is essentially on the nervous system and this is neutralized by the pyrexia and toxemia; these should be overcome by the use of strychnin, etc. A more competent and thorough study of the pulse was urged as being the great indicator for the drug-action of digitalis.

DR. WASHINGTON AYER, of San Francisco, believed the lancet a most excellent agent, although requiring caution in its use. When the pulse is feeble, the secretions thick, tenacious, and viscid, the respiration difficult, and the patient appears to be in *articulo mortis*, venesection is the only measure that offers any hope of relief.

DR. DEWITT, of San Francisco, stated that, according to his personal experience, fifteen-minim doses of tincture of digitalis are too large. He has found a "reflex action" occur, making him rather timid; with such large doses he has always found nausea to follow.

DR. HURST, of Indiana, cited two cases in his early practice in which digitalis was being given in full doses of the infusion. One case presented a pulse of 40 per minute, with profuse sweating and nausea. The digitalis was withheld and whiskey and general stimulating treatment given, and the patient was saved. The other case ended fatally, because of the injudicious use of digitalis, it was believed.

DR. LORING, of Chico, indorsed the use of digitalis, but found that, as a rule, not more than one or two doses of ♏xv of the tincture could be tolerated. He usually used only ♏viij per dose, nausea occurring almost uniformly under larger doses.

DR. AYER, of San Francisco, stated that he uses whiskey and ammonium carbonate when the heart becomes weak. He recommends their use diligently and fearlessly; unless some stimulation is resorted to there is likely to be venous stasis in the lungs.

DR. KERR, in closing, said that the dosage of digitalis recommended referred to the U. S. P. tincture; he again emphasized the fact that the dose must be diminished as soon as the pulse showed the effect of the drug-action. He had rarely had any nausea result in patients with croupous pneumonia, although he had observed nausea result from digitalis in some heart-cases. He did not advocate the indiscriminate use of digitalis in pneumonia, but in those cases indicating its use there is always benefit.

In the absence of DR. DOUGLASS W. MONTGOMERY, of San Francisco, his paper, entitled "Leprosy in San Francisco," was read by the Secretary, Dr. Pierson. The ground was taken that leprosy is a contagious disease, as has been shown by clinical evidence. In view of this fact care should be taken by all municipal authorities to isolate those suffering with the disease. Dr. Montgomery took the Chinese quarter of San Francisco as an example of a favorable soil for the growth of leprosy. He cited a number of cases that had come under his observation, in the persons of Chinese, that would seem to show that the disease was contracted in this country, but a more careful investigation of the history showed, in every instance, that it was probably contracted in China. He has never met with a leprous Chinese native of this country. The period of incubation in the cited cases was very variable.

DR. W. R. CLEAVELAND, of Biggs, Cal., read a paper entitled "Importance of Early Diagnosis and Prompt Treatment in Acute Catarrhal Pneumonia." He dwelt upon the necessity of careful physical examination of the chest, especially in the old and in debilitated subjects in whom there was a suspicion of pneumonia. Percussion will clear up any doubt in the diagnosis between catarrhal and croupous pneumonia. Auscultation will first give warning of the impending trouble. The earlier free expectoration can be brought about the better the chances of the patient. In the experience of Dr. Cleaveland many cases followed influenza, and the majority of cases of catarrhal pneumonia occurred in strong, robust individuals.

The treatment includes the application of a jacket of surgeons' lint, covered with oiled silk or mackintosh, and the internal use of ammonium carbonate and ammonium iodid as expectorants. The air of the sick-room should not be dry, but should be kept moist and

impregnated with vapors of turpentine and eucalyptus. Strychnin and quinin should be used in tonic or stimulating doses. Alcohol, in the form of whiskey, and as eggnog, is of the utmost service; alcohol in some form must be used. For the febrile symptoms acetanilid or phenacetin was recommended. Apomorphin is an important and most excellent expectorant. If the case comes under observation early, and if free expectoration is established, and the digestive apparatus attended to, favorable results may be looked for.

Digitalis and trinitrin may be used in cases with weak heart. Vesicants should be used to hasten absorption of consolidated areas, while internally, syrup of hydriodic acid and syrup of the hypophosphites should be given.

SECTION ON SURGERY.

FIRST DAY—JUNE 5TH.

The address of the Chairman, DR. JOHN B. ROBERTS, of Philadelphia, was entitled "Some Surgical Sins." He directed attention to a class of surgeons claiming wonderful results and performing operations simply for the sake of operating, with no view to a satisfactory result and full of dogmatic assertion. Operative madness is endemic among those whose preliminary training has been deficient and who possess limited scientific knowledge. Preliminary education is a corrective, and a reaction is fast taking place. A true surgeon, possessed of a thorough pathologic knowledge, must be a man of broad culture and have had an adequate preliminary education. Surgeons should be careful to make accurate statements and to refrain from criticising others. A great surgical sin is the overlooking of the influence of the nervous system upon disease. The evil of physicians controlling private hospitals was condemned. Such institutions become hotels for patients, and, of course, those interested are tempted to strive to keep them filled with long-staying guests. The sin of charging large fees was also condemned. The refusal to consult with a brother-practitioner because the patient is poor constitutes another sin, as also does the charging for services rendered to a physician or his family. Secret nostrums were denounced as being unscientific, not precise, and never to be used, because usually their contents are unknown.

DR. A. P. OHLMACHER, of Chicago, read a paper entitled "A Critique of the Sporozoan Theory of Malignant Neoplasms from a Micro-technical Standpoint." He pointed out that many objects have been described as the parasites of carcinoma, because the subject has been handled unscientifically. A great number of reagents have been used; hence the diversity of results. Artificial products are sometimes found by the reagents. It has been found that sporozoa treated by different fixing solutions act differently. Some agents distort the spores and interfere with the subsequent staining. All of the present methods of investigation are faulty and no results are to be looked for until new methods are devised.

DR. R. A. MCLEAN, of San Francisco, read a paper on "The Necessity of Early Surgical Interference in Malignant Tumors." He said that when malignancy in a growth has once been established its removal must be immediate. Recurrence is frequent because the operative interference is delayed until the case is hopeless. Among the causes of failure of operations are: great size of the growth; infiltration of adjacent tissues; metastases; ulceration; exhaustion, and septicemia. The great mistake is not insisting on a radical cure. A temporizing policy is fatal. In suspected cases malignancy, tuberculosis, and syphilis are to be differentiated. One month's observation should clear up any doubts. Another cause of delay is the attempt to label the growth. Early in the case a small operation only is, as a rule, necessary. In operating, as much involved tissue as can be removed with safety should be extirpated. The incision should go well around the probable limits of infiltration. In carcinoma of the tongue or lip the bone should be taken out if it is eroded. In the extremities, amputation should be performed on the proximal side of the next articulation above the growth. Excision should be practised in all cases in which the general health is good,

DR. JOHN PARMENTER, of Buffalo, read a paper on "The Value of Caustics in Malignant Growths." Among the many claims made for caustics are: 1. The less frequent recurrence. 2. The selective action of the agents used. 3. A reduction in the size of the enlarged lymphatics. These claims are, however, not well grounded. The value of a caustic resides in the selection of a proper agent and the selection of proper cases. A proper caustic is one that entirely destroys the diseased tissue, and it should be rapid in its action. Caustics must be used in conjunction with common sense. All diseased tissue should be burned. The application should not be made too extensive. The pain should be mitigated as much as possible. Suitable cases include those (1) located in a favorable anatomic situation; (2) in which there is no involvement of the lymphatic glands. Unsuitable cases include those in which the growths are inaccessible, involve bone, or are in proximity to large vessels. Bad results follow poor technique, too limited application, tardy diagnosis.

DR. L. DUNCAN BULKLEY, of New York, read a paper on "The Value of Caustics in Malignant Growths." He stated that the indications for caustics are as follows:

In the early stages, they are useless after metastasis, extensive ulceration or glandular involvement has taken place.

In the formative period.

In epitheliomata in accessible regions.

The best form of caustics are: wheat flour; arsenic; cinnabar; ammonium chlorid; mercuric chlorid; zinc chlorid.

Mild caustics are useless; silver nitrate is of no value.

Pyrogallic acid is serviceable after curetting.

DR. J. H. WYTHE, of Oakland, Cal., read a paper entitled "The Radical Cure of Malignant Tumors by Operation." He emphasized two principles:

I. Operate early.

II. To remove with the growth a quantity of the neighboring tissue.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

FIRST DAY—JUNE 5TH.

The Section was called to order by DR. J. MILTON DUFF, who introduced Dr. Joseph Eastman, of Indianapolis, President of the Section. (For Dr. Eastman's address see THE NEWS, June 2, p. 629.)

On motion a vote of thanks was tendered the President

and his paper requested for publication. In the absence of the Secretary, Dr. Newman was appointed Secretary *pro tem.*

DR. FRANKLIN H. MARTIN, of Chicago, read a paper on "Operative Treatment of Fibroid Tumors of the Uterus;" in which he made a summary report of six previously published cases, and a first report of two recent cases of his new operation for fibroids. The following are the conclusions of the paper:

1. In hysterectomy we have an operation which is bearing the test of time well; in selected cases in the hands of well-trained men it is the only absolute cure yet demonstrated for a certain class of fibroids.

2. The objections to hysterectomy for fibroids are the long training necessary to safely equip an abdominal surgeon for this most formidable of pelvic operations; the great death-rate of this operation in the hands of the tyro; the long prostration accompanied frequently with nervous symptoms following otherwise successful hysterectomies; its inapplicableness to extremely exsanguinated and otherwise reduced patients, and finally its inevitable death-rate of at least 5 per cent. in the hands of expert surgeons.

3. Removal of the appendages is usually unsatisfactory, and should not be resorted to ordinarily, except as a last resort in a complicated case when the abdomen has been opened for the purpose of removing the uterus, and the latter operation for some reason has proved impracticable.

4. If the appendages are removed for the purpose of establishing an artificial menopause and for the purpose of reducing small fibroids by modifying their nutrition, make sure to include in the ligature the main channel of the ovarian artery.

5. Vaginal ligation of the base of the broad ligament for fibroid of the uterus is an operation still on trial. As far as we have the history of cases to back the theories of the operation, it has stood the test.

6. Vaginal ligation of the broad ligament is a minor operation from the standpoint of mortality, and it is a minor operation from the standpoint of immediate and remote shock to the patient. It can be performed on any patient without risk in almost any condition of physical prostration or weakness, so long as she is capable of taking an anesthetic.

7. The operation is prompt in saving blood. It succeeds in cutting off one-third more blood to the uterus than does the Battey-Tait operation. Theoretically and practically it immediately checks uterine hemorrhage, and at once begins the diminishing of the myoma by depriving it of its nourishment.

8. The operation of ligation of the broad ligament does not leave an abdominal scar, and does not unsex the woman, as do hysterectomy and the Battey-Tait operation.

9. There are no good reasons why ligation of the broad ligament should not be an early procedure in all conditions of uncomplicated fibroids of the uterus in which the operation is practicable, even though in a few cases, subsequently, a more radical operation might be necessary.

10. The operation of vaginal ligation of the broad ligament is practicable in all interstitial or moderately sub-peritoneal fibroids in which it is possible by careful dissection to expose the base of the broad ligament high enough to include in a ligature the uterine artery and its branches.

DR. E. E. MONTGOMERY, of Philadelphia, followed with a paper on "The Removal of Fibroid Tumors through the Abdomen."

DR. R. E. HORTON, formerly President of the Illinois State Medical Society, said that we must be guided in the selection of the method by the condition of the case. He commended Dr. Martin's operation for controlling hemorrhage and starving small fibroids.

DR. MCCALL, of Michigan, spoke of the President's method as an ideal one, but thought that in many cases it could not be carried out. He recommended the conservative method of Dr. Martin whenever applicable, and spoke of the excellent results he had had with this operation. He thought that the failures in the operation for the removal of the appendages were largely due to the fact that the ligatures were not placed deeply enough and close enough to the uterus. It is well even to include the cornu of the uterus itself.

DR. LAPTHORNE SMITH, of Montreal, followed with a plea for the trial of electricity before more radical measures are resorted to. He believed in using the positive galvanic current and constitutional treatment for two or three months, and if the case showed no improvement, then to operate. Of the operations he preferred Dr. Martin's, in which there was no death-rate, to that which in the best of hands gave a mortality of 5 per cent. Only in extreme cases should the graver operations be resorted to.

DR. MCMONAGLE, of San Francisco, summarized the dangers of fibroids of the uterus under the heads of hemorrhage, pressure, and malignant degeneration. With regard to Dr. Martin's operation he inquired, "Will the degeneration be simple or malignant?" The operation, he felt, was still *sub judice*. He had the misfortune to see electricity continued so long as to change a fibroid into a sarcoma. He also asked Dr. Martin, "What if the woman should become pregnant?" also, if a starving of the uterus might not result in degeneration of the mucous membrane and in septic infection. He suggested that, as a preliminary to the operation, the uterus be curretted and packed.

DR. H. O. MARCY, of Boston, said that he had never used electricity without the patient feeling benefited by it. He has discarded its use for fibroids. If the patient is young, and the tumor small, it is best treated by ligature of the vessels and removal of the appendages. If the growth is larger, removal of the appendages may fail. He spoke of the extra-abdominal treatment of the stump as not being ideal surgery. It was still resorted to simply because the experience of older men taught it to be safe. If surgery is aseptic, nothing is gained by this method. We simply confess that we are afraid of hemorrhage and infection.

DR. E. E. MONTGOMERY, of Philadelphia, thought that the loss of so large a quantity of blood as took place in Dr. Martin's operation might cause degeneration, sloughing, and danger of sepsis. He feared that the use of electricity might produce malignant degeneration.

In reply to a question put to Dr. Marcy, he said he had never seen malignant degeneration follow the use of electricity.

DR. SMITH said, in respose to an inquiry, that he never used the galvano-puncture, as it contained an element of danger, and the use of electricity should be free from danger. He thought that the cases in which electricity was charged with causing malignancy represented errors of diagnosis. He cited a case in which a supposed fibroid not improving by electricity was operated upon, when it proved to be a sarcoma of the ovary in which the uterus was imbedded.

In closing the discussion DR. MARTIN said he wished to eradicate a false impression made on the minds of some. He did not believe that his operation was applicable to all cases. When the case demanded it, he was always ready to open the abdomen. He said he never knew a case of malignant degeneration to follow the use of electricity; but, on the contrary, a case diagnosticated by an eminent pathologist as one of bleeding sarcoma, had been cured by him by this method. He called the attention of the section to Dr. Byford's operation of hysterectomy as one of the best.

With regard to the results feared from cutting off the blood-supply in his operation, he said that in his first operation he was moved by the same fears, and it was the least successful of his cases, because it was not sufficiently thorough. While perhaps two-thirds of the blood-supply is cut off, there is still more than the normal amount going to the uterus. Dr. Martin thinks that pregnancy can take place and come to a successful termination, and hopes to demonstrate this in the near future. He stated that as a preliminary to his operation he always curetted the uterus, so as to make a clean field for his vaginal wounds.

Upon motion of Dr. Martin, the President was given the privilege of closing the discussion. DR. EASTMAN showed that gangrenous masses existed in some of the specimens of fibroids exhibited. He asked Dr. Martin how he could tell that these did not exist before tying the broad ligament. All methods are not applicable to all cases. If any one method is applicable to all, it is that of enucleation. He thought that if it was necessary to draw the uterus through the vagina at all, a wide incision should be made upon a staff and the cervical canal packed, or a tube surrounded with gauze introduced. He protested against drainage that did not thoroughly drain. He thought the strongest point in favor of the abdominal method of fixation of the stump was that there was one wound instead of two.

The President then announced the following Nominating Committee: Drs. E. E. Montgomery, Philadelphia; J. M. Duff, Pittsburg; J. H. Davisson, California; J. C. Coles, California; Lapthorne Smith, Montreal.

NEWS ITEMS.

Dr. Middleton Michel, a distinguished physician of Charleston, S. C., died on June 4th, at the age of seventy-two years. He received his medical education at Paris, but afterward graduated from the Medical College of the State of South Carolina. At one time he conducted a "Summer Institute," in which he delivered lectures on anatomy, physiology, and obstetrics to large classes. He had been one of the editors of the *Charleston Medical Journal* and occupied for many years the chair of physiology and medical jurisprudence in the Medical College of the State of South Carolina. He was a member of numerous learned societies and a frequent contributor to medical literature. He was a physician of high attainments, a teacher of rare ability, a scholar of great versatility, a writer of eminent merit, and a charming gentleman of the old school who, while alive to the demands of the crowding present, was not unmindful of the historic past.

Changes in the Medical Department of the University of Virginia.—Dr. William Christian has been elected to the Chair of Anatomy and Dr. J. Staige Davis Adjunct Professor of Pathology and Hygiene.

Dr. Theophilus Parvin has been elected an honorary member of the Obstetrical and Gynecological Society of Berlin.

ORIGINAL ARTICLES.

THE REMOVAL OF STONE IN THE BLADDER.[1]

BY WM. S. FORBES, M.D.,

PROFESSOR OF ANATOMY IN JEFFERSON MEDICAL COLLEGE, AND CLINICAL SURGEON TO JEFFERSON MEDICAL COLLEGE HOSPITAL.

IT is my purpose to demonstrate:

1. The measured crushing resistance of vesical calculi.

2. The measured strength of the lithotrite.

3. The lithotrite from a mechanical point of view.

4. A new lithotrite.

Given the problem—a stone in the bladder, a limited viaduct to reach it: remove the stone without injuring the parts. There are two unknown factors in this problem: First, the crushing resistance of the stone, and second, the strength of the lithotrite used in reducing the stone so that it may be removed with facility. Knowing the crushing resistance of the strongest vesical calculus in our possession, we are in a position to proceed to so construct a lithotrite that we can successfully crush and safely remove such a stone were we to meet with it in the human bladder. So far as I know, the exact crushing resistance of a vesical calculus has never been stated by any writer. Such vague statements as "very hard," "very tough," "very large," etc., have been used in describing stones, but the measured crushing resistance of any stone taken from the human bladder has always been overlooked. The same may be said of the lithotrite. "Very strong," "very powerful," etc., have been the vague terms used in describing it; but its measured strength computed by any unit has never been stated. In order to inform myself exactly on these points I addressed a letter to the Librarian of the Surgeon-General's Office, Washington, asking for any information whatever the Library contained in regard to them, and his reply was that the Library contained nothing relating to the matter.

It is manifest, therefore, that I have entered an entirely new field of investigation. Now, with a perfect disposition to respect the written law of this body to study economy of time, I shall strive to aim at all practicable condensation and brevity. A very liberal expenditure, however, is at times demanded by the wisest economy; and if it shall be found—as I fear it may, from the almost elementary manner in which, to meet all exigencies, the questions that arise must be discussed—that my own outlay offends against the letter of the law, I hope it also will be found that it is in harmony with its spirit.

In order to attain the necessary knowledge for the solution of the problem in question, it is necessary first to measure the crushing resistance of a large number of stones taken from the human bladder, a very large number of every size, embracing the hardest, toughest, and largest specimens, for it must be borne in mind that it is especially these that we seek to investigate, rather than those that are small and readily broken by very moderate pressure. So far I have been able to collect from all sources only 184 human vesical calculi for this investigation.

The table herewith annexed, in which the results are given, is so arranged that any number can be added. I propose to continue these investigations, and from time to time I shall add and publish the results observed. I shall begin my task impressed with that fine saying of Coleridge: "The conditions of science should be weighed in the scales of a jeweller, and not like the commodities of the market on the weigh-bridge of common prejudice and vulgar error."

We find that the 184 vesical calculi tabulated are divided as follows:

Oxalate of lime	55
Phosphate of lime	64
Uric acid	27
Oxalate and phosphate mixed	15
Uric acid and phosphate mixed	8
Uric acid and oxalate mixed	7
Oxalate, phosphate, and uric acid mixed	4
Combustible, requiring further examination	2
Carbonate of lime and oxalate	1
Cystin	1
	184

Had time permitted, the grouping of the calculi in the table below would have been made on the basis of their chemical constitution, as indicated in the foregoing summary.

At some future time this grouping will be arranged and all additions to it will be made upon this basis.

[1] Read before the American Surgical Association, June 1st, 1894, during the Triennial Congress of American Physicians and Surgeons.

TABLE OF THE MEASURED CRUSHING RESISTANCE OF 184 VESICAL CALCULI.

No.	Appearance of calculus.	Composition of calculus.	Diameters, in millimeters.	Volume, in cubic centimeters.	Weight, in ounces and grains.	Specific gravity (approximate).	Axis of holding between jaws of lithotrite.	Actual crushing resistance of calculus, in lbs., with Forbes' lithotrite; friction of lithotrite and testing apparatus deducted.	Direction of fracture to line of force applied.	Time slowly increasing pressure was applied to calculus, in min.	Number of fragments.	Flying fragments.	Distance fragments were thrown, in inches.	Size of lithotrite used (French scale).	Impaction of lithotrite, measured by increased size, in degrees of French scale.	Point of fracture in lithotrite.	Calculus loaned by

NOTE.—I am indebted to Professor Henry Leffmann, M.D., Pathological Chemist to Jefferson Medical College Hospital, for the chemical analysis of these vesical calculi.

Attention is called to the large percentage of oxalate of lime calculi. This is probably accounted for from the fact that they had been especially cared for by their collectors, while other stones not receiving such attention were lost.

I have attempted to deduce from this table a general law for the crushing resistance of vesical calculi, considered under the heads of chemical composition, weight, size, and specific gravity, but owing to the great variation in the ages of the calculi since being removed from the bladder (from one to seventy years) and the consequent hardening or softening of the colloids due to atmospheric exposure, it has been found impracticable for the present at least. It would seem, however, as one element of the law, that there is a marked decrease in the crushing resistance of vesical calculi relatively to their size and weight as they grow larger.

The crushing resistance and other physical properties such as size, weight, etc., of the calculus are as much as its chemical composition a part of its clinical history. Hereafter by the use of this new lithotrite, having the measuring mechanism in its handle, the crushing resistance of a calculus will be recorded at the time of the operation.

Thus, in time a table may be compiled from the reports of observing lithotritists which will enable a more judicious selection of a lithotrite of proper size for the reduction of a given calculus.

It is my purpose to demonstrate from experiments the relative crushing resistance of vesical calculi and the strength of the new lithotrite. The line of safety in this new lithotrite will be pointed out by having stamped on its handle, with the maker's name, the number of pounds to which the instrument has been safely tested in a machine which has been made for this purpose, before it leaves the maker's shop.

The testing machine and the lithotrite were designed and made by my son, Mr. John S. Forbes, engineer.

I will venture to ask permission to allow him to describe them.

TESTING APPARATUS. (BY MR. JOHN S. FORBES.)

This apparatus (Fig. 1) consists first of a rigid frame of wrought-iron pipe, A; second, of a longitudinally adjustable cast-iron bridge, B, spanning the frame and secured at any point by clamps, C C. Mounted on this bridge is a universal brass clamp, D. for holding the cylindrical handle of the lithotrite,

A cast-iron bed-plate, E, spans the frame and is secured at one end of it. This bed-plate carries a rotatable shaft, F, turning in ball-bearings, whereby the friction is reduced to a minimum. This shaft also has an end movement of about one and a quarter inches. One end of the shaft is provided with an independent four-jaw chuck, G, for holding and turning the screw-handle of the lithotrite. Upon the middle portion of the shaft, and between the ball-bearings, is a flat, grooved, brass wheel, H, so arranged that it may be turned independently of the shaft or locked to it. Secured to the wheel is a cord, I, which passes over an overhead grooved pulley, J, and is provided at its dependent end with a pan, K, for the reception of weights. The friction due to turning the wheel and its accompanying parts, and weight of the pan is eliminated by the small bottle, L, containing shot. The operation of the apparatus is as follows:

A lithotrite is placed in position and its cylindrical handle clamped with the brass clamp, D, on the cast-iron bridge. The screw-handle is secured in the four-jaw chuck, G, on the rotatable shaft, and the whole is gotten in perfect line and accord. By locking the instrument and turning the wheel, H, over to the right, the male jaw of the lithotrite is propelled toward the female jaw, and by unlocking the instrument the male jaw, together with the shaft, chuck, and wheel, may be slid backward and forward just as the instrument may be operated in the hands. The result so far, then, is that we have a lithotrite held in an apparatus, and the objects are: first, to measure the crushing resistance of a calculus placed between the jaws of the lithotrite; second, to learn what pressure may be obtained between the jaws of the lithotrite without injury to them or any other portion of the lithotrite; and third, what pressure between the jaws will break them or any other part of the lithotrite. In order to obtain the crushing resistance of a calculus held between the jaws of a lithotrite we must consider mathematically the mechanical elements of the testing apparatus and the lithotrite.

We may use the formula:

$P = p \times c \times w$ in which P = equals the pressure between the blades; p = the pitch of the screw in number of turns per inch; c = the circumference of the wheel, H, of testing apparatus; w = the weight in the pan, K, of the testing apparatus.

Thus it will be seen that the forces are inversely as the paths.

Now this will give us the theoretical pressure between the jaws, but we must consider the friction in the lithotrite arising from the screw-thread and the tendency of the male blade to buckle. In order to obtain this friction we place a dynamometer, or other pressure-recording instrument, between the jaws and apply weights to the pan of the testing apparatus. In this way we will get the coefficient or ratio of friction in the lithotrite to the weight applied for various pressures between the jaws. We can therefore lay out a table of actual frictions for each pressure. The formula must now have the factor of friction introduced, and it may be expressed thus:

$P = (p \times c \times w) - (F\ w)$ wherein F = the friction corresponding to the weight, w. The dynamometer is now removed and we are ready to measure the crushing resistance of any given calculus. The table of crushing resistance of vesical calculi which is before you was obtained in this way. In order to obtain the second and third objects, viz: the pressure which may be obtained between the jaws of the lithotrite without injury to any part of the in-

strument, and what pressure and where the instrument will first give way, we again make use of the dynamometer and apply weights to the pan of the testing apparatus until something happens, for something is bound to occur if we apply enough weights. The dynamometer ceases to move when this event takes place, and we read the ultimate pressure which the now useless lithotrite was able to record. In this manner the table of the strength of various lithotrites which is before you was obtained.

DESCRIPTION OF LITHOTRITE. (BY MR. JOHN S. FORBES.)

This lithotrite (Fig. 2) has some of the elements that are common to the Civiale, Thompson and

FIG. 1.

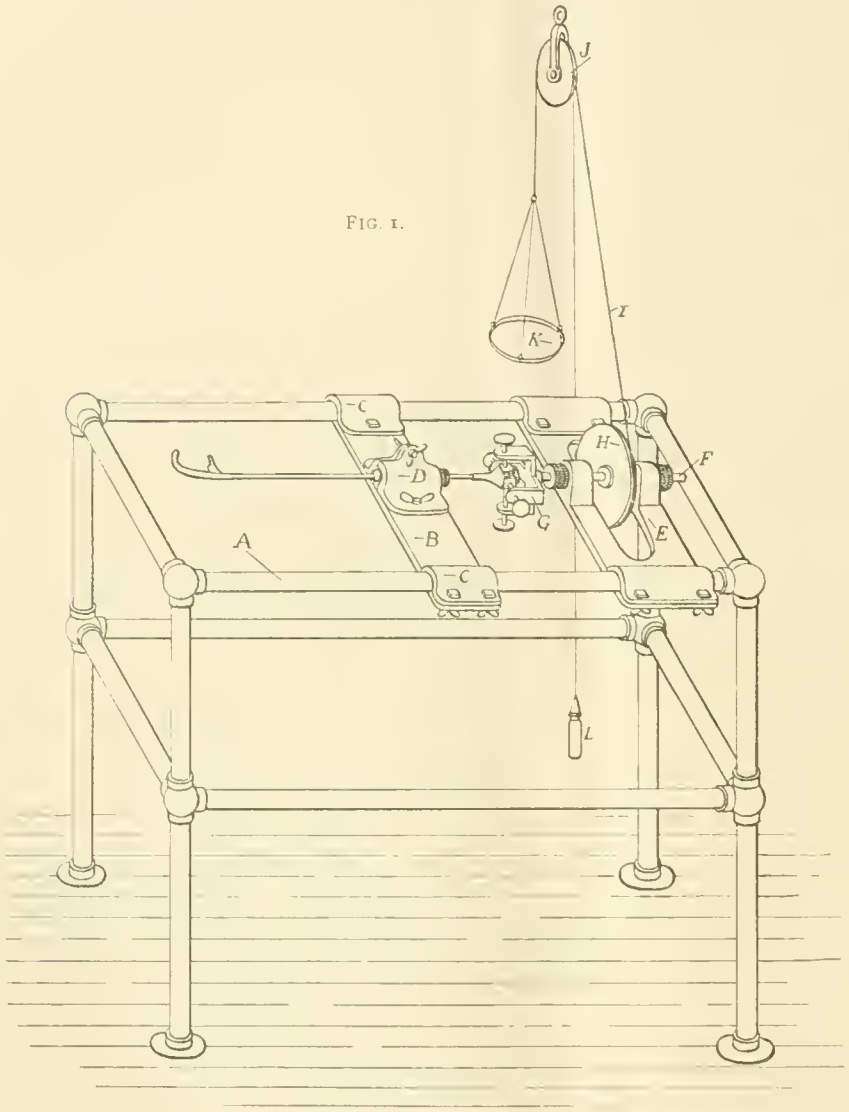

FIG. 5.

FIG. 6.

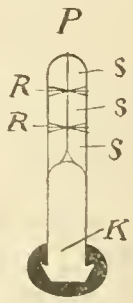

FIG. 7.

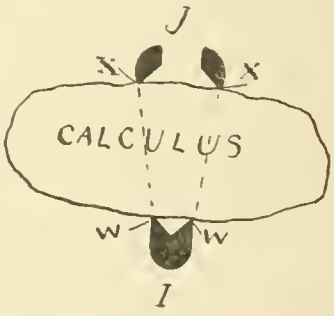

FIG. 8.

FIG. 2.

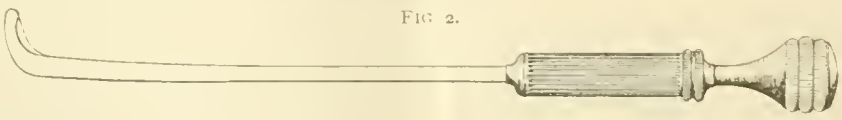

FIG. 3.

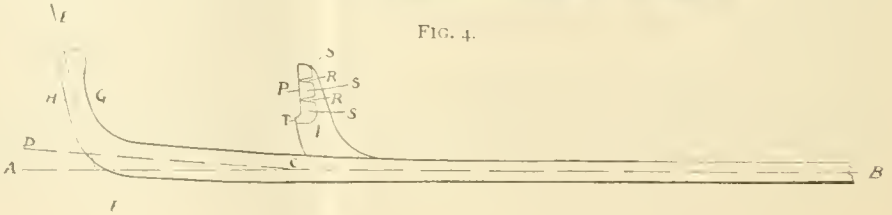
FIG. 4.



Bigelow instruments, viz: a pair of jaws capable of being separated and brought together and a handle mechanism for their operation. The construction and general lines of it are, however, entirely original and widely different from any lithotrite now in existence. It may be thus described:

The penile and vesical end consists of a male blade sliding within a female blade and held within the latter by means of a slightly angular under-cut slot, Fig. 3.

This is done to prevent the male blade rising out of the female when under a strain, so that the greater the strain the tighter the male blade is held within the female. The long axis, B C, Fig. 4, of the shaft is straight from the handle to within about two inches of the crook or curve; here it rises, C D, at an angle of about five degrees until it meets the curve.

This accomplishes six important objects: First, it gives an easy introduction of the instrument through the urethra, because of a wide angle. Second, it increases the strength of the female jaw by giving it support higher up. Third, it allows a larger stone to be grasped without incurring a long female jaw. Fourth, it places the metal of the female shaft where it is most needed to give strength. Fifth, it prevents side movement or twisting of the male jaw by giving it a deeper slot to move in, and thereby supporting it higher up, for the male blade works in a straight slot along the axis, A C B. Sixth, the angle between the axis, E F, of the female jaw and the long axis of the shaft, A C B, is the same as if the shaft were straight all the way to the curve.

The female jaw has its proximal surfaces concave, G, preventing the calculus from slipping out when the power is applied, and tending as well to drive the calculus lower down, thereby placing it in a position where the instrument gains strength. The female shaft is elliptical and of uniform size from the handle up to within about three inches of the crook; here it begins to increase slightly in caliber until it reaches the maximum which is at the crook (Fig. 4). This results in great strength for the female shaft at the point where it is most needed, and at the same time places the extra metal within the bladder and within the prostatic portion of the urthera only, where it is easily accommodated.

The shoe of the female jaw (M, Fig. 5) is made abundantly larger than the male jaw, so that all débris is expelled, and impaction of the instrument prevented, and the wall of the bladder is thus protected from being pinched or cut (Fig. 5). The female blade is elliptical in cross-section (Fig. 6), in order to give a thick septum, K, to the male blade, and yet not increase the caliber of the shaft (Fig. 6). The female jaw is made thin in a fore-and-aft direction (G, H, Fig. 4), in order to take up less room in the bladder. The proximal surface (P, Fig. 5) of the male jaw is in the form of a wedge of about sixty degrees, in order to penetrate a calculus with the least power propelling it. The cross ridges (R, R, Figs. 4, 5, 6) prevent the stone from flying when broken, and the parallel spillways (S, Fig. 4, 6) permit the débris to escape without causing impaction of the instrument.

Sir Henry Thompson, in his book (*The Urinary Organs*, note 1, page 79, says: "Only slight approximation to the form of the wedge in the opposing surface of the male blade is permissible. If it has an angle, say, of ninety degrees, some danger is incurred. It may be driven through almost any stone, it is true, but the fragments will fly off right and left with prodigious force, even in fluid, and injure the coats of the bladder. Also, when the male blade has the form of a rather sharp wedge, the calculus is seized, and retained with greater difficulty than with a male blade which is less salient."

Perhaps he does not realize it, but after saying the foregoing he has deliberately designed and adopted a wedge in his instrument of less than ninety degrees; in fact, a wedge of forty-five degrees, with no means whatever beyond it to prevent the fragments flying (W, W, Fig. 7). A great deal of the success of his instrument is owing to the sharp wedge, of which he is evidently not aware, for it allows his instrument to cleave a stone with less force propelling it, and when anything is disrupted with a small force the energy stored up in the parts so separated is less, and they will come to rest sooner. The iceman, with a thin-bladed axe, splits the block of ice gently and with ease, and the parts so separated do not fly. What would happen if he used the broad head of an axe?

As regards the alleged difficulty of seizing and retaining a calculus with a sharp single wedge, it is a well-known fact that an uneven object adjusts itself more readily to three points of contact than four. More especially is this true when the three points form apices of a triangle. Moreover, it may be said that out of 184 vesical calculi crushed by this lithotrite in the testing apparatus, not one slipped in the least, except to adjust itself lower down on the female jaw, owing to the concave surface of that member, as already mentioned. I greatly doubt if all four of the opposing edges (W, W, X, X, Fig. 7) in the Thompson lithotrite are at the start in contact with a calculus.

The spur (T, Fig. 4) rises to a great height on the male jaw to give it greater strength. This spur interferes in no way with the holding of the stone.

The great breadth of the septum (K, Fig. 6) of the male blade is permitted by the elliptic shaft.

The handle or screw mechanism belongs to what is known as the interrupted screw-type. It consists of an internally screw-threaded barrel (Fig. 8) having the threads cut away for the entire length of the barrel at alternate spaces of ninety degrees each.

This screw-barrel has an end movement in the cylindrical handle of about one-sixteenth of an inch. Working in this barrel is a pair of screw-blocks, likewise having their screw-threads interrupted at alternate spaces of ninety degrees each. Thus the screw-blocks may be slid up and down the barrel without the threads engaging. When it is necessary, however, to apply the power, the screw-blocks are turned by means of the screw-handle, and the threads engage immediately. One screw-block is rigidly keyed to the screw-handle shaft, and the

other is so formed that it may have a motion of ninety degrees around the screw-handle shaft. Thus, when the screw-handle shaft is turned to the right the screw-block that is rigidly attached to the shaft is brought into mesh with the threads of the screw-barrel, and a further turn of the handle of ninety degrees brings the rotatable screw-block also into mesh. The screw-threads on these two blocks are, therefore, now no longer interrupted, relatively to the barrel, but continuous, and we have in substance a solid plug, or screw-block, engaged with the threads in the screw-barrel. As long as the screw-handle is turned to the right this state of affairs continues, and the male jaw is propelled toward the female jaw. After the calculus is crushed the instrument may again be unlocked and the jaws separated by turning the screw-handle to the left until it stops. This left-hand motion is never more than half a turn. Owing to the sixteenth-inch play of the screw-barrel in the cylindrical handle it readily adjusts itself to engage with the thread of the screw-block, and the calculus is, therefore, never dropped (perhaps after a hard search for it) in locking the instrument. The screw-thread of this instrument has been made slow for several reasons. First, it increases the power of the instrument for crushing, because it brings in the well known and important factor of time in crushing the calculus. A certain pressure may be applied to a stone without crushing it, but if the same pressure is allowed to remain acting upon the stone for a short time the stone will crumble without the addition of further pressure. The slow thread is, therefore, adopted that the stone may have time to break without unduly straining the instrument. The operator is also spared using an

Bigelow	No. 29	381	400	Male jaw snapped off at crook with force; female jaw snapped off near top of fenestrum with force; instrument can be closed and withdrawn from bladder.	Fig. 11
Thompson	No. 33	449	472	Instrument this size not tested; figures were calculated, and are therefore only approximate.	
Thompson fenestrated	No. 29	355	382	Female shaft badly bent down 1¾" from end; screw thread slightly burred; instrument cannot be closed within 1½".	Fig. 12

NOTE.—The conditions of these tests were identical, and the resistance of the dynamometer was applied between the extreme ends of the jaws. The Forbes and Bigelow instruments were made by Tiemann & Co., of New York, and the Thompson fenestrated by Weiss, of London

undue amount of strength, for with him it is the old story of 33,000 pounds one foot high in one minute, or one pound 33,000 feet high in one minute. The screw-handle has been made larger than heretofore, because it has been ascertained that any stone will give way before the instrument suited to it is damaged, and a large screw-handle aids the easy and gentle manipulation of the instrument. The shape of the handle is also different, and calculated to serve its purpose. Being made of very thin sheet-metal it is at once strong, and as light as the lightest handle now employed, which is, perhaps, the soda-water-fountain wheel of Thompson or Civiale. I have designed a mechanism which may be placed within the hollow screw-handle, whereby the operator can see what power he is exerting between the jaws of the lithotrite. This mechanism, though it will add a trifle to the weight of the lithotrite, will not increase its size in any part. To sum up this instrument, it may be likened to a chain in which each link is of equal strength, and that means the maximum strength for a given size and weight, or, in other words, a correct disposition of metal.

Messrs. George Tiemann & Co., of New York, will make this instrument, and it is proposed to place this testing apparatus in their workshop, where every instrument, will, before it leaves the shop, be tested to a proper pressure in accordance with its size, and the pressure it has been so subjected to stamped plainly upon the handle. Thus the surgeon may operate with the greatest confidence in his lithotrite, knowing the pressure it has been subjected to and the crushing resistance of the hardest calculus thus far obtained by us, as indicated in the table.

As a final result of this series of experiments, which have been conducted with the utmost care and impartiality, we may draw several conclusions. First, as regards the lithotrite, its shape and action: After seven operations on the living subject it has demonstrated its complete fitness. It has broken a hundred and fifty-eight calculi while in the testing apparatus, and it has been subjected to a pressure of five hundred pounds between the jaws for thirteen times. Its ultimate strength after this trying ordeal was six hundred and fifty pounds, and, moreover, after this enormous pressure the instrument was closed and could have been introduced and withdrawn from a human bladder with ease and without injury to the parts. As regards the calculi crushed to make the table which is before you, it may be stated that the large majority were many years old and much harder than they would have been if only recently taken from a living subject. The greatest resistance offered by any calculus so far encountered by us was four hundred and six pounds. (No. 27.)

FIG. 9.

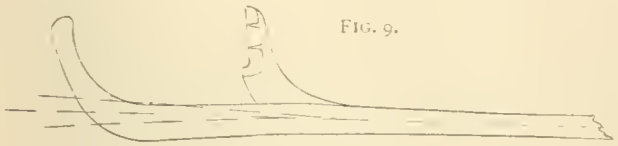

FIG. 10.

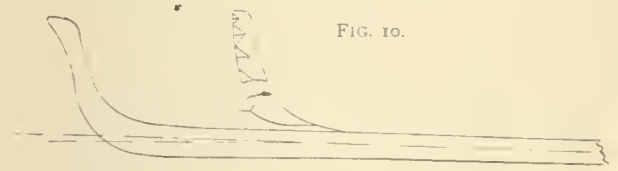

FIG. 11.

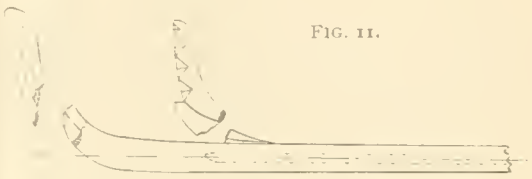

FIG. 12.

FIG. 13.

SYNOPSIS OF CONSTRUCTION OF THE LITHOTRITE. READ BY DR. W. S. FORBES.

1. Designed with the view of meeting, first, the anatomical conditions; second, conforming to the laws of mechanics, special attention being given to the economic disposition of material.

2. Double curve, permitting easy introduction, giving greater strength to the female shaft and jaw, and better support to resist side movement of the male jaw.

3. Elliptic cross-section of the shaft, to give greater breadth of septum, prevent side movement of the male jaw, and be of minimum circumference.

4. Angular undercut slot or V groove, to prevent the male blade from rising out of the female shaft and to bind the two closer together under strain.

5. Concave shape of the female proximal surface, to prevent the calculus slipping out, as well as to drive it down to the lower part of the curve and so gain strength for the female jaw.

6. The female jaw made flat in a fore-and-aft direction, to take up a minimum amount of room in the bladder.

7. Large clearance between the outside of the male jaw and the inside of the female jaw, to prevent injury to the bladder, and impaction.

8. All exposed edges gently rounded to prevent injury to the bladder.

9. All internal corners rounded to avoid starting cracks.

10. Shape of the male proximal surface strategic, *i. e.*, best adapted to the more easily penetrate a calculus, to keep fragments from flying and clear itself, to prevent impaction.

11. Plea for the slow thread (strain on the instrument and work done by operator reduced to a minimum and time gained).

12. Plea for the large screw-handle ; it is not too large because few men can break an instrument with it ; moreover, the instrument as constructed will break any calculus before it is injured itself. Metallic, hollow, and very light.

13. Interrupted screw-mechanism. It is stronger, less complicated, and easier to operate.

14. Cylindrical handle, same size as Bigelow's, and of proper size to allow of holding tightly.

15. Power-recording mechanism in screw-handle, to measure strain on lithotrite and crushing resistance of calculus.

16. The size of the instrument is one and three-quarter inches shorter than the Bigelow of equal caliber and opening, and five-eighths of an inch longer than Thompson's of equal caliber and opening.

17. The weight of this instrument is the same as Bigelow's and a trifle more than Thompson's of equal caliber and opening.

Owing to the kindness of Messrs. George Tiemann & Co., of New York, in executing the thoughts of my son and in following his drawings and models in the various evolutions to the final instrument, which is now brought before you, and in supplying the already existing types of instruments for testing, he has been enabled to carry these experiments to a higher degree of refinement than my purse would otherwise have allowed.

During the crushing of these calculi there were present on various occasions the following gentlemen: Dr. G. M. Gould, of The Medical News, Prof. Frederick P. Henry, Prof. Harrison Allen, Dr. A. Hewson, Prof. Joseph Hearn, Dr. Charles H. Reckefus, Jr., all of Philadelphia. During the breaking of the lithotrites in the testing machine there were present Professor Orville Horwitz, and Dr. A. Hewson, Demonstrator of Anatomy, Jefferson Medical College.

A word, and I have done—a word, but a necessary one. I know that I incur the risk of displeasing my son in what I am going to say ; but, in this body of men and on this occasion, I trust a father may be pardoned for venturing to digress from the injunction of his son.

In the paper I have had the honor of reading every thought, every idea expressed, indeed, the entire habendum of the paper, came from and belongs to my son, Mr. John S. Forbes, mechanical engineer.

1704 Walnut Street.

INEBRIETY AS A DISEASE, ANALYTICALLY STUDIED.[1]

By R. M. PHELPS, M.D.,
of Rochester, Minn. ;
Assistant Superintendent Rochester State Hospital; Member American Neurological Association, etc.

During the last year, basing my convictions on the study of nearly two hundred inebriates who have been committed to this Hospital, I presented to the State Medical Society the subject of "inebriety," especially considering whether or not it deserved the name disease. This especial consideration is needful, not to establish or controvert the fact, but because of the somewhat logical deduction drawn from such designation by various writers, and secondarily by the people also as to the "irresponsibility" of inebriates.

The subject is difficult to define because of the symmetric character of the frequent brain-impairment ; because of the vagueness of the secondary pathology ; and because definitions pushed back to their fundamentals, here sooner than elsewhere, reach the inexplainable. Some of the advocates of the disease-theory have held to me that the subject needs still farther analytic study. The logical conclusions which are drawn from the statement that "inebriety is a disease" comprise the responsibility of action of many hundreds of thousands in this country, and are therefore highly important. I will first quote a few paragraphs from the preceding article mentioned to show the stand there taken.

Speaking of the writings of the Association for the Study and Cure of Inebriety it was said : "The trend of the literature, however, is not so vague, and is quite plainly toward inebriety as a disease of the brain, resembling insanity or constituting insanity. While hesitating to call inebriety an insanity, except in occasional cases, the writers yet hover about this idea as one giving most significance to their statements."

Definition was given as follows: "We might define inebriety, as far as it deserves the name of disease, as including those cases in which the drinking of alcoholic liquors, either from inherited appetite, from inherited predisposition, or from acquired habit, becomes accompanied by apparently uncontrollable impulse or by mental defects, such as *amnesia*, *trance-state*, *transitory mania*, or by the more chronic *dementia*. But this definition merely defines an insanity, so that we tend, as does the current literature, toward making inebriety merely an insanity, having drinking as its most prominent exciting cause.

[1] This article was prepared for the twentieth annual meeting of the American Neurological Association, held at Washington, D. C., May 29 to June 1, 1894, but was not read on account of the absence of the author.

"But, although we have made our ideas far more clear, we have still exceeding great difficulty in making the practical application at hand. For it is hard to say *who* has the mental defect and *when* one's will-power is overborne. Dr. Crothers tries to find these defects in *all* of those who try to use alcohol to excess. He pictures as strongly as he can a kind of dulled moral sense, dulled mental power, and dulled will-power gradually overcoming the victim.

"But even granting that there is dulling of mental and moral keenness in all drinkers, commencing theoretically with the first drink, and increasing proportionately to the amount and duration of the drinking, yet should we not hesitate to call a man insane or irresponsible until signs of insanity are so distinct as to be clearly formulated?"

Concerning the predisposition it was said: "One man has a genius for music, another could not do the same work after a lifetime of study. One man is alert and nervously active, always in action, another slow and steady-footed, and could not by any training attain the genius-like standard of others. In like manner one has that nervous susceptibility that is excited and weakened by alcohol, while his comrades, with the lifetime of habitual association with alcohol, are never drunk. One may possibly call it disease, but as purely a tendency in itself; I can hardly think it a vice or disease, but rather a defective constitutional state. So much for the tendency itself. The habitual yielding to that tendency I should call a *vice*. The diseased condition following, be it mental, physical, or both, I should call a *secondary disease;* if it is mental I should call it *insanity*.

"From the above it will be seen that the yielding to the habit-element is on exactly the same plane as yielding to swearing or pernicious habits of any kind."

A study of the present attitude of the profession reveals something like this: *The Journal of Inebriety* and occasional articles elsewhere by the same class of writers, prominent among whom have been Crothers, Kerr, Wright, Mason, Hughes, and Parish, hold, though in varied meanings, that inebriety is a disease. The prominent neurologists of the country have hardly well defined their position, the subject being somewhat neglected. Dana, in two or three articles, has seemed to call for more conservative views, and has set forth distinctions tending to exhibit the fallacy of classing all inebriates alike.

So many disputes of the past have depended upon differences in meaning attached to the same word that we begin first with definition. "Inebriety" may have four stages: First, taking first or occasional drinks; second, drinking to produce tipsiness or occasional drunkenness; third, drinking to excess, which means frequent and habitual intoxication; fourth, drinking, seemingly uncontrollable, with occasional periodicity of manifestation.

This division is one of degree, and we hold is better than one of "amount drunk," or "duration of habit," or "purpose in drinking."

Now it will hardly be contended that the first stage is a disease, rarely that the second is a disease, while stages three and four, especially the latter, seem to be most frequently meant by writers, though unfortunately they do not often so limit their meaning.

But before going farther we must also define "disease." In looking over writings we find that disease is used to mean usually, 1st, a clinical entity exclusive of other entities, such as measles, smallpox, rheumatism, etc.; but that it is occasionally used to designate, 2d, a more subordinate element or symptom, such as pain or headache; and again a little differently it may mean, 3d, groups of mental symptoms which are thought to have special lesions, though these may not be demonstrable. Defects or neuroses are *not* usually called diseases.

By "habit" we may refer to actions, which by repetition have become far more apt to be reënacted than those not so repeated. The action so designated may have first, only the *mental excitement* or incitement, as in swearing or lying; or secondly, it may have also a *physical craving*, natural or induced, which shall make it more binding. Smoking has a small and vague amount of this physical element, but drinking has a quite large amount. The habit part does not cease, however, because the physical craving comes in.

By "vice" we mean an action or habit which in the judgment of the one acting has evil tendencies. It is a matter of difference of judgment at times, whether a special act is a vice or not (for example, smoking).

Now with our terms defined, what is inebriety, "vice," "habit," or "disease"? May not inebriety be any or possibly all? The first drinking could hardly be a disease; it has hardly become a habit, and it is a vice only if the evil is recognized as such by the drinker. In the second stage it is probably becoming a *vicious habit*, while in the the third or fourth stages the habit seemingly grows stronger and is bound by induced physical failure which had been gradually invading the system. This outlines the *ordinary* case.

Let us separate inebriety into still finer elementary parts. Inebriety may be *caused by* insanity. It is then merely a symptom of an unstable mind, and is the true irresponsible state, though not a disease *of itself* then.

Again, inebriety may be caused by a physical disease, not in any mysterious way, but to relieve pain

or depression. The physical disease then is a temptation. Again, inebriety may induce mental disease. This seems sure, as there is a quite distinct degenerative type so produced. But, is not such mental disease secondary—just as a pneumonia would be secondary to exposure to cold? Frequently the preceding causation cannot be clearly outlined, and the forms are mixed, but the principles remain the same.

But, it will be said that we have left out of our analysis the "hereditary" cases; the "uncontrollable" cases, and the "periodical" forms. As regards heredity, I have not among two hundred of the worst cases in the State seen any marked cases of *direct* heredity. But, by heredity is usually meant the inheritance of defective nervous make-up, which may in the descendant bring epilepsy; or excess in appetite; or mental disease, etc. Of this *indirect* heredity there are a considerable number of cases. This was quite thoroughly brought out in an article by T. D. Wright, that prolific writer on inebriety. In this we believe thoroughly, and have many examples. This kind of heredity, however, only increases the tendency. It only makes the habit more easy. It does not truly constitute any disease, any more than tuberculosis in the parent makes the son diseased. It simply makes disease easily acquired. We all have more or less of tendency or neurosis toward one disease or another, and though by microscope or scalpel we cannot find predisposition, we do not deny its existence.

As regards "uncontrollableness," the appetite grows surely more and more strong, but it is a little rash to say that it is *fully* uncontrollable unless the man is insane. By the study of cases under the restraint provided here, I have come to think that they have always some control left; although the pitiless surety of chances that they will again drink if free is remarkable. I would, then, personally deny absolute uncontrollablenes, and admitting an approximation would not admit it to be a disease-entity, but only symptomatic of both the habit and the natural or induced nerve-changes, and instability of nerve or brain.

"Periodicity" is a mysterious element, which has ever been regarded as clinching the disease-argument. But if we study periodicity by itself we find it prominently in insanity in from one-eighth to one-fourth of all cases. We find it in epilepsy, migraine, malaria, and in the physiologic function of menstruation. Nay more, there is in most diseases a tendency to spontaneously recede and the liability to another attack.

Periodicity in its extreme form in inebriety has not been seen in much more than 2 per cent. of the cases here. In modified and irregular forms, hardly noticeable as periodic, it is seen in a good many more. But at any rate, admitting its mysteriousness, I am inclined to consider it only one sign of a neurotic or nervously unstable temperament; and whether it appear in migraine, epilepsy, insanity, or inebriety, to be the same in kind, and in the latter to be an accompaniment of the drinking rather than any element of it. The periodicity in some cases I have studied was inherent in nervous instability, in the neurasthenic attacks, or whatever they may be called, which in turn induced the drinking. It was a physical or emotional state which recurred. The inebriety followed if opportunity offered as an element of relief for the nerve-unrest.

We have now considered most of the elements entering into inebriety. In none of these forms is inebriety (drinking) a disease-entity, though it is in some a disease-symptom, and in many or all the cause of impairments of nerve or brain, which in the end may be grouped together with other bodily impairments, and designated as a disease, called inebriety.

It remains now to try and make our meaning a little more clear by noting the steps which a drinker successively takes. He takes a first drink; the reason is probably a mixture of sociability and desire of emotional excitement. If of unstable nerve-condition it affects him much; if more normal, but little. He repeats the act at various times, and finally becomes drunk. This is to him simply an undesirable ending, the emotional and nerve-exaltation and the sociability being still the ends sought. Habit, as everywhere holds its power, and a strong craving is at times recognized. Years pass, and so many times and so frequently has intoxication occurred that it is called uncontrollable. The nerve-instability, if not originally present, has been induced. The emotional exaltation and social pleasure are but a flicker now. But the nerve-depression to which he sinks *without* any sustaining liquor, are now the main elements he flees from.

In this the worst case, has habit gone? Has vice gone unless the man be definitely deserving of the name insane? Judging not from the inebriety, but from the ordinary evidence, I hardly think so; though I can readily see that they have sunk to a subordinate place.

For complete answer as to sanity, we can judge only by placing the man in favorable circumstances, and away from drink; if then insane, so judge him. If not, then do not call him so, nor infer that he is so, because of inebriety. My concluding point, thus is, judge of insanity or irresponsibility by ordinary rules, and not by the fact of inebriety.

In conclusion I quote a paragraph from a previous writing, concerning the ordinary inebriate state:

"Some years ago I watched and cared for some

morphin-eaters through the agonies of abrupt withdrawal of morphin. What I witnessed then I called intense unrest; an intense hunger of the nervous system for support. It is this hunger and unrest in kind, I think, that comes on many inebriates paroxysmally, and impels them to drink. It is to a degree a neurasthenic state. Nor do I think it peculiar to inebriates. The exhaustion of mental labor without exercise seems allied to it. The nervous system blindly hungers for something to brace it up, which the liquor temporarily does. This admits, of course, the existence of a gradual impairment of nerve or mind from drinking; theoretically, it is, perhaps always present, as some seem to claim."

"Practically we are obliged to speak of inebriety as having a tendency toward such impairment, sometimes observable, at other times not."

The preceding discussion would be of little value if disease were not held by the writers of the only medical inebriate society in this country to be to a certain degree synonymous with irresponsiblity. With this in mind, clear ideas assume vast importance. We have not discussed the pathology of alcoholism, as it is to a great extent secondary, like that of other secondary diseases.

We hold that physical or mental cravings (temptations) are not to exclude habit or intent any more in inebriety than in sexual excess, in criminal life, swearing, smoking, etc. Whether the habitual burglar is any less criminal because of his habitual practice than in the first act of burglary, it is hard to say. The law usually holds him more rigidly, but it does so for society's safety, rather than on account of any idea of the person's increasing responsibility. I would grant freely grades of responsibility, but would think human judgments and human laws not perfect enough as yet to allow for them. I would consider insanity from alcoholic origin as of slow growth. In most cases it passes slowly the arbitrarily adjudged lines between sanity and insanity. Moreover, it is usually of that symmetric type of failure that is so little noticed at first and so hard to define.

In order to show the standing of the disease-advocates as truly as possible, we quote one of the latest and clearest of their statements.

The *Journal of Inebriety*, October, 1893 says: "Inebriety is a psychopathic disease, and no theories which assume a degree of health up to a certain border line, and disease beyond this, are of any value. We have persistently urged the full recognition of inebriety as an organized, progressive degeneration. All half-vice and half-disease theories mean faith-cures and hospitals, pledges and specifics, drugs and punishment, as means of cure and treatment. The term inebriety must be recognized in the same way as insanity is, and be used to designate a disease in which the use of narcotic drugs is a symptom."

We can answer best this view by stating our own.

First. We do recognize inebriety (meaning the resulting condition) as a disease, in much the "same way" as insanity. As far as judging whether it be a disease or not, and as far as thinking of both in many cases as gradually growing impairments, we do, but not as regards their origin. It would seem if ever there was a vice, it was in the first drinking; provided of course its hurtful nature is known.

The disease inebriety (meaning again the varying and complicated combinations of effects produced by drinking) has been compared in its origin to that of lead-poison. Each would be a "progressive" impairment, initiated and increased by repeated acts, in the one case vicious, in the other not. Neither would be called a disease in the first contact with the poison. Each would be called disease when a combination of well-defined symptoms appears.

Second. That inebriety is an "organized progressive degeneration" we would amend by substituting the statement that *progressive inebriety* (progressive drinking) *produces progressive toxic degeneration*, which affecting the whole nervous system may show itself most in the brain in the form of insanity, or most in various peripheral symptoms. We would think of its action in accordance with Strümpell's views as summarized in the *Journal of Mental and Nervous Diseases*. Speaking of delirium tremens and heart-failure, he says, "they are due to a summation of minute toxic effects, just as wrist-drop and epileptic seizure are due to the summation of exceedingly small quantities of lead absorbed daily. The toxic effects of alcohol, a readily oxidized substance, cannot be due to an accumulation of toxic material, but a change of structure resulting from its chemical action on nerve tissue. From an insignificant alteration, a chronic pathological condition gradually results. Comparatively small amounts of alcohol taken regularly and habitually are as effective as an oft-repeated, severe, acute intoxication. As in other acute and chronic intoxications, there is a pronounced difference of individual disposition to the action of alcohol, and undoubtedly a different individual disposition of the internal organs also exists. Alcohol, like most other poisons, attacks the nervous system first."

Third. The assumption of a border line between disease and health is not only not mysterious, but something we as physicians have to do in almost every case. Few insanities come on with even approximate suddenness. In few cases can the exact day or week of beginning be ever ascertained. What matters it if the day of beginning of locomotor ataxia is never known? That imaginary boundary line between health and disease was passed *somewhere*, and

it is true and just to assume some time of beginning arbitrarily.

Our conclusions, then, would be something as follows:

1. We should, for the sake of clearness, not mingle or use interchangeably the words inebriety and irresponsibility; but in the cases in which it can clearly be shown to exist, we should make inebriety mean the drinking, and irresponsibility the insanity so produced.

2. Disease should not be carelessly used to mean predisposition, or neurosis; nor should it be used to mean a disease-symptom unless so specified. But when unqualified it should designate a fairly well defined entity composed of a group of symptoms with known or presumed pathology and causation.

3. Inebriety (excessive drinking) can then be stated to be not a disease, but as tending to produce various diseased conditions.

These diseased conditions are quite general in character, but most notably seen in nerve-failure and brain-failure.

4. The predisposition varies in different persons and constitutes a temptation.

5. Irresponsibility is of varying grade, and the law does not necessarily follow these grades, but adjudges penalty—first by the consequences of the act, and secondly for the safety of society.

6. In our opinion none of the early degrees of inebriety as a rule produces sufficient effect to be named disease or irresponsibility. This being true, even if there be a growing mental impairment, we would call the mental state insanity only when it would be so called if induced by other causative conditions.

Insanity as a disease is also subject to this same rule. The name is not applied to all mental changes, but only to those which have a considerable definition. Multitudes of mental impairments are not called insanity at all.

CLINICAL MEMORANDUM.

INTESTINAL ANASTOMOSIS.[1]

By W. T. DODGE, M.D.,
of Big Rapids, Mich.
Physician and Surgeon to Mercy Hospital.

The following case was under the joint care of Dr. J. L. Burkhart and myself:

Gunshot wound of left wrist and abdomen; fecal fistulæ of ileum and colon, both closed by intestinal anastomosis with Murphy buttons; recovery.—E. McM., aged nineteen, was admitted to the Mercy Hospital, October 20th, 1893. The previous day, while hunting, he had climbed on top of a stump, and the gun slipping from his hand had been discharged, the contents passing through the anterior portion of the left wrist and entering the abdominal wall just above the crest of the ileum. Nothing had been done for him, and as he was very weak from the loss of blood and the fatigue of a long journey, we made no attempt to dress the wounds that night, but administered stimulants freely and secured rest with morphin. The following morning, his condition being much improved, an anesthetic was administered and the wounds thoroughly cleaned. The tissues of the wrist and abdomen were badly burned by the powder, and the entire charge of the gun was found in the abdominal wall, the greater portion of it resting against the peritoneum. The shot removed were of all sizes, from fine birdshot to buckshot, and altogether a good sized handful of wadding and shot was obtained. No evidence could be obtained that the peritoneum had been perforated, but the membrane was bruised and blackened by the contact of the foreign bodies. We satisfied ourselves with thoroughly cleaning the wounds, clipping off bruised tissues and establishing drainage. The young man experienced much pain in the abdomen for several days, when it was relieved by a discharge of fecal matter from the wound. At first only a portion of the feces came from the wound, a natural movement of the bowels taking place occasionally, but as the quantity escaping from the wound gradually increased and he was constantly soiled by the discharges we concluded to attempt closure of the fistula. The first attempt was made October 28th, but was a failure on account of the friable condition of the intestines. There were two fistulæ, one in the sigmoid flexure of the colon and one in the ileum. The gut-walls were covered by granulations, and suturing was impossible. We discovered an intraperitoneal abscess, however, evacuated the pus, and established drainage. Two weeks later, the suppuration having ceased, another attempt was made to close the fistulæ. We sewed up the intestinal openings without liberating the adhesions, being desirous to avoid additional contamination of the peritoneum. In two days the sutures sloughed out and the condition was worse than before. Two weeks later, or about December 1st, a third attempt was made to close the opening in the small intestine by suture, leaving the opening into the colon as an artificial anus. The walls of the intestine were found to be in a softened condition and to tear when an attempt was made to introduce sutures or to separate adhesions, and, the patient being in a feeble condition, the attempt was, for the time, abandoned. Our efforts were now limited to general supporting treatment and to maintaining cleanliness, an exceedingly difficult matter on account of the constant discharge of liquid feces from the small intestine. The man was, in spite of the free use of protective powder, constantly excoriated from the contact of this irritating discharge. A month of this sort of thing brought us to the determination to close the opening in the small intestine or close the patient's earthly career, and on January 2, 1894, with the assistance of Dr. Griswold, we undertook the final operation on the small intestine. The tissues were found to be in better condition than they had been a month previously, and the adhesions binding the small intestine to the abdominal opening were easily separated. The hole in the intestine was found to be so large and the portion of the bowel around it was so friable that we concluded to cut out the

[1] Read before the Michigan State Medical Society, March 3, 1894.

portion of gut containing the opening and make an end-to-end anastomosis. This was accordingly done by means of the Murphy button, the largest size of the regular set being used. The procedure occupied a quarter of an hour. The peritoneum was irrigated and the bowel returned to the abdominal cavity. The colon was stitched into the abdominal wound to close the opening and establish an artificial anus. The patient had no bad sysmptoms after the operation, gained rapidly in strength, and on the eighth day the button escaped from the artificial anus. By February 1st, the patient having become strong and able to walk about the ward, we determined to attempt to close the artificial anus in the same manner that had proved so successful with the small intestine. Truax, Greene & Co., of Chicago, made for us, after specifications furnished by Dr. Murphy, a special size button with a diameter of one and half inches and a central opening of seven-eighths of an inch. February 16th, assisted by Drs. Griswold and Dockry, we separated the adhesions binding the colon to the abdominal wall, and liberated intra-peritoneal adhesions for several inches on either side of the fistula. Four inches of the gut were then removed and the ends joined together by means of the large button. The patient delayed us a great deal by persistent vomiting, but the operation was completed within an hour. As the small intestine appeared in the wound we examined it carefully and located the site of the former anastomosis by means of a band of adhesion. No difference whatever could be discovered in the appearance of the intestine at that point. The caliber was the same as it was at contiguous points, and it was only by the presence of the band of adhesion that the anastomosis site was located at all. The abdominal wound was drawn together as much as possible and a drainage-tube introduced. The patient was kept on a liquid diet and laxatives administered daily. The only complaint he made was on account of the liquid diet, as he had a strong desire for more substantial food, and on the morning of the 7th day I had the pleasure of extracting the button from the anus. A few days later, by means of a flap-splitting operation, we closed the abdominal wound completely. Healing occurred rapidly, and on March 26th the patient was discharged.

MEDICAL PROGRESS.

A New Method for Reduction of Fractures of the Lower End of the Radius.—At a recent meeting of the Philadelphia County Medical Society, DR. T. S. K. MORTON described a method of reducing fractures of the lower end of the radius that he has found satisfactory during a number of years.

The surgeon stands in front of the patient, and interlaces his fingers beneath the supinated wrist and palm of the injured member, so that his two index fingers lie parallel, crosswise, beneath the lower end of the upper fragment of the radius. The palms of the surgeon's hands are then closed in upon the thenar and hypothenar portions of the patient's hand respectively, while the surgeon's thumbs rest parallel, lengthwise, upon the upwardly displaced lower fragment of the radius. The parts are thus firmly grasped by the surgeon while the following movements are made: The patient's wrist is excessively extended by carrying his hand upward. When hyper-extension has thus been secured the surgeon makes powerful traction upon the wrist in the line of hyper-extension. While this traction is maintained the hand is suddenly carried into full flexion, and at the same time powerful downward pressure upon the upwardly displaced lower fragment of the radius is made by the surgeon's thumbs, opposed by the interlaced index fingers beneath the lower end of the upper fragment.

The excessive extension of the first portion of the movement loosens or disentangles the displaced lower fragment, while the subsequent traction, flexion, and direct thumb-pressure force the lower fragment into proper position. A separated epiphysis of the lower end of the radius is likewise easily reducible by this manipulation. For comminuted or complicated or very oblique fractures extension and molding alone are called for in most instances.

Anesthesia is unnecessary for making a single effort at reduction by the proposed method. The patient does not anticipate what is coming, the two movements are made with lightning-like rapidity in a small fraction of a second, and in nearly every case perfect reduction has been accomplished before the patient realizes that he has been hurt. Should the manipulation fail to secure perfect reduction at the first attempt, anesthesia had better be induced, for the pain of repeating the maneuver would be intolerable.

In cases older than one week, with displacement persisting, anesthesia is induced before any effort at reduction is made. The manipulation will often be found to be the best means of performing both refracture and reduction.

For making a diagnosis a modification of this method is most useful. If the surgeon will take the hand and wrist in which fracture is suspected into his hands, as described, and, while the thumbs press firmly upon the lower end of the radius or first row of the carpus, make a series of gentle, quick, short flexions and extensions of the joint—rocking it through an arc of perhaps 25° or 30° above and below the forearm as a horizontal plane—he will be astonished at the ease with which crepitus of the bones of the joint and of any small or large bony or cartilaginous fragment will be elicited. And, best of all, the diagnosis of these obscure fractures about the wrist can thus, after some practice, be brought out without giving unbearable pain to the patient.

Vaginal Hysterectomy in a Woman Sixty-six Years Old.—LAWRIE (*British Gynecological Journal*, February, 1894, p. 385) has reported the case of a woman, sixty-six years old, who for about a year had suffered with pain in the region of the uterus and a vaginal discharge. The latter had at first been muco-purulent, but had subsequently become bloody. The menopause had occurred at the age of fifty. The uterine cervix presented a catarrhal condition. A sound entered the cavity of the uterus for the normal distance; its introduction was followed by slight hemorrhage. On bimanual examination the uterus was found to be somewhat tender but quite movable. Upon dilatation of the cervix an indurated, nodular mass was found occupying the upper part of the uterine cavity. By means of a curet this was

thoroughly scraped away, and the surface left fairly smooth. This operation was followed by great relief, the discharge disappearing and the pain ceasing. The patient gained in health and strength, but in three months the symptoms had returned with their previous intensity. The uterus was again dilated, and the growth, which had attained greater size than before, was a second time thoroughly curetted. There was again temporary improvement, but at the end of six weeks the old symptoms began to return. The growth had returned, and it was determined to make the removal as thorough as possible. With a strong curet the growth and underlying tissues were completely scooped out, till almost the whole thickness of the uterus at that part had been removed. Severe constitutional symptoms followed, but the result was satisfactory for four or five months. The pain then recurred in a severe form, and was attended with considerable hemorrhage. It was now determined to remove the uterus through the vagina. As the woman had never borne children the operation was attended with no little difficulty. The removal was, however, finally accomplished, and the after-history was entirely uneventful. Upon histologic examination the new-growth, which was a sessile tumor of the posterior wall of the uterus, proved to be an epithelioma.

The Amount of Nitrogen contained in the Red Blood-corpuscles in Health and Disease.—Von Jaksch (*Zeitschrift f. klin. Medicin*, B. xxiv, H. 5, 6, p. 430) has determined that the amount of nitrogen contained in 100 grams of moist red blood-corpuscles in health equals 5.2 grams, corresponding to 34.5 grams of albumin; during and following acute diseases the average rises to 5.80 grams of nitrogen, corresponding to 36.81 grams of albumin; in the course of chronic diseases that do not lead to anemia almost the same figures prevail as during health: 5.56 grams of nitrogen and 34.75 grams of albumin. All secondary anemias, as well as leukemia, lead to a diminution, a *hypalbuminæmia rubra*. The same relation is found to exist in chlorosis, though in a more marked degree. Pernicious anemia, on the other hand, in its last stages leads to a distinct increase in the amount of nitrogen present in the red blood-corpuscles, 100 grams containing 6.48 grams of nitrogen, corresponding to 40.5 grams of albumin—*hyperalbuminæmia rubra*.

THERAPEUTIC NOTES.

Recovery from a Large Dose of Tartar Emetic.—Perry (*Birmingham Medical Review*, vol. xxxv, No. 189, p. 291) has reported the case of a man, twenty-seven years old, who mixed for himself what he believed to be an effervescent draught. Being thirsty, he drank the mixture before he noticed that it had a peculiar taste and did not effervesce. He then discovered that, instead of sodium bicarbonate, he had taken tartar emetic. He passed his finger down his throat, and succeeded in inducing vomiting fifteen minutes after he had swallowed the poison, keeping up the vomiting with draughts of warm water. In half an hour purging began, and some time later the man was found in a semi-conscious condition in the water-closet. His skin was bathed in cold perspiration; he was almost pulseless, and could not be made to answer questions. He was at once carried to bed, and hot bottles and blankets were applied. Strong tea and brandy were given, followed by decoction of oak bark in considerable quantity. The man soon rallied and became able to answer questions. He vomited three times after having been put to bed, and from the bowels there was continually passing thick mucus having the appearance of boiled sago. There was much complaint of thirst. The purging continued for twelve hours, but neither in the stools nor in the vomit was there any blood. There were cramps in the legs and feet, subsequently becoming general, and being most distressing in the situation of the diaphragm and in the muscles of the neck. For a time the man was almost unconscious and nearly pulseless, with the extremities and the surface of the body cold, and he was apparently dying. The administration of stimulants, however, produced a good effect, and improvement now gradually set in. On the day after the accident the man passed half a pint of coffee-colored urine, being the first since preceding day. After this the urine and stools became normal. For three days there was complaint of general stiffness, especially across the abdomen, with an undue readiness of fatigue, but without further inconvenience. It is estimated that the amount of tartar emetic taken was not less than 200 grains.

Quinin Locally in the Treatment of Blennorrhagic Ophthalmia.—Having by an inadvertence used a solution of quinin by injection in the treatment of a case of gonorrheal urethritis, and obtaining good results, Reich-Hollender (*Archives of Ophthalmology*, vol. xxiii, Nos. 1, 2, p. 30) was led in the treatment of a troublesome case of gonorrheal ophthalmia to use the same agent, in conjunction with ice-compresses and applications of solutions of argentic nitrate, and with equally good results. Further investigation showed that the gonococcus of Neisser was destroyed by solutions of quinin. It is recommended that quinin be dissolved by hydrochloric acid, and in the following proportions:

Quininæ sulphatis	2.
Acid. hydrochloric. dilut. . . .	0.75
Aquæ destillat.	180. —M.

Ft. solutio.

S.—Shake well, and use as an eye-lotion every hour.

Frictions of the Feet as a Resuscitating Measure.—Urbaschek (*Hygeia*, 1893; *Memorabilien*, xxxviii, 3, 172) has reported the case of a small, corpulent man of advanced years, with fatty heart, who suddenly lost consciousness following some excitement, collapse virtually ensuing. Other measures of resuscitation failing, and the condition becoming alarming, the lower extremities were thoroughly rubbed with cloths wrung out of fresh water. Feeble respiratory efforts soon returned, and these were followed by deep respiration, together with the resumption of consciousness, and the condition of weakness was overcome by means of a general cold rubbing.

For Urticaria.—

R.—Liquor calcis.	
Aquæ laurocerasi	āā f℥j.—M.
Glycerini	

S.—Apply topically and cover with cotton-wool.

SATURDAY, JUNE 23, 1894.

THE TEACHING OF CHEMISTRY IN MEDICAL COLLEGES.

The Medical News has been severely taken to task for its position in regard to the teaching of chemistry in American medical colleges; nevertheless, the subject is one too important to permit us to be silent until the reform we seek to bring about is an accomplished fact. Let one who doubts the truth of our strictures ask thoughtful clinicians among the younger generation of leaders—we say younger generation in order to confine observation to a period recent enough to be properly the subject of comment—wherein they feel most keenly the deficiencies of their training. We venture to assert that seven out of ten will answer, "in advanced chemistry." They will confess, if they are honest, that they are not only unable to participate in, but are sometimes hardly able to follow, recent studies in pathology and therapeutics; that the whole subject of infection and immunity is for them beset with unnecessary difficulties, simply because they have not been properly grounded in organic chemistry.

Nor are the majority of recent graduates—even yesterday's graduates—much better off. The kindergarten chemistry-lectures, supposed in many medical colleges to be all-sufficient for graduating classes, are not up to the standard that should be exacted for admission to the first year's course; and even in some of the otherwise first-class colleges the time devoted to physiologic chemistry and pathologic chemistry is ridiculously inadequate.

The truth is that old superstitions as to what constitutes a liberal education have hampered even scientific institutions. The knowledge of books and of men who have written books is a liberalizing knowledge, but the knowledge that is required by a physician is not so much of letters as of things. Physics and chemistry, general biology, and even considerable geology are absolutely necessary before the science of medicine can be approached. The art of medicine can be learned in a fashion without these—and also without languages. Hitherto our medical schools have been—not unjustifiably—exalting the art of medicine, and hence the faulty organization of many of them. But the day of higher education and of exact research has dawned—and the schools that desire to keep high rank in the new day cannot stop with half-way measures. Physics and inorganic chemistry must be made preliminary requisites. General organic chemistry must be taught thoroughly during the first two years, in the laboratory, by a sufficient number of competent teachers, and for hours at a time, not for occasional minutes. The junior class must devote a sufficient time to physiologic chemistry, and the senior class study pathologic chemistry and be trained in methods of original research. Post-graduate courses must be organized for those who desire to continue these studies. The immediate future of medical science demands accurate and extensive chemic knowledge, and if American schools do not give it, American physicians will be left far in the rear. It is true that all cannot be done in a day, but a beginning can be made at once. The first practical step is to abandon the elementary lectures now given to first-year and second-year classes in medical colleges, and insist on a knowledge of general chemistry as a preliminary qualification. The rest will follow.

SWEAT-SHOPS AND DISEASE.

A recent investigation made in this city developed the fact that in some of the worst "sweat-shops" garments were being made for many well-known establishments. These garments were often of the best quality, and not, as is usually supposed, only cheap goods. A sweat-shop is synonymous with all that is filthy and unsanitary. In it the workmen are crowded together, and no factory-laws

regulate the manner of work. It often is also the living-room and sleeping-room of the family. The children, healthy or unhealthy, commingle with the workers and come in close contact with the materials. Diphtheria and other contagious diseases are very prevalent in the "sweaters' section." Often the Board of Health is informed only when a death occurs.

A quarantine means much to these poor people, and they have rather profanely nicknamed our sanitary agents the "Board of Hell." My lady's silk-waist or my gentleman's dress-coat may form a pillow for some sick child (not altogether a bad use for it), and herein lies the risk, particularly to the children in the families of those who receive articles of apparel made under the conditions stated.

If a proper popular sentiment were created, our wealthy merchants would be compelled to have their own shops, in which their goods would be manufactured under proper conditions. As it is, they are not bothered by factory-inspectors or by strikers, and are not obliged to go to the expense of rent, equipment, etc., but a contractor or middleman calls for the work and distributes it among his sweaters and guarantees the return of the manufactured article. It is simply a matter of convenience, and for the merchants' convenience his patron must run the risk of contracting disease.

The workmen are compelled to live under most unsanitary conditions, and in the end entail an expense on the city in the increased amount of disease. Besides, child-labor is called into use, which under existing factory-laws could be prevented, but which cannot be reached in sweat-shops. The subject is in every aspect a most important one, and well deserves the attention of sanitarians as well as sociologists.

The sweating system is spreading. At first it was in the hands of the Russians; now the Italians are taking it up, and whole blocks are given over to it. We trust that the medical profession will take some united action in the matter and so arouse public opinion that, for their own advantage, our prominent merchants will condemn "sweat-shop work" and do their own manufacturing.

EDITORIAL COMMENTS.

The American Pharmaceutical Association has issued a circular detailing the aim of the Association as the union of the educated and reputable pharmacists and druggists of America in the following objects:

1. To improve and regulate the drug-market by preventing the importation of inferior, adulterated, or deteriorated drugs, and by detecting and exposing home-adulteration.

2. To encourage proper relations between druggists, pharmacists, physicians, and the people at large, which shall promote the public welfare and tend to mutual strength and advantage.

3. To improve the science and art of pharmacy by diffusing scientific knowledge among apothecaries and druggists, fostering pharmaceutical literature, developing talent, stimulating discovery and invention, and encouraging home production and manufacture in the several departments of the drug-business.

4. To regulate the system of apprenticeship and employment, so as to prevent, as far as practicable, the evils flowing from deficient training in the responsible duties of preparing, dispensing, and selling medicines.

5. To suppress empiricism, and to restrict the dispensing and sale of medicines to regularly educated druggists and apothecaries.

6. To uphold standards of authority in the education, theory, and practice of pharmacy.

7. To create and maintain a standard of professional honesty equal to the amount of our professional knowledge, with a view to the highest good and greatest protection to the public.

To all of which we most heartily assent, but we would supplement these worthy endeavors with yet three propo-propositions, viz.:

8. *To suppress counter-prescribing.*

9. *To suppress the unauthorized renewal of prescriptions.*

10. *To discourage the sale of secret nostrums.*

The Summer Care of the Children of the Poor.—A most commendable and praiseworthy enterprise, which should especially receive the encouragement and support of the medical profession, has been undertaken by a number of public-spirited and philanthropic citizens of Philadelphia, with the end of furnishing to poor families, virtually or actually at cost, sterilized milk, pure milk, and infants' foods. As is but too well known, the summer diseases of children and the frightful resulting mortality are due to improper food and clothing, intense heat and unhygienic surroundings. The most important of these is without doubt the improper character of the food, and it is the object of the Philadelphia Sterilized Milk and Ice Society to eliminate as far as possible this prolific source of disease and death. For the present there will be but one depot, and that in a district in which a large number of poor people reside, but the establishment of others is contemplated if such funds can be raised. The Mayor of the city, Mr. Stuart, is the President of the Society, and Mr. Philip Lewin is the Treasurer. The Rev. J. Leonard Levy, who has been most active in the movement, is the First Vice-president and the City Treasurer, Mr. McCreary, is the Second Vice-president. A similar enterprise has been for some time in successful operation in New York.

Through the courtesy of the Board of Health, the Society will be furnished with disinfectants, to be distributed where they will do the most good.

The Prevention of Tuberculosis and the Prevention of Smallpox.—We have on several occasions pointed out the wisdom of establishing a hospital for the treatment of tuberculosis. The prophylactic utility of vaccination is too well known and too universally admitted to require comment here. The Pennsylvania State Board of Health, at a recent meeting, adopted the following timely resolutions:

Resolved, That it is the sense of the State Board of Health of Pennsylvania that the time has come when the State should provide hospital accommodations for persons suffering from pulmonary tuberculosis in the case of those who cannot be properly cared for in their own homes, and who through carelessness might be dangerous to the community at large. It is believed that the establishment of such hospitals might be of great value in educating the people.

Resolved, That it is the sense of the State Board of Health of Pennsylvania that all inmates of prisons, reformatories, almshouses, hospitals, schools and other public institutions be vaccinated immediately on admission.

This action is in the spirit of progressive and preventive medicine, and should be the precursor of legislation looking to the enforcement of the views so well expressed.

For Higher Medical Education.—The New York College of Dentistry has set a worthy example in higher education that such medical institutions as have not yet raised their standards of preliminary requirements and lengthened their course of study may well emulate. The college announces (1) a prospective, yearly advance in the preliminary educational entrance-requirements, the details of which are explicitly set forth; (2) a prospective, yearly lengthening of the lecture-sessions—that of 1894–95 to six months, that of 1895–96 to seven months, and that of 1896–97 to eight months; (3) the requirement of evidence prior to graduation of three years' actual study and practice of dental surgery, inclusive of attendance on three lecture-sessions in separate years; (4) the inauguration during the lecture-session of 1894–95 of graded courses of practical work in sub-classes, for the classes of the first, second, and third years, respectively. The further announcement is made that the purpose of the institution is to educate men to practise dental surgery as a special branch of medicine; therefore, the curriculum includes the fundamental departments of medicine, with dental surgery and oral prosthetics.

CORRESPONDENCE.

POTASSIUM PERMANGANATE AS AN ANTIDOTE TO MORPHIN.

To the Editor of THE MEDICAL NEWS,

SIR: In the *Journal of the American Medical Association* for May 19, 1894, p. 755, an editorial entitled "Permanganate of Potassium as an Antidote to Morphin" contains the following as its closing paragraph: "A new antidote to morphin was not urgently demanded, and it could not, in fact, be truthfully denominated as a 'long-felt want,' since the treatment already in general use is very efficient and, as a rule, successful. But even allowing some usefulness to potassium permanganate as an antidote, when swallowed immediately after morphin has been taken into the stomach, this will not warrant the assumption that in such cases its hypodermatic administration will have any beneficial effect. Certainly, we are not warranted at this stage of the investigation in abandoning our well-known physiologic antagonists in the treatment of poisoning, either by morphin or by opium or its preparations. When a human life is trembling in the balance and fatal coma is threatening, it would be criminal to lose time by experimenting with therapeutic novelties, to the exclusion of the established treatment, and the 'rejection of the accumulated experience of the profession.' Some might be led to do so, however, were no word of protest raised against the implication that the suggested treatment is a safe and efficient substitute for the approved methods already in use."

It is scarcely a debatable question if suffering humanity is ever poorer for the discovery of any new method for the amelioration of even the least of those innumerable ills to which flesh is heir, even if that method be only within the reach of a favored few, as compared with the multitude beyond the pale of its relief-bearing influence. And when a measure is proposed whose adoption under certain conditions (as has been undoubtedly shown) means the actual saving of human life which must surely have been sacrificed had "the treatment already in general use" for those conditions been persisted in, shall it be denied consideration at our hands, because, if it shall demonstrate its claims as a valuable antidote to opium narcosis, "it necessarily means the rejection of the accumulated experience of the profession?" Does it not seem incredible that, in the face of undoubted instances of the great value of potassium permanganate in cases of extreme opium-narcosis, any should be found willing to oppose it on such puerile grounds, or be desirous of prejudicing the minds of the profession at large against it by an argument whose mere statement is at once a confession of weakness that must deprive it of any significance?

The editorial writer in the *Journal* hardly treats his subject in that dispassionate style so clearly demanded of one that occupies so exalted a position. The opening paragraphs of the article incline one to the belief that he will find in them a calm, unprejudiced treatment of this new method of meeting the toxic conditions of morphinism, and he invites one, very courteously, to a "study of the chemic and physiologic considerations upon which its employment is based." Further perusal finds the subject of the employment of the potassium salt treated of in all its aspects, and when its use under the conditions of morphin-poisoning or opium-poisoning is taken up, the ultra-conservatism of the writer reveals itself but too clearly. It may be understood that the permanganate can act as a "chemic antidote, and renders inert the poison yet unabsorbed, with which it must be brought in contact. There is absolutely nothing to warrant the view that this agent can act as a systemic or physiologic antidote to morphin or any other toxic agent. . . . From what is known of the chemic nature and physiologic effect of permanganate of potassium, we must admit that the successful use of this agent administered hypodermatically in cases of lauda-

num-poisoning, is something we were not prepared for. . . . It is possible that when hypodermatically administered, although decomposed in the tissues, the nerve-centers may be influenced by some of its products; but even if so, it would not be the permanganate *per se*, but something else which does the work. . . . In the meantime, the distinction between a chemic and a physiologic antidote must be kept in view and, above all things, we should not require of a chemic antidote that it shall also be a physiologic one." Then follows that paragraph which forms the text for these remarks, and at its close we are left in wonderment as to what danger threatens our medical life, or how our professional standing will be compromised should we be led to employ this remedy in the management of some desperate case of opium-narcosis, when the established treatment has failed, as I have twice known it to fail, after most faithful and prolonged trial. Why, under such trying circumstances, "when a human life is trembling in the balance and fatal coma is threatening," must it be kept in view that a chemic antidote and a physiologic one are two distinct things, and even although the established treatment has failed thus far to bring relief, why should it be adjudged "criminal," this so-called experimentation with a therapeutic novelty, when its employment only implies "the rejection of the accumulated experience of the profession"—at the risk of saving a human life?

A few days ago I was hurriedly summoned to a patient exhibiting all the symptoms of profound morphin-poisoning. One hour previously I had administered a hypodermatic injection of morphin and atropin for the purpose of overcoming a condition of acute maniacal excitement that had persisted almost continuously for forty-eight hours, and which other means had entirely failed to relieve. The family had been apprised of the risk of so doing, for not only was I ignorant of any possibly existing idiosyncrasy of the patient,[1] but her exhausted state of system, as the result of a prolonged illness, in the closing stages of which I had been summoned, led me to fear a possible overwhelming effect of the morphin, which, in a less debilitated subject, need not have been anticipated from the amount of the drug employed. The nurse had been cautioned to watch closely the respirations, and not to lose any time in summoning aid should they fall to ten per minute. When I reached the patient I found her in profound stupor, with a livid aspect of countenance, and the coldness of extremities and of body-surface characteristic of the asphyxiated condition. The pulse was feeble, rapid, and irregular, and the few efforts at respiration, which were *three per minute*, were but faint gasps, in the intervals between which the woman lay without semblance of life, the faint, thready pulse being the only indication of the slight hold she maintained upon it. I at once entered with energy upon "the established treatment," which, "as a rule, is successful." Hypodermatic injections of atropin sulphate were given at frequent intervals, as much as gr. $\frac{1}{48}$ being administered when it was found that smaller doses were useless. An hour passed, and the outlook was a hopeless one. For fully half a minute there would be no effort at breathing at all, and artificial respiration alone maintained life for a time. It then occurred to me to try the potassium salt, and, ignorant of the necessity requiring one not to expect a chemic antidote to act as a physiologic one, I injected ten drops of a *saturated* solution of potassium permanganate into the forearm. Tweny minutes of anxious waiting passed, and twelve drops more were thrown into the tissues, and then for the first time there came an improvement in the depth and number of respirations. A third injection of fifteen drops was given twenty minutes later, as the improvement was not maintained. This proved entirely satisfactory, as the woman returned to consciousness, and voluntary efforts served to maintain respiratory effort on a safe basis. I did not leave her, however, for another hour, as she manifested a disposition to drowsiness, and I preferred taking no chances. No further treatment was employed, however, other than the administration of strong coffee and moral suasion, and when I left her it was with such feelings of gratitude to the potassium salt as could only find real expression in combating the very erroneous views of its efficacy advanced by the editorial in question.

In the face of such testimony as this regarding the value of "the new treatment," will any be found unwilling to make trial of potassium permanganate in a desperate case of opium-poisoning because he may, by so doing, be acting against the teachings of the profession, and disregard the theories concerning the action of this salt when taken into the human economy? Of what concern is it to us, or our patients dying from opium-poisoning, whether, when hypodermatically administered and decomposed in the tissues, it be "the permanganate *per se*" or "something else" which does the work? If only favorable results attend the use of the potassium salt when employed, even in most desperate cases of opium-poisoning, due either to ingestion of the poison into the stomach, or to its administration through hypodermatic means, why should it be asserted by any that "a new antidote to morphin was not urgently demanded," particularly, when the numerous failures that have attended "the treatment already in general use" are borne in mind? If Dr. Moor's experiments prove the entire reliability of the permanganate when "given immediately after the poison is swallowed;" and if the use of the salt hypodermatically has been the means of saving life in every instance but one in which it has thus been employed (and that one a necessarily hopeless case under any treatment, *vide* MEDICAL NEWS, vol. lxiv, No. 19, p. 514), why should not every reason exist for its employment at the very outset of the treatment of cases of opium-narcosis, if not as a special treatment of that condition, then as an adjunct, and a most valuable one, to the atropin and strychnin method, rather than

[1] I learned subsequently from the husband, who was absent from home at the time, that his wife had never been able to take morphin, as it always produced decidedly unpleasant effects. This statement was confirmed by the unusual result in the present instance, as for an hour after the injection had been given the woman slept quietly and the respirations were easy and natural. The change came suddenly and without warning, the breathing becoming labored and the number of respirations falling to six per minute, while the face became livid, and stupor appeared, and within fifteen minutes, when I had reached her bedside, her condition had become as described,

as a *dernier ressort*, and after the more usual methods have failed? And may we not justly question the position taken by the editorial writer in the *Journal* wherein he refuses to acknowledge "that the suggested treatment is a safe and efficient substitute for the approved methods already in use?" Yours very truly,

JAMES STRATTON CARPENTER.

POTTSVILLE, PENNA.

PERNICIOUS ANEMIA FOLLOWING PREGNANCY.

To the Editor of THE MEDICAL NEWS,

SIR: Mrs. M., pregnant for the third time, was troubled with obstinate nausea and vomiting during the last two months of her gravidity, instead of the first two, as had been the case before. Her health, however, seemed excellent and her strength quite good, despite this trouble. On May 2, 1894, she was delivered, the labor being entirely normal in every respect and scarcely the ordinary amount of blood being lost. Her gastric disturbance now subsided. On the day of the confinement the temperature was 100° in the morning and 101° in the evening; it remained elevated for about two weeks, after which it rose about one degree. Not till the tenth or eleventh day after confinement, however, was anything serious suspected. At this time the woman tried to sit up, but almost fainted from her great weakness. She had no pain, distress, or tenderness at any time. She complained only of weakness. She was quite pale and grew more so till the skin assumed a typically cachectic appearance as in carcinoma of the stomach, and her breath was very offensive as in that disease. Emaciation was not marked. In spite of heroic treatment with iron, arsenic, and other tonics, with nutritive enemata, the woman slowly and gradually failed and died June 2, 1894. At the post-mortem examination, made by Dr. Chamberlain, it was seen that the body was not at all emaciated, but the anemia was so extreme that the instruments and hands when washed did not even tinge the water. There was no blood in any of the vessels except the aorta. Not the slightest evidence of disease, acute or chronic, was found in any of the internal organs. The article on "Fatal Nausea and Vomiting of Pregnancy," in THE MEDICAL NEWS of June 2, 1894, has prompted me to report this case.

Yours truly, J. A. BROBERG.

DELAVAN, MINN.

THE TRANSMISSIBILITY OF TUBERCULOSIS.

To the Editor of THE MEDICAL NEWS,

SIR: In the discussion before the College of Physicians, of Philadelphia, upon the registration of tuberculosis, on January 12, 1894, I made the following statement: "Dr. Williams, of the Brompton Hospital, has been quoted as an opponent of the theory of contagion, but he has written a paper in which he shows that a large number of nurses of the Brompton Hospital have contracted tuberculosis. I think that he has traced some fifteen or twenty cases."[1] Dr. Williams has called my attention to the fact that I misquoted his article and a rereading shows that this is true. In my remarks, I spoke from memory and entirely extemporaneously. The fifteen or twenty cases which I credited to nurses occurred among persons who had been employed in one capacity or another about the hospital, and only one case occurred in a nurse during her term of service. The time covered by Dr. Williams' investigation is thirty-six years. Whilst I still believe that the conclusion drawn from Dr. Williams' paper (namely, that the experience of the Brompton Hospital cannot be used as an argument against the theory of the contagiousness of tuberculosis) is correct, I deeply regret having misquoted Dr. Williams and cheerfully make the correction. Dr. Williams contends that his paper "furnished only one case of consumption, contracted during residence, among the Brompton nurses, and that a doubtful one, in a period of thirty-six years." Respectfully,

LAWRENCE F. FLICK.

PHILADELPHIA, 736 PINE STREET.

RECOVERY FROM TOXIC DOSES OF MORPHIN.

To the Editor of THE MEDICAL NEWS,

SIR: The comment on "Recovery from Toxic Doses of Opium and its Derivatives" leads me to report in brief a case never before published.

In September, 1889, Dr. Akins, of Loraine, Ill., and I were called to see a strong girl who had taken fifteen grains of morphin sulphate four hours before, with suicidal intent. So long a time having elapsed after the ingestion of the poison, we did not try to empty the stomach. We gave hypodermatic injections of atropin sulphate till the pupils were dilated, and used inhalations of amyl nitrite as a stimulant. The girl regained consciousness in about fourteen hours, was delivered of premature twins soon after, and made a good recovery.

Respectfully, D. D. STEINER.

QUINCY, ILL.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Forty-fifth Annual Meeting, held at San Francisco, Cal., June 5, 6, 7, and 8, 1894.

(Specially reported for THE MEDICAL NEWS.)

GENERAL SESSION.

THIRD DAY—JUNE 7TH.

THE apparently perennial contest over the revision of the Constitution and Code of Ethics of the American Medical Association was renewed at this session. For a time the battle between the majority and the minority factions waged fiercely, but at its close the situation remained exactly as it was before the struggle began several years ago.

Odd Fellows' Hall was well filled when PRESIDENT HIBBERD called the meeting to order. After the usual announcement of plans to promote the pleasure of delegates, prepared by DR. PLUMMER, the majority report of the Committee on Revision was presented by DR. HOLTON. It was essentially the same as the new Constitution proposed at Milwaukee two years ago. The revised Constitution and Code would open the doors to all members of the profession in good standing and remove the barriers now existing.

The minority report was offered by DR. DIDAMA, of

New York. DR. FERGUSON, of New York, moved the substitution of the minority report for that presented by the majority of the committee.

DR. QUIMBY, of New Jersey, made a vigorous speech in favor of the minority report. Applause and hisses, equally mingled, greeted his remarks.

By a vote of 161 to 70 the minority report was made the report of the committee, and the conservative element was in its glory.

DR. WALKER, of Virginia, then moved the adoption of the report as a whole.

The roll was called and 215 delegates responded to their names. The Chair stated that a three-fourths vote was necessary to change the Constitution. The vote was announced as 151 ayes to 64 noes, and the motion was declared lost. The old Constitution and Code, without amendment of any kind, therefore, remains in force.

After the adoption of a resolution designed to promote the interests of the *Journal*, the session was adjourned.

FOURTH DAY—JUNE 8TH.

The meeting was called to order by PRESIDENT HIBBERD. After the usual announcements by the Chairman of the Committee of Arrangements, the question of the amendments to the Constitution was taken up. After a lively contest the consideration of the matter was indefinitely postponed. DR. HOLTON presented a majority report on the Revision of the Code of Ethics. DR. DIDAMA followed with the minority report.

A motion by DR. INGALLS to lay the whole matter on the table was carried. Later in the session DR. MARCY, of Boston, moved that all matter relating to the Constitution and Code which had been laid on the table be again taken up for consideration. Carried.

He then moved to indefinitely postpone the revision of the Constitution. Carried.

A motion that a statement making clear the provisions of the Code be published in the *Journal of the American Medical Association*, explanatory of the exact position of the revision contemplated, was adopted.

DR. WINGATE, Chairman of the Committee on the Establishment of a Department of Public Health at Washington, urged the advisability of endeavoring to put an officer in the Cabinet. In case this could not be accomplished a national sanitary officer should be appointed.

DR. COCHRAN, of Alabama, suggested there should be a conference held at Washington annually for the consideration of questions of public health. Both suggestions were adopted.

The report of the Business Committee, recommending that members be allowed to go three years without paying dues before they are dropped from the roll, was adopted.

A resolution apropos of the death of DR. J. H. RAUCH, of Illinois, was presented and unanimously adopted.

A letter from the Minnesota State Medical Society, extending to the members of the American Medical Association an invitation to visit the St. Paul Medical Convention on their way East, was read by SECRETARY ATKINSON.

The following preamble and resolution were offered:

Whereas, The interests of the *Journal of the American Medical Association* require that it should command the confidence of the members of the Association in affiliation with the Association; and,

Whereas, The *Journal of the American Medical Association* has continued to publish unethical advertisements like those of Antikamnia, Labordine, and other secret nostrums, and that of the American Physicians Sanitarium Company offering $100 worth of stock to physicians sending it patients; and,

Whereas, The Trustees of the *Journal* have defended such a course on the ground that the money from such advertisements was needed to publish such a journal as they thought creditable to the Association;

Resolved, That the various State Medical Societies in affiliation with this Association are hereby requested to inform this Association whether their members approve the policy of admitting such advertisements to the pages of the *Journal of the American Medical Association*.

A motion to lay the resolution on the table was lost.

On motion, it was referred to the Judicial Council.

A vote of thanks to the medical profession of California for courtesies extended to the American Medical Association was adopted unanimously.

The addresses on "General Surgery," by DR. ERNEST LAPLACE, of Pennsylvania, and on "State Medicine," by DR. GEORGE H. ROHÉ, of Maryland, were read by title, owing to the absence of their authors.

The newly-elected President, Donald McLean, was escorted to the platform. He delivered a short address replete with expressions of the kindest feeling toward the members of the Association, and full of appreciation for the honor and courtesies bestowed upon him.

After a few words of thanks to the Association for the consideration shown him during the past year, Dr. Hibberd closed the session.

SECTION ON PRACTICE OF MEDICINE.

SECOND DAY—JUNE 6TH.

DR. C. M. RICHTER, of San Francisco, read a paper entitled "The Influence of Atmospheric Pressure upon the Prevalence of Pneumonia." He contended that pneumonia does not evince a bacillary origin, and that even in well-marked cases the specific germ is rarely found. There are several forms of pneumonia. Epidemics generally affect children under five and adults over fifty years of age in greater proportion. The liability to pneumonia begins with zero at the poles and gradually increases to a point in the temperate zone, then again diminishing toward the equator. Winter and early spring show the greatest proportion of cases; summer and early autumn the least. This may be explained by the greater maximum atmospheric pressure during the months when pneumonia is prevalent, *i. e.*, the more continuous the maximum high atmospheric pressure the greater the occurrence and mortality of pneumonia. Statistics were given covering a number of years and including the large cities of Europe, America, and Australia, in support of the position taken. A more extensive and thorough line of research was urged, with a view of learning the effect of continuous or extreme high atmospheric pressure upon the organism.

DR. A. W. PERRY, of San Francisco, expressed doubts as to high pressure acting as a causal agent in pneumonia. He pointed out that pneumonia is common in the mountain towns of California. Information gained

from practitioners in these towns does not indicate that the disease is more prevalent or more fatal because of the high barometric pressure. The question was asked if it was meant that pneumonia was caused by high or low barometric pressure, by the oscillations, or by outbursts of pressure.

Dr. Kellogg, of Milwaukee, asked if the statistics given were made from deaths or from all reported cases.

Dr. Richter in closing said that according to his statistics pneumonia was not more prevalent in the mountainous districts than in the valley towns and cities. It is not the oscillations of pressure, but the maximum continued high pressure to which he referred. His statistics were prepared only from the deaths, as there is no means of learning the actual number of cases.

Dr. Washington Ayer, of San Francisco, read a paper entiitled "Fever and the Relations of Microörganisms to Disease." He assumed a negative position as to the germ-theory, stating that he considered some conservatism necessary in this day of bacteriology. He looked upon fever as an important factor in almost every disease. In its ordinary sense fever means an exalted temperature of the blood as a result of increased tissue-destruction. Mutation and nutrition are interrupted. He called attention to the fact that even the same type of fever shows great variations in different patients and even in the same individual. From this he concluded that if the germs were the *materies morbi* there would be more uniformity. Does convalescence show that the germs have ceased to proliferate or that they are subdued by therapeutic measures. Typhoid fever is generally milder in course on the Pacific slope than on the Eastern coast, and yet the *casus belli* is claimed as one and the same. In the opinion of Dr. Ayer one example, viz., intermittent fever, makes the germ-theory for fevers untenable. He concluded by urging more careful work in practical medicine and less in the dreamland of microscopy. At present investigation has only proved the existence of organisms.

Dr. W. F. McNutt, of San Francisco, read a paper entitled "Tubercular Peritonitis." He reported four cases in which he had performed celiotomy for *primary* tuberculous peritonitis. Ordinary abdominal drainage was employed, but no medication. In all, complete and permanent recovery took place. They were considered primary because no evidence of a tuberculous process in other organs was found. In all four cases the peritoneum was thickened, covered with myriads of miliary tubercles, and the abdominal cavity contained an exudation varying in character in the different cases. Microscopic examination of a piece of the peritoneum, the site of tubercles, showed the histologic elements to be those of tubercle, although no tubercle-bacilli could be detected. A point dwelt upon was the peculiar shape of the abdomen noted in cases of tuberculous peritonitis with effusion. It resembles that due to cystic disease and not that common in ordinary ascites. This peculiarity was attributed to the fact that the effusion occurs into the thickened peritoneal wall.

Dr. John F. Carpenter, of Pottsville, Pa., read a paper entitled "The Pathology of Tetany." He stated that from recent contributions tetany is now considered a nervous disease, although no distinctive post-mortem changes have been found to show the exact nature of the disease. A second cause of pathologic uncertainty lies in the fact that the disease occurs in various forms, viz.: (1) Rheumatic, acute, or epidemic tetany, which is generally fatal; (2) Chronic, due to chronic diarrhea, prolonged lactation, etc., from which recovery is usual; (3) Occurring in the course of dilatation of the stomach; (4) Surgical tetany, following removal of the thyroid gland especially, which is generally fatal. Tetany is also found to follow such diseases as induce a morbid discharge from mucous surfaces and such as are due to sepsis. This is especially true of the puerperium when complicated by septic infection. It was contended that sepsis is clearly traceable as the causal agent of tetany. In all of the conditions predisposing to its occurrence septic infection is clearly probable. Furthermore, sepsis and septic absorption will account for other grave nervous disorders by causing profound anemia, which is the proximate cause of nervous irritation. Habit also has some influence. Thus attacks of tetany may be kept up by a condition of unstable equilibrium set up by the original attack. Owing to antiseptic precautions tetany is but little known, and the belief was expressed that in the near future the disease would be wholly one of the past.

Third Day—June 7th.

Dr. John Eliot Woodbridge, of Youngstown, Ohio, read a paper on "Typhoid Fever." He expressed confidence that the disease could be aborted by the use of antiseptics, such as thymol, guaiacol, and eucalyptol.

Dr. A. W. Perry, of San Francisco, read a paper entitled "Diagnosis and Treatment of Diseases of the Stomach by the Stomach-tube." He stated that most disorders of the stomach depended upon fermentations or abnormal accumulations in quantity or quality in that organ. The fermentations were acetic, lactic, butyric, cellulose, etc. Lactic-acid fermentation develops normally within from fifteen to twenty minutes after digestion commences, but is held in check by the hydrochloric acid of the gastric juice. Acetic and butyric fermentations are prevented by a more rapid and complete emptying of the stomach. By means of the stomach-tube we can determine the existence or non-existence of dilatations as well as the chemic composition of the gastric contents.

Spasm of the glottis may interfere with the introduction of the tube. This may be overcome by touching the back of the pharynx with the finger. Cocain can also be used. In some cases the circular fibers of the esophagus contract, and thus obstruct the passage of the tube. The stomach-tube should be used only every second, third or fourth day. During the intervals the internal administration of an anti-fermentative was recommended. Resorcin, gr. v, after meals, does not interfere with the digestive processes. The use of the stomach-tube will prove valuable in the diagnosis of carcinoma and ulcer of the stomach by allowing a quantitative test for hydrochloric acid.

Lavage has been found of benefit in the treatment of acute and chronic gastric catarrh; dilatation of the stomach not dependent upon pyloric obstruction; various fermentations, causing reflexes; carcinoma; ulcer; and finally in obstinate singultus.

DR. FREEMAN, of Indiana, related that he had found that by the frequent use of the esophageal bougie, between the acts of lavage, the esophagus became tolerant of the presence of the tube.

DR. R. W. MURPHY, of San Francisco, read a paper entitled "The Law of Equivalence in Medical Science." He expressed the belief that before many years have passed prophylactic measures will be discovered for such diseases as nephritis, carcinoma, tuberculosis, etc., as has already been the case with smallpox, hydrophobia, etc. He called attention to the great diversity of treatment directed toward the same disease, and believed we should have more practical text-books on drug-actions, both as regards maximum and minimum dosage.

He predicted that the physician of the future would be the man who closely watches the dual action of his drugs. In the case of calomel, cited as an instance, we may find physicians recommending a dosage varying from gr. $\frac{1}{20}$ to gr. xl for the same disease, and under apparently the same conditions. The same may be said regarding almost all of the drugs in use. Among other remedial agents electricity is largely employed without any thought of the laws of equivalence.

The following papers were read by title:

"Champagne and Strychnin in Chest-troubles of the Aged," by DR. G. EDWARD BUXTON, of National City, Cal.; "The Treatment of Erysipelas," by DR. JAMES M. ANDERS, of Philadelphia, Pa.; "The Use of Turpentine in the Treatment of Diphtheria," by Dr. E. W. KELLOGG, of Milwaukee; "Lung-gymnastics in the Treatment of Chronic Disease," by Dr. L. P. WALBRIDGE, of Decatur, Ill.; "A Clinical Study of Scarlatina at High Altitudes," by DR. J. N. HALL and DR. WM. P. MUNN, of Denver.

Dr. E. W. Kellogg, of Millwaukee, was elected Chairman of the Section, and Dr. W. E. Quine, of Illinois, Secretary, for the ensuing year.

SECTION ON SURGERY.

SECOND DAY—JUNE 6TH.

DR. EMMET RIXFORD read a paper entitled "Early Symptoms and Diagnosis of Tubercular Joint-disease." He detailed briefly the symptoms that are to be depended upon in the early recognition of the disease and its differential diagnosis.

DR. L. H. SAYRE, of New York, read an interesting and instructive paper on the "Conservative Treatment of Tubercular Joints." He laid much stress on the manner of applying the plaster cast in the treatment of joint-disease.

DR. S. STILLMAN, of San Francisco, followed with a paper on the "Treatment of Tubercular Joints by the Injection of Iodoform." He dwelt on the technique of the operation and on the location of the tuberculous foci.

This was followed by a general discussion of the various methods employed.

DR. L. C. LANE, of San Francisco, read a paper on "Concussion of the Brain." After reviewing the history of the subject and giving a general *résumé* of the various theories brought forward in regard to the subject since 1840, he explained why in most cases the diagnosis is easy, whereas in other cases it is most difficult, especially when there is no history of a blow or a fall upon the head. He divided the cases into three general classes or grades: (1) the mild; (2) the severe; and (3) the fatal cases.

As symptoms, he enumerated vertigo, faintness, weakness, drowsiness, and coma. The prognosis depends on the extent of the injury. As after-effects in some cases were mentioned melancholia and mania.

A paper on the "Treatment of Fractures of the Lower End of the Humerus," by DR. O. H. ALLIS, of Philadelphia, who was absent, was then read by the Chairman. The main point brought out was the advantage to be derived from treating such injuries with the arm in extension and the patient in the recumbent posture. This facilitates the circulation of the blood, the examination of the part, and the renewal of the dressing. Passive motion was only to be used in the latter half of the treatment. A lengthy discussion followed, which was represented on the one side by DR. LANE, who favored the method employed by Dr. Allis; and on the other side by DR. SAYRE, who favored the rectangular position.

The subject of hernia was then taken up.

A paper entitled "The Treatment of Strangulated Hernia," by DR J. RANSOHOFF, of Cincinnati, Ohio, was listened to with marked attention. He emphasized the great importance of immediate operative interference in the case of strangulated hernia and the great danger to be apprehended from prolonged taxis, which has a tendency to decrease the vitality of the gut, as well as to make the subsequent operative procedures less favorable in their results.

DR. A. E. ROCKEY, of Portland, Oregon, then followed with an interesting paper on "Observations on the Radical Cure of Inguinal Hernia." He advocated the idea of operative interference also in many cases of long standing and in cases in which the hernia is very large.

DR. H. O. MARCY then read a paper on "The Radical Cure of Hernia." He advocated the use of kangaroo tendon in suturing in preference to catgut.

A lively discussion followed, which showed that there are still many adherents of the conservative method of treatment.

DR. SCHIEL read a paper entitled "A Plea for the Better Teaching of Anatomy." He said that among all medical studies anatomy probably ranked first in importance. The lack of interest shown by students in the study of anatomy was, he thought, largely due to the methods of teaching. He also laid great stress on the evil results consequent upon a deficient education in this branch of medical science. These, he said, were not only meted out to the physician but also to the patient, who, falling into the hands of a practitioner with only a superficial knowledge of anatomy, was like a lamb being led to slaughter, unconscious of the danger that awaits him.

THIRD DAY—JUNE 7TH.

DR. C. F. BUCKLEY, of San Francisco, read a short paper on "The Symptoms and Treatment of Tumors of the Bladder." He related three cases of tumors of the bladder undoubtedly produced by traumatism to the perineum. He indicated that in his opinion not enough attention was paid to injuries of this sort.

This paper was followed by a voluntary contribution on the subject of "Anti-fermentative Surgery," by DR. HOGAN, of Texas.

DR. C. F. BUCKLEY then exhibited two very interesting specimens. One was a slate-pencil removed from the bladder of a male subject by the median operation. The other specimen was a collection of gall-stones removed from the gall-bladder of a patient during life.

DR. DAVID POWELL, of Marysville, Cal., read an instructive paper on "The Pathology and Symptomatology of Hemorrhoids, Anal Fistule, and Anal Fissure." Clinically he divided piles into external and internal, although the pathology of both is the same. The veins involved are the inferior and superior hemorrhoidal plexuses. In the initial stage the condition is nothing more than one of dilatation of the rectal veins. Later, characteristic changes take place and the tumor enlarges. As causes he enumerated fecal accumulations, the gravid uterus, or some obstruction to the hepatic circulation. Internal hemorrhoids he classified into (1) venous, (2) arterio-venous, and (3) capillary. Anal fistule, it was pointed out, usually originates in an ulcer. It may also be caused by a thrombus or by tuberculous foci that undergo suppuration. This trouble is often not accompanied by any urgent symptoms.

Anal fissure was considered a most important subject practically, not because of its pathology, but rather because of the pain and annoyance that invariably accompany it. Among the characteristic symptoms are dull, aching pain, aggravated by evacuation of the bowels, morning diarrhea, loss of blood, continual irritation of the genito-urinary organs, and tender prostate. The constitutional disturbances are often marked. If the trouble remains unrelieved the patient becomes pale, anxious, and looks careworn.

DR. G. B. SOMERS, of San Francisco, read an interesting paper on "The Treatment of Anal Fistule." It was shown that the treatment is by no means always simple, on account of two complications: (1) cicatricial tissue was frequently found in the canal, and (2) collateral sinuses often existed, hindering the surgeon in his work. In most cases the fistula is preceded by an abscess, which may be either pyogenic or tuberculous in origin, and which imparts to the fistula its characteristic aspect.

The methods of treatment are mainly four: (1) by injection, (2) by ligation, (3) by Mathews' fistulatome, and (4) the radical operation with the knife. Dilatation of the sphincter should always precede the operation.

DR. THOMAS W. HUNTINGTON, of Sacramento, read a paper on "The Treatment of Anal Fissure." He stated that anal fissure, though more common between the ages of twenty and thirty-five, occurs at times during infantile life and in old age. It occurs as often in men as in women, a view not generally held up to this time.

The symptoms are morning diarrhea, tenesmus, intense paroxysmal paralyzing pain, quite out of proportion to the size of the ulcer.

There are two general methods of cure, (1) by dilatation of the sphincter, and (2) by incision. Incision should always be done under anesthesia. Dr. Huntington favored the combined plan of incision and dilatation.

A paper was read by DR. ROSENSTEIN on the subject of "Treatment of Stricture of the Urethra." He briefly detailed his experience with the employment of gradual dilatation and internal urethrotomy. In summing up he stated that he decidedly favored gradual dilatation, and that in his opinion internal urethrotomy will eventually be abandoned because of the dangers associated with the operation, and because the cure after urethrotomy is not any more permanent than after gradual dilatation.

DR. THOMAS, of Pennsylvania, said that in certain cases he decidedly favored internal urethrotomy, in others divulsion.

DR. HUNTINGTON remarked that he rather favored internal urethrotomy, as gradual dilatation did not always cure the discharge.

DR. DODGE, of Michigan, said that he had seen worse reactions from the use of the sound than from internal urethrotomy.

It seemed to be the consensus of those present that internal urethrotomy was well adapted to many cases, and that it will always occupy a place in surgery.

It was also thought by many that the cure of stricture is not a permanent one, and that sounds have to be used at shorter or longer intervals to keep the stricture from again contracting.

FOURTH DAY—JUNE 8TH.

The first paper presented was entitled "New Plastic Operation for Varicocele," with presentation of a case, by DR. O. J. MAYER, of San Francisco. The feature of the operation is the transverse suturing of the longitudinal wound, by which the scrotum is considerably shortened. A case that had been operated on was presented.

Dr. MAYER then read a paper on "Bloodless Vaginal Myomectomy," the essential step in the operation being the temporary ligation of the uterine arteries.

An interesting and instructive paper was presented by G. W. WOODS, of Mare Island, California, on "The Use of Acetanilid in Medicine and Surgery, with Special Reference to its Use in Minor Surgery." He maintained that acetanilid is a good antipyretic, and not poisonous if given in small doses at the commencement, even to children. It acts slowly, and is both a diaphoretic and diuretic. It may be given in any and all fevers and inflammations. It is a good substitute for iodoform in venereal sores. Its application to a granulating surface is followed by a burning sensation, which, however, persists only a short time. It is useful in the dressing of all forms of burns, ulcers, moist eczema, gunshot wounds, abscesses, etc. When applied to extensive granulating surfaces it sometimes produces cyanosis, which is not due to a disturbance of circulation, but to deficient oxygenation of the blood. The following advantages of acetanilid as a surgical application were pointed out: Its cleanliness, its lack of odor, its antiseptic and desiccating qualities, its practical freedom from toxicity, the absence of crusting and the ease of removal, the insignificant cost, and its resistance to moisture.

A paper, by DR. THOMAS, of Pennsylvania, on "How Long is Syphilis Contagious?" followed. He expressed his conviction that syphilis is only contagious in the primary and secondary stages—that is, only for three or four years after the primary lesion.

A very rare and interesting case of multiple, symmetrical, bilateral lipomata was then presented by DR. SCHIELS. The lipomata were not limited to any partic-

ular part of the body, but occupied positions from the neck down to the groin.

DR. BONWILL, of Philadelphia, then read a paper on "A Surgical Engine." This engine, which was very similar to the ordinary dental engine, caused the trephine or burr to revolve from 100 times to 20,000 times a minute. It is said to be adapted to the performance of all sorts of surgical operations, both upon the soft parts and upon bony tissue.

DR. JOSEPH RANSOHOFF, of Cincinnati, was elected Chairman, and DR. REGINALD H. SAYRE, of New York, Secretary.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

SECOND DAY—JUNE 6TH.

The first paper was one by DR. LLEWELLYN ELIOT, of Washington, D. C., on the subject of "Placenta Prævia." In his absence, the paper was read by the Secretary. Placenta prævia was considered, next to puerperal convulsions, the most serious complication that can occur to the puerpera. The physician is usually not called till hemorrhage has appeared. No woman should be allowed to suffer from these hemorrhages if the child is viable, for it is as easy to resuscitate a child at seven months as it is a child at nine that has been subjected to the weakening effects of repeated hemorrhage. It was considered the proper course to pursue, to forcibly dilate, turn, and deliver, the child acting as a tampon in controlling the hemorrhage. Dr. Eliot would hesitate to resort to Cesarean section.

DR. ESHLEMAN, of Fresno, said that placenta prævia is much more common than is generally supposed, a large number of abortions being due to this complication. He objected to forcible dilatation and introduction of the hand for the performance of version. All that is necessary is to dilate the cervix sufficiently to introduce a small forceps, seize the head, and using it as a tampon, bring it down and deliver the child. The os is usually very dilatable, particularly if the hemorrhage has been severe.

DR. MCCHESNEY, of Philadelphia, said that in a case of placenta prævia there is no time for nice distinctions. One must use what means he can to dilate the cervix, then turn, and deliver. Hemorrhage after delivery is checked by copious injections of hot water, massage, and ergot, or ergot and strychnin hypodermatically, or by the mouth.

DR. MARTIN, of Chicago, said that it had been noticed formerly that fever invariably followed the delivery of women in cases in which it had been necessary to introduce the hand into the uterus. We know now the cause of this. As much care should be taken in preparing the hands preliminary to introduction into the cervical canal and uterus as in a case of celiotomy. He recommended for this purpose the use of a saturated solution of potassium permanganate and oxalic acid, as used at the Johns Hopkins Hospital.

DR. MONTGOMERY, of Philadelphia, believed that placenta prævia was the one condition in which the life of the child should not be considered. In central placenta prævia hemorrhage usually begins about the fifth month. The patient may have a fatal hemorrhage at any moment. As soon as the diagnosis is established the uterine contents should be evacuated. When there is lateral implantation and the hemorrhage slight and later, we may temporize; but even in these cases it is well to bring on premature labor. Cesarean section was not deemed necessary or advisable.

DR. NEWMAN, of Chicago, thought that dilatation, version, and delivery constituted the best and safest method. The case should be treated strictly on surgical principles. With regard to the use of an anesthetic, he would hesitate to use chloroform after extreme hemorrhage. He thought better work was done with the use of an anesthetic, and ether was safe.

DR. E. M. WESTLEY, of California, has adopted different methods. If the patient is exsanguine when the physician arrives the life of the child cannot be considered. The placenta should at once be detached and brought down; then the head of the child should be brought down and the child delivered. If hemorrhage is slight and the child alive, version before delivery is to be preferred.

DR. ESHLEMAN, of Fresno, Cal., emphasized the fact that in turning it was necessary to dilate the cervix to the size of the physician's hand and run all the risk of septic infection. In introducing the forceps according to his method, a dilatation of an inch was sufficient.

DR. CARPENTER, of Pennsylvania, reported that he has had three cases lately. In two he applied the forceps high up after getting the head into position by external manipulation. He then brought the head down so as to compress the placenta, which had previously been pushed to one side. In one case he held the forceps in place one-half hour before dilatation was accomplished. The patients were sustained by hypodermatic injections of whiskey and strychnin. In the third case, one of central implantation, he found the patient moribund when he arrived. He tore through the placenta and found a foot, which he seized, and delivered the child as soon as possible. The patient died. With the hemorrhage controlled the physician can afford to wait, and Dr. Carpenter believed that if he had been less hurried in his procedure, and had improved the delay by the administration of proper stimulants, he might have saved his patient.

A communication upon "Tetanus Puerperarum," by DR. ALLISON MAXWELL, of Indianapolis, was read by Dr. E. E. Montgomery. The history of a case of this rare disease was detailed, the etiology of the disease reviewed, and besides prophylactic measures, the use of antispasmodics and the antitoxin recommended in its treatment.

DR. MCCHESNEY, of Philadelphia, said that the offending cause resided in some kind of diet. The disease presupposed some point of infection, and should have directed against it local treatment aimed at its removal. In a case in which the initial symptoms of tetanus had appeared, Dr. McChesney used an intra-uterine douche of two quarts of a 1:3000 bichlorid solution every eight hours, following this by water that had been recently boiled. He used at the same time hypodermatic injections of atropin and rectal injections of peptonized milk.

At the request of the inventor, DR. MONTGOMERY presented an instrument designed to be used in cases of prolapsed uterus to fix the uterus to the abdominal wall. The instrument was generally condemned.

The PRESIDENT replied to some remarks made in the

Surgical Section reflecting upon private hospitals and their owners. He said that the attack upon private hospitals struck at the very life of abdominal surgery. It was in a private hospital that it was born, nourished, and grew to full maturity. He resented the imputation of dishonesty on the part of surgeons.

THIRD DAY—JUNE 7TH.

DR. X. O. WERDER, of Pittsburg, Pa., read a paper entitled "A Case of Didelphic Uterus, Unilateral Hematometra, Hematosalpinx, and Hematocolpos."

At the conclusion of this paper DR. CHESTNUT, of Philadelphia, moved an adjournment, so that the members might participate in the General Session. The motion was carried and the Section adjourned to 3 P.M.

At 3.30 P.M., the President of the Section being absent, DR. MEADE, of San José, moved that Dr. G. W. Davis, of San Francisco, act as temporary chairman, and that the work of the Section proceed. The motion was carried and Dr. Davis took the chair.

DR. BRIGGS, of Sacramento, read a paper on "The Function and Form of Obstetrical Forceps," using in demonstration instruments invented by himself.

DR. E. S. MEADE, of San José, pointed out that these forceps presented an anatomic defect, as the pelvic curve was wanting. She thought the instrument was too complicated. Great force was not necessary in delivering a child with instruments. She applied the forceps, used traction during the pains, and readjusted the instruments as it might be necessary during the intervals between pains. Sometimes as long as half an hour would be necessary to accomplish the delivery. Too often physicians thought only of quick work, without considering whether or not the mother and child were wounded. She considered that it was impatience and lack of anatomic knowledge that destroyed so many uteri and perinei.

DR. OSCAR MAYER, of San Francisco, thought the complicated nature of the instruments was opposed to the principles of obstetric asepsis.

DR. WINTERBERG, of San Francisco, thought it a very easy matter to find an obstetric case in which this and all other necessary instruments can be placed and the whole thoroughly sterilized by heat.

DR. BRIGGS said that the curve was greater than it seemed, being equal to three inches. It appeared less than this because the handle was parallel to the axis of the blade, while in the ordinary forceps it formed an angle.

DR. OSCAR J. MAYER, of San Francisco, read a paper upon "Massage in Gynecology." He said the object of uterine massage is to bring about a healthier state of the circulation and to impart tone to the various structures of the genital tract. It is indicated in all chronic inflammatory disorders, as well as in conditions that cause uterine displacements, such as relaxation of the ligaments or pelvic exudation, with or without adhesion. It is very important to form a correct diagnosis of the disease and to exclude all pyogenic disorders. The indications for massage in gynecology are the same as those for massage in surgery. By massage-treatment it is hoped to produce: 1. Acceleration of the absorption and retrogression of inflammatory and traumatic exudation and deposits. 2. Stretching, loosening, disintegration of cicatricial or hypertrophied connective tissues, caused by inflammatory processes. 3. Stimulation of the circulation and restoration of the normal elasticity and tone in (*a*) contracted, hardened, and hypertrophic tissues, or (*b*) relaxed tissues.

The sphere of usefulness may be tabulated as follows: 1. Pelvic exudations and hemorrhagic infiltrations. 2. Chronic parametritis and perimetritis. 3. Retroversion of the uterus. 4. Chronic metritis. 5. Prolapse of the uterus and vagina.

Massage is contra-indicated in all diseases of the genital tract requiring perfect rest of the whole body or of the genital tract alone.

The best and quickest cures from massage are observed in chronic diseases following the puerperal state. A longer time is required in conditions following acute inflammatory processes; also when coincident with anomalies of position of the pelvic organs, especially in retrodeviations of the uterus. Even if we do not succeed in some cases in restoring the uterus to its exact normal position we can obtain a symptomatic cure without recourse to surgical procedure. The combination of massage with electricity is to be recommended in the relaxations of the supports of the uterus, provided the structures are intact.

By exercising proper circumspection, we can often achieve more by alternating massage with other treatment than by long-continued massage. It was not claimed that massage constitutes an independent and sufficient form of treatment. It is only a mechanical therapeutic agent, intended to be used in combination with other tried and accepted remedies, in affecting a permanent cure, or in considerably lessening the time formerly required therefor. American gynecologists have been somewhat slow in accepting massage as a new remedial agent to be employed in diseases of women, and have been suspicious of the beneficial results that have been claimed for it. But the constant encouraging reports of European authorities, many of them at first bitter opponents of massage, are bound to work a change in this American sentiment.

DR. J. H. BARBAT, of San Francisco, bore testimony to the great good accomplished by massage, combined with electricity and glycerin tampons, even in cases in which the removal of the ovaries had been recommended by competent physicians.

DR. SHUEY, of Oakland, Cal., said that she had used massage in the painful menstruation of young women with the result of conferring perfect relief. The treatment was repeated every day for three or four weeks, and for three or four months longer during the menstrual period.

Dr. C. N. Martin was elected Chairman, and Dr. X. O. Werder, Secretary, for the ensuing year.

ASSOCIATON OF AMERICAN ANATOMISTS.

Sixth Annual Meeting, held at Washington, D.C., May 29, 30, 31, and June 1, 1894.

THE Secretary reported that Dr. Charles B. Ewing and Dr. F. C. Schaefer had resigned, and that three members had died, namely: Dr. William Lee, Dr. William B. Towles, and Dr. Corydon L. Ford.

The following new members were elected: Dr. John

A. Boger, Dr. H. B. Ferris, Dr. Robert L. Greene, Dr. William Keiller, Dr. Joseph Leidy, Dr. Mary B. Moody, Mr. Robert O. Moody, Dr. Charles D. Smith, Dr. William O. Stillman, Dr. W. C. Woodward. Sir William Turner, of London, was elected an honorary member.

The officers elected for the ensuing year were: Dr. Thomas Dwight, President; Dr. B. G. Wilder, First Vice-President; Dr. F. J. Shepherd, Second Vice-President; Dr. D. S. Lamb, Secretary and Treasurer.

Professor C. L. Herrick, of Denison College, Granville, Ohio, Delegate to the Congress of American Physicians and Surgeons; Dr. D. K. Shute, Alternate. Dr. Theo. N. Gill was elected to the vacancy in the Executive Committee.

The following papers were read: "On the Identity of Structure of Protoplasm with that of Striped Muscle," by Dr. Carl Heitzmann, of New York City.

"Some Problems relating to the Cerebral Fissures," by Dr. Burt G. Wilder, of Ithaca, N. Y.

"A Plea for a Methodically-written Text-book on Anatomy," by Dr. Edmond Souchon, of New Orleans.

"The Study of the Human Cranium;" also, "The Shortening of the Face-axis in the Evolution of the Mammalia," by Dr. Harrison Allen, of Philadelphia.

"Methods of Estimating the Height from Parts of the Skeleton," by Dr. Thomas Dwight, of Harvard University.

"The Perineum and Perineal Body," by Dr. D. K. Shute, of Washington, D. C.

"The Study of the Muscular Tunic of the Large and Small Intestine of Man in the Region of the Cecum; also, "A Note on the Occurrence of the Scapuloclavicular Muscle," by Mr. R. O. Moody.

"Theoretical Anatomy of the Sympathetic System," by Dr. William Carr, of Columbian University, Washington.

"The Female External Genital Organs: a Criticism on Current Anatomical Description," by Dr. Lamb, of the Army Medical Museum, Washington, D. C.

The following papers were read by title in the absence of the authors:

"In Our Two Years' Study of Anatomy what part of the Subject should be Covered in the First Year's Work, what part in the Second?" by Dr. A. D. Bevan, of Rush Medical College.

Two papers, by Professor P. A. Fish, of Cornell University, namely: "The Form and Relations of the Nerve-cells and Fibers in Desmognathus Fusca," and "The Terminology of the Nerve-cell."

An abstract of these papers and the discussions will be published with the proceedings of the Association.

NEWS ITEMS.

A Pestilence in China.—It is reported that China has been visited by a pestilence which is said to resemble in character the great plague of London in 1665. The plague first appeared at Canton toward the end of April, following a period of prolonged drought. Tens of thousands of persons are said to have succumbed to its ravages in Canton and Pakhoi. It was first observed at Hongkong on the 8th of May, and on the 10th from thirty to forty deaths were reported daily. The disease is described as of a bubonic character, with purplish or black swellings of the glands, in the groins, armpits, under the knees, and in the neck, accompanied by intense fever, the temperature rising to 105° or 106°. It is rapid in its course. With or without premonitory warning in the shape of malaise or chill, there is a sudden elevation of fever, rising to 105° or over. There is much headache and cerebral disturbance, accompanied by stupor. Diarrhea at once sets in, and a state of delirium followed by coma is reached in three or four hours in bad cases, death ensuing, and the body turning black and becoming putrid and swollen to thrice its size in the course of from twelve to twenty-four hours. In other cases, in from twelve to twenty-four hours glandular swellings appear in the neck, armpits, and groins, rapidly enlarging to the size of fowls' eggs. They are hard and exceedingly tender. With or without a decline of the fever the patient sinks more deeply into a condition of coma and dies, usually at the end of forty-eight hours or sooner. If six days are reached recovery is hopeful. The glandular swellings show no signs of suppuration. In some cases epistaxis or hematemesis occurs; petechiæ appear in a few cases, but there is no regular eruption. Very strong men have resisted the attack for two days and then succumbed, but as many as 80 per cent. of those attacked in Canton died in one day. Those who held out for three or four days generally recovered, but they were very few.

A German Emgirant-station.—It is reported that the North German Lloyd and Hamburg-American steamship companies have taken steps to establish jointly an emigrant-station at Illowo, East Prussia, where steerage-passengers will be received, examined, washed, and disinfected before going aboard ship. The sheds at Illowo will cover some four hundred and fifty square meters.

An official notice says that the cholera was brought to Myslowitz, on the East Prussian frontier, by a Russian tramp. The members of the Health Board are convinced that the cholera is not likely to spread far from the frontier. All the patients have been isolated and no fresh case has been reported for several days.

Changes in the Woman's Medical College of Baltimore.—Dr. Charles E. Simon has been elected Professor of Physiology and Histology; Dr. Charles O'Donovan, Professor of Diseases of Children; Dr. Pearce Kintzing, Professor of Chemistry; Dr. Berwick B. Lanier, Lecturer on Pathology; Ralph Robinson, Esq., Lecturer on Medical Jurisprudence; Dr. Claribel Cone, Lecturer on Hygiene. The seven-months' session will be lengthened to eight months. A three-years' course has been required since 1884.

The Church and Cremation.—The Pope has expressed his opinion that cremation, while heretic in principle, may be allowed under special conditions which amount to a guarantee against a public scandal. The Catholic clergy may officiate at services over bodies which are to be cremated, but not at a crematorium.

Sir James Paget and Lady Paget celebrated the golden anniversary of their wedding-day on May 23d.

Dr. George G. Shoemaker died at his home at Knox, Pa., on May 20, 1894, at the age of thirty-eight years.

CHRONIC VALVULAR DISEASE OF THE HEART.[1]

A Study from Clinical Observations of 1024 Cases, with Especial Reference to the Causative Influences and the Relative Distribution of the Lesions.

BY THOMAS G. ASHTON, M.D.,

CHIEF OF THE OUT-PATIENT MEDICAL DEPARTMENT IN JEFFERSON MEDICAL COLLEGE HOSPITAL, AND DEMONSTRATOR OF CLINICAL MEDICINE IN JEFFERSON MEDICAL COLLEGE.

ALTHOUGH in the analysis of the following cases some points already well known are reiterated, the number of cases collated is so large that even a confirmation of these facts cannot fail to be of value. In addition to this, however, I trust that the report will be found to possess features that will throw additional light upon the interesting subject of which it treats. These observations were made during a period of six years in the course of examinations of applicants for life-insurance. I regret that I am unable to give the total number of cases examined, and thus indicate the prevalence of valvular diseases in its various forms.

Statistics dealing with the relative frequency with which the different cardiac valvular lesions occur, together with the various combinations and associations of these lesions, are found to differ very much. The reason for this difference becomes obvious if we take into consideration the different conditions under which the observations are made. If these observations be made in a series of cases which have never presented so-called cardiac symptoms, and in which the finding of the cardiac disease occurred accidentally, as in the course of a routine examination, the result will be found to differ vastly from that obtained by analyzing a series of cases manifesting cardiac symptoms, and which seek advice on account of those symptoms. In the former group of cases the predominating lesions will be found to be simple in character and unassociated with any alterations in other valve-systems; in the latter there will be found to predominate those pure and associated valvular lesions that are most prone to give rise to changes in the walls of the heart, and hence cause cardiac symptoms.

Again, if we compare the results obtained under either of the conditions noted with those obtained by post-mortem examinations the difference will be yet more striking. Of course, the results obtained from post-mortem examinations are accurate as regards evidence of organic disease, but such results would not represent the frequency with which cardiac bruits are heard during life, as murmurs, and especially the murmur of mitral incompetency, occur in many cases that at the autopsy fail to present demonstrable lesions.

At the outset, therefore, it is well to understand that this report includes but few cases that presented cardiac symptoms, and that in almost every instance the cardiac lesion was discovered in individuals presumably in the best of health and themselves totally unaware of the existence of any serious disease. For this reason it will be found that the number of cases presenting combined or associated lesions is relatively small, and from this standpoint alone the study of these cases assumes additional interest as emphasizing the well-known fact that cardiac disease may exist for years and the knowledge of his condition not be forced upon the attention of the victim.

In order to present the facts of the report in as clear a manner as possible I have tabulated the cases in such a way as to show the relative frequency of the various valvular lesions, the predisposition of the sexes, the various ages at which the lesions were found, and such history of antecedent disease as it was possible to obtain and to which might be ascribed the existence of the valvular disease. (See table on next page.)

In common with other statistics, the fact is brought out in this analysis that in by far the largest percentage of cases the mitral valve was the seat of the lesion.

Thus we find that there were of cases of—

	Males.	Females.	
Mitral insufficiency	295	262	557
Mitral stenosis	15	17	32
Mitral stenosis and insufficiency combined	13	19	32
The total being			621

or 60.6 per cent. of the entire number of cases under observation.

The percentage of cases showing simple mitral insufficiency is 54.4 per cent., while the lesions of mitral stenosis alone and combined with insufficiency each reached 3.13 per cent.

[1] Read before the College of Physicians of Philadelphia, June 6, 1894.

There were of cases of—

	Males.	Females.	
Aortic stenosis	101	35	136
Aortic insufficiency	32	15	47
Aortic stenosis and insufficiency combined	27	11	38
The total being			221

or 21.58 per cent. of the total number.

Of combined aortic stenosis and insufficiency associated with mitral insufficiency there were 93 cases, or 9.08 per cent. of the cases collated, and of these 65 occurred in males and 28 in females.

Of aortic stenosis associated with mitral insufficiency there were 45 cases, or 4.39 per cent. of the total—31 of these occurred in males and 14 in females; while of aortic insufficiency in association with mitral insufficiency there were 33 cases, or 3.22 per cent.—26 occurring in males and 7 in females.

Insufficiency of the tricuspid valves was met with in 11 cases, or 1.07 per cent. of the whole, 7 being in males and 4 in females.

sponds closely with that found by Duroziez,[1] it is at marked variance with the results obtained by Middleton,[2] who found that women are more liable to these lesions than men, the proportion being three of the former to one of the latter. With Middleton's statistics also agree those of F. J. Smith,[3] which are based upon an analysis of the records of the London Hospital for eleven years, and which show that mitral stenosis, alone and combined with incompetency, occurred in 71 women and 22 men.

To aortic disease we find that the male sex is much more liable than the female; thus, including all cases in which evidence of aortic disease existed, whether associated with mitral disease or not, there were 282 men and 110 women, a proportion the accuracy of which is corroborated by an analysis of F. J. Smith's statistics, which show that 263 cases of aortic disease occurred in men, while in only 105 cases were women the subjects of this lesion.

This difference in the relative liability of the sexes to the various valve-lesions is, I think, readily explained by the fact that mitral lesions usually result

Lesion.	Sex.		Age.																Occupation.		Antecedent history.						Total.	Per cent.

A study of the relative liability of the sexes to cardiac valvular disease, based upon the accompanying table, shows that a considerable majority of the cases occurred in males: thus, 612 men, or 59.77 per cent., were affected, while the disease was found in only 412 women, or 40.23 per cent. of the whole, although the number of each sex examined was about the same.

By lesions of the mitral valve the sexes were almost equally affected, there being in a total of 621 cases but 25 more males than females. In a total of 64 cases in which mitral stenosis, alone or combined with mitral insufficiency, was found, the relationship of the sexes was 28 men to 36 women. While this relative liability of the sexes to these lesions corre-

from a cause to which, taking all ages together both sexes are almost equally liable, viz., rheumatism. On the other hand, as aortic disease occurs most frequently as the result of arterial sclerosis and atheroma, and as men are more frequently the subjects of the causes, such as laborious occupations, syphilis, and alcoholism, which lead to sclerotic changes in the vessels and valves, it follows that they are more predisposed to aortic disease than women.

[2] Lancet, London, October, 1889

[3] Sansom: The Diagnosis of Diseases of the Heart and Thoracic Aorta, 1892, p. 387.

[4] Including 6 cases of chorea.

An analysis of the ages yields a number of interesting results. Up to the sixtieth year of life, the period at which valvular disease of the heart occurs least frequently is between the first and tenth years. After the sixtieth year there is a sudden decline in the number of cases, probably because many have already succumbed to the effects of the disease.

During the first decade of life the sexes show almost an equal predisposition to mitral disease, while during the second decade a considerable majority of cases occur in women. Statistics show that during this period of life acute rheumatism affects the female more frequently than the male, and this observation is confirmed by the fact that we find from the table, that at this age mitral disease occurred in 81 women and 52 men. In the decade between twenty and thirty, however, we enter upon that period of life most prone to endocarditis.[1] At this time, as men by their mode of life and occupations are more predisposed to acute rheumatism than women, and as the mitral valve, as already stated, is the one most frequently affected by rheumatism, the statistics under consideration show that 122 males were affected by mitral disease and only 58 females. In the succeeding two decades, also, the preponderance of instances of mitral disease is with the male rather than with the female, while subsequently the relative positions of the sexes are again reversed.

As would naturally be supposed, but a small proportion of the cases of aortic disease are shown to occur in early life. It is not until after the thirtieth year that the effect of those causes which eventuate in the production of sclerotic changes begins to be evident. Thus, prior to the thirtieth year we find that there were only 105 cases in which the existence of aortic disease was discovered, while after the thirtieth year the number of cases showing aortic disease was 287. Or if, in order to have for comparision two periods of equal duration, we deduct from the latter figure those cases occurring after the sixtieth year, the proportion will be found to be 105 cases from the first to the thirtieth year and 253 cases from the thirty-first to the sixtieth year.

The cases of tricuspid disease noted number 11, the lesion consisting in incompetency of that valve. In every instance the disease was primary and not a relative incompetency depending upon mitral disease. In order that we may understand the reason for the non-occurrence of the latter condition in a single instance, it must be remembered that these statistics include but few cases that presented cardiac symptoms, and it seems hardly possible that mitral disease should progress so far as to produce relative tricuspid incompetency and at the same time cause no rational signs of cardiac disease.

A point of extreme interest in the analysis of these cases of tricuspid disease is the age at which the majority of them were found. In 7 of the 11 cases the age was between the first and the tenth year. In only one of these cases was a personal history of rheumatism obtainable; but in four of them, three males and one female, an hereditary tendency to rheumatism was clearly made out, in one instance upon the paternal, in the other three upon the maternal side. The presumption seems, therefore, justified that, in these cases at least, the lesion was congenital, the result of endocarditis occurring during fetal life, at which time, as is well recognized, the right heart is more prone to suffer from endocarditis than the left.

A result shown by the table that I am unable to explain is the relative infrequency with which pure mitral stenosis, or mitral stenosis combined with incompetency, is found to occur. Guttmann,[1] in stating the relative frequency with which the various valve-lesions are found, places the combined lesion of mitral stenosis and incompetency directly after the lesion of pure mitral incompetency. So also, Middleton's statistics, already quoted, show pure mitral stenosis and mitral stenosis combined with incompetency to occur in almost as many cases as do all the lesions of the aortic valves combined. In this connection, also, Sansom states that the most frequent combined murmurs, restricting the word combined "to murmurs of differing rhythm generated at one orifice," are the presystolic and systolic mitral of stenosis and incompetency; and the table of F. J. Smith, quoted by Sansom, shows this lesion to have occurred in nearly 9 per cent. of the cases analyzed by him, occurring next but one in frequency to the lesion of mitral incompetency. The presystolic murmur of mitral stenosis, uncombined with the systolic murmur of mitral incompetency, is, however, shown by Dr. Smith's tables to have occurred in 3.38 per cent. of his cases—a result which corresponds very closely with that noted in the table upon which the present article is based, where it will be seen that this lesion occurred in 3.13 per cent. of the total number of cases.

Pure aortic stenosis, uncombined or unassociated with other valve-lesions, is found to occur in a much larger proportion of cases than is shown by the table of F. J. Smith, or the statistics adduced by Middleton. In explanation of this variance I must again call attention to the fact that but few of the cases here considered presented cardiac symptoms; hence complex lesions, which are so much more likely

[1] Rosenthal: Real-Encyclopädie der gesammten Heilkunde, 1887, Bd. ix, S. 391.

[1] Real-Encyclopädie der gesammten Heilkunde, 1887, Bd. ix S. 353.

to produce these symptoms, are relatively few in number.

An analysis of the various factors in the antecedent history of the cases to which might be ascribed the causation of the valve-lesions shows that a clear history of rheumatism, or rheumatic pains, was obtained in 383 cases, or 37.40 per cent. of the whole. An antecedent history of the infectious fevers was the only cause that could be adduced to account for the endocarditis in 100 cases, or nearly 10 per cent. of the total. These cases include only those in which one or more of the infectious fevers constituted the sole ascertainable cause to which the disease might be ascribed. In those instances in which a history of the infectious fevers was obtained, in conjunction with a history of the more probable causes of endocarditis, such as rheumatism, alcoholism, or syphilis, the latter were considered as the etiologic factors in the production of the disease.

A history of syphilis, undoubted or obscure, was obtained in 91 cases, or nearly 9 per cent. of the total; and a history of alcoholism in 184 cases, or nearly 18 per cent. of the total. In all the cases in which a history of syphilis or of alcoholism was elicited, decided arterial sclerosis or atheroma was present; and in this connection it may be well to call attention to the large number of cases in which this condition of the bloodvessels was present. In 324 cases, or over 31 per cent. of the whole, disease of the vessels existed, and in many instances arterial sclerosis was the only apparent cause for the valvular lesion.

An interesting fact, to which I would call attention, is the large number of cases for which no cause could be assigned. These number 218, or over 21 per cent. of the whole. In Middleton's cases a history of rheumatism was obtained in over 62 per cent. of the cases, while in over 37 per cent. no rheumatic history could be elicited. That so many cases of chronic valvular disease of the heart should exist without evident cause is remarkable. Many of these cases were found in young individuals whose occupations entailed no overstrain, and from whom, by the closest questioning, no history of rheumatism, or even rheumatic pains, could be obtained. Upon close inquiry into the family history, however, the frequency of the occurrence of rheumatism in either parent was remarked. I think the knowledge to be gained from this fact is the probability of rheumatism producing endocarditis, even when the disease produces no evident disturbance of the functions of the joints; and that, therefore, the endocardium may, in some instances, be the only serous membrane that the rheumatic poison may attack. That this is a rational explanation of the occurrence of endocarditis in this class of cases is, I think, confirmed by the fact that in many of them a family history of rheumatism was obtained, that the age at which the disease was found was in many instances during that period of life most prone to rheumatism, and by the further fact that no other cause for the existence of the disease could be elicited.

In reference to occupation, it will be noticed that most of the cases occurred in those whose occupations were laborious. The statistics were collated from among the working class of people, whose daily work, as a rule, entailed the severest kind of muscular exertion. Laborious occupations favor the development of cardiac valvular disease, for the most part by causing either heart-strain or arterial sclerosis. It is not surprising, therefore, that a history of hard work should have been obtained in such a large proportion of the cases.

In conclusion I would say that all doubtful cases have been excluded from these statistics; that, as far as possible, only cases of chronic valvular disease have been included, and that all cases possessing murmurs of possibly hemic or functional origin have been carefully sifted out.

ELEPHANTIASIS.

By L. L. HILL, M.D.,
of Montgomery, Ala.

In discussing the geographic distribution of elephantiasis, we find the assertion made by some American writers that it is a disease of great rarity in this country. Such statements are misleading, as it is by no means a surgical curiosity among the negro race in this, the so-called "Black Belt" of Alabama.

Elephantiasis is more common in adult life, though it may be congenital. It occurs three times as often among men as among women. Damp, malarious regions and bad hygienic surroundings, common conditions with the negro race here on cotton plantations, are important predisposing influences.

There are different grades of elephantiasis, "from moderate thickening of the skin and subcutaneous tissue up to enormous enlargement, and similarly great variations in aspect exist, according to the papillary hypertrophy or lymphatic and blood-vessel varicosity and their relative proportions," but every grade is the result of occlusion of the lymphatic channels, and it matters not whether involving the trunk or periphery of circulation. The obstruction may be congenital or due to filaria sanguinis hominis, cicatricial contractions, tumors or tuberculous or carcinomatous infiltration, or to an acute infective inflammation.

The result of this obstructive lymphangitis is an

edema, rich in active leukocytes, which, according to Robinson, not only become connective-tissue corpuscles, but also induce a hyperplasia of the fixed cells already present, producing a hardening and thickening of the skin, with general connective-tissue hypertrophy and increased vascularity, but muscular wasting.

The symptomatology of elephantiasis in its commencement varies according to whether the disease is endemic or sporadic, though the ultimate termination, pathologically, is the same. According to Mr. Crocker, of London, the beginning of the endemic presents a similarity to the remittent type of malarial fever, differing, however, in that the fever is of greater severity. The affected parts rapidly increase in size and present an erysipelatous blush, with great tenderness. A milky exudation is often present. Such an attack is usually followed by a calm, which may last for months, when there occurs another outburst, always leaving the part larger than before. In elephantiasis scroti the spermatic cord frequently becomes involved to the extent of dilating the abdominal ring, so that upon the subsidence of the swelling a hernia occurs.

In the East, where the disease is endemic, it is almost invariably the result of a parasitic nematode. The worm was first discovered by Bancroft, of Brisbane, in 1876, and is described by Patrick Manson as "a long, slender, hair-like animal, quite three inches in length, but only $\frac{1}{100}$ inch in breadth, of an opaline appearance, looking as it lies in the tissues like a delicate thread of catgut animated and wriggling. A narrow alimentary canal runs from the simple club-like head to within a short distance of the tail, the remainder of the body being almost entirely occupied by the reproductive organs. The vagina opens about one twenty-fifth of an inch from the head; it is very short and bifurcates into two uterine horns, which, stuffed with embryos in all stages of development, run backward nearly to the tail." The male worm is smaller and not as frequently found. These entozoa are often conveyed from one person to another by mosquitoes sucking blood containing filaria and afterward contaminating drinking-water. Having once gained access to the human stomach, they bore through into the thoracic duct and pass to the lymphatics, where they locate. How they bring about an obstruction resulting in elephantiasis is not very clear, but the most plausible theory and the one generally accepted is Manson's, who says they give off embryos that, if of natural size, $\frac{1}{90}$ inch long and $\frac{1}{3200}$ inch broad, will circulate readily without disturbing the equilibrium of the host, but if prematurely discharged, they are shorter and thicker, $\frac{1}{750}$ inch in diameter by $\frac{1}{300}$ inch in length, and give rise to obstruction in the lymphatics and lymphatic glands.

In this country, where the disease is rarely of parasitic origin, there are no constitutional symptoms, unless of erysipelatous cause, and the development of the disease is always slow. The skin is coarse, darker than natural, and eczematous. Ulceration not infrequently occurs. The decomposition of the elephantoid discharges is very offensive.

In the sporadic cases there is usually loss of sensation, and mendicants with Barbadoes leg take advantage of this fact and stick needles and pins in their limbs to excite sympathy and increase their revenue.

The prognosis, so far as the life of the patient is concerned, is always very favorable, especially in this country, but the patient may be rendered miserable by the immensity of the growth—sometimes weighing more than one hundred pounds.

The treatment of the sporadic cases is very unsatisfactory without surgical interference. During the elephantoid fever of the endemic cases, Sir Joseph Fayrer recommends opium to relieve pain and magnesium sulphate to move the bowels, and a tonic of iron and quinin. Locally, he applies hot fomentations. A change of climate is of paramount importance as soon as the patient's condition will warrant removal.

My clinical experience with this interesting disease is limited to six cases, which I will briefly report:

CASE I.—W. D., a negro laborer, forty years of age, in good health, was sent to me by Dr. C. N. Dorsette, of Montgomery, Ala., in April, 1886, to be operated on for elephantiasis scroti. The enlargement extended a little below the knees, and weighed thirty-one pounds, seriously interfering with locomotion. The disease was confined to the scrotum; neither penis nor legs were involved. Unlike the two interesting cases of scrotal elephantiasis reported by Mr. Hutchinson in his *Archives of Surgery*, my patient gave no history of having had syphilis. In 1870, sixteen years before I saw him, he had gonorrhea, which caused a stricture, complicated with a perineal abscess. When I saw him there were two fistulæ, through which the larger portion of the urine was passed. About eighteen months after the formation of the abscess he gave a history of intense inflammation of the scrotum, which I suspect was a scrotal cellulitis the result of irritation from the fistulæ. After the subsidence of the acute attack the patient suffered no more pain, but noticed that the scrotum did not return to its normal size, but steadily increased.

I advised an operation, to which he readily consented. To render the operation as bloodless as possible, I had the tumor elevated for fifty minutes, and then applied a small rubber cord, tightly drawn, around its pedicle. To prevent slipping I had an

assistant hold it with retractors. I made a circular incision at the neck of the tumor, and as it deepened and reached the cords and testicles I dissected these out, and afterward partially covered them with skin loosened from the thighs. The numerous bloodvessels were ligated with catgut. Before the patient recovered from the anesthesia I dilated his stricture and tied in his bladder a catheter, which served the treble purpose of relieving the stricture, curing the fistulæ (despite the assertion of Sir Henry Thompson, that "tying in an instrument never insures the transit of all the urine through it; some will always escape by the side, and defeat its purpose"), and kept the penis from the granulating surface. In six weeks the patient left the city entirely relieved, and there is at this time no evidence of a return.

It occurs to me that Wyeth's method of controlling hemorrhage in hip-joint amputations might be used in these cases, provided an irreducible hernia is not present.

Case II.—N. T., a negress, forty years old, of Pike Road, Ala., was brought to me by her husband, in June, 1889. She had been married twenty years, but had borne no children. I found elephantiasis of the clitoris, but no other portion of the vulva was involved. The growth measured fourteen inches in circumference at its largest part, and had a pedicle of about half an inch in diameter. The surface was rough, irregular, and ulcerated in several places, but not sensitive to the prick of a needle. The vulva was covered with eczema, which gave rise to intolerable itching. The woman attributed the enlargement to the irritation caused by her scratching, which, she said, had commenced about ten years before I saw her. The patient had tertiary syphilis. I removed the clitoris with an écraseur, and at one point, where there was a tendency to bleed, I applied the Paquelin cautery, which completely controlled the hemorrhage. I placed the woman on antisyphilitic treatment, and used an ointment containing salicylic acid for the eczema. When last seen she reported her health as perfect.

Case III.—W. P., a very muscular negro, twenty-five years old, consulted me on February 5, 1893, concerning an elephantoid prepuce. I found it measuring near the frenum two and one-half inches in diameter, and four-fifths of its circumference involved. On the under surface, about one quarter of an inch behind the affected foreskin, was a cicatrix one-half inch in diameter, the result of a former chancroid, which he gave a history of having contracted twelve months previously. The prepuce soon afterward commenced to increase in size. There was no evidence that the patient had ever had syphilis. He suffered no pain, and had had no erection during the last four months previous to consulting me.

I applied a rubber band around the penis and injected thirty drops of a 4 per cent. solution of cocain just posteriorly to the diseased prepuce, where I made my incision, without pain. The vessels were tied with catgut, and the wound left to heal by granulation, which it did in three weeks. The growth was very hard and an unusually small quantity of the yellowish-white lymph exuded on pressure. The skin was smooth, as is generally the case when the under surface of the prepuce is involved, as it comes in contact with the thighs and scrotum.

According to Jacobson, of London, the statistics of the Calcutta Hospital show that only about 3 per cent. of the cases of elephantiasis commence in the prepuce. These cases were found in negroes, who usually have very long foreskins.

Case IV.—A. R., aged twenty years, white, of Greenville, Ala., was sent to me by the late Dr. Job Thigpen, in March, 1893, to be operated upon for elephantiasis of the penis. The patient stated that he had never been able to draw the prepuce behind the glans, and that the stream of urine had always been very small. About six years before consulting me he had noticed his penis getting larger, and this continued until the organ measured twelve inches in circumference, and was involved for three-fourths of its length. The elephantiasis was evidently due to the congenital stricture of the meatus urinarius and the phimosis.

After placing a rubber band around the root of the penis to control hemorrhage, I made an incision in the whole length of the organ, and extending in depth to the erectile tissue, which was normal, removing all of the diseased tissue. Loosening up the skin freely at the upper end of the wound, I was enabled to get a covering for two-thirds of the organ, and the balance was left to heal by granulation. Fearing an erection, I was careful to have the skin as loose as possible. I directed the man to sleep upon his side, and gave fifteen grains of sodium bromid three times a day for ten days. The patient made a good recovery, and was discharged in about five weeks. He has since married, and says the member gives entire satisfaction. I operated on the stricture by incision while the patient was under the influence of the anesthetic.

Kaufmann states that it is exceedingly rare to see cases in which the penis alone is involved without

the scrotum, this involvement occurring in about 1 per cent. of the cases.

The accompanying photograph gives a good idea of the patient's condition before the operation.

CASES V, VI.—These two cases were under my professional care at the County Almshouse, in 1887. They were both in negro men, and were so similar in their clinical aspect that I report them together.

S. J. was about fifty years old, and in fairly good condition, with the exception of elephantiasis of the whole leg and lower third of the thigh. The former was about double its normal size, and considerably ulcerated. The man stated that the growth had made its appearance about 1865.

F. W. was apparently sixty-five years old, with elephantiasis, involving more particularly the foot, but extending up the leg to within two inches of the knee-joint. Being feeble-minded, he could give no intelligent history of himself.

Neither case showed any evidence of ever having contracted syphilis.

The method of ligating the femoral artery to starve the growth, as was first performed by Dr. Carnochan, of New York, in 1851, has fallen into merited disrepute.

Martin's India-rubber bandage worn constantly renders the patient more comfortable than any other contrivance. In some cases amputation may be justifiable.

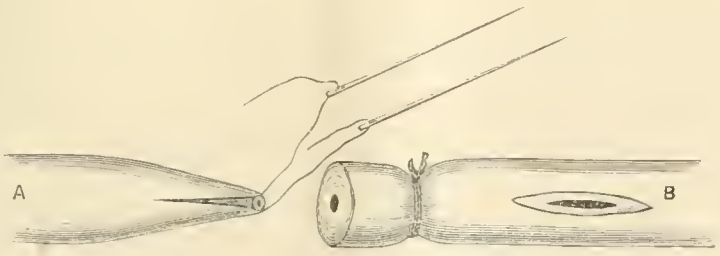
EXPERIMENTAL REUNION OF THE TRANSVERSELY DIVIDED VAS DEFERENS.[1]

BY WELLER VAN HOOK, A.B., M.D.,
PROFESSOR OF SURGICAL PATHOLOGY AND BACTERIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, OF CHICAGO.

AFTER a number of unsuccessful efforts I have found a simple method by which the vas deferens can be reunited after complete transverse division. It may be recalled that I have already succeeded in reuniting the ureter after complete transverse injury, by lateral implantation of the proximal into the distal fragment through a slit in the wall of the latter portion of the duct.[1] This method has been successfully employed in the human subject by Dr. Howard A. Kelly, of Baltimore, in a case in which the ureter was severed unintentionally during an operation for the removal of a large myoma uteri. In the report of the case[2] the operation is termed uretero-ureterostomy or uretero-ureteral anastomosis. The term lateral implantation seems to me preferable.

Experiment, January 15th, 1894. A very large Newfoundland dog was laid upon his back in a trough, and the skin over the scrotum and base of the penis shaved and carefully disinfected. Under ether-anesthesia an incision three-quarters of an inch long was made over the left spermatic cord just below the inguinal ring. The vas deferens was easily drawn through an opening made in the fascia and pulled out through the skin-wound. The duct was then divided transversely with scissors, and retraction of the cut ends prevented by forceps. A tight ligature was applied, one-fourth of an inch from the end of the upper fragment, and, with a very fine, sharp-pointed scissors, a longitudinal incision was made in the wall of this portion of the duct at a point one-fourth of an inch above the ligature. This incision penetrated to the lumen of the tube and extended upward a distance of one third of an inch. Next the distal fragment of the duct was prepared for implantation into the slit in the upper portion. The lumen of the vas deferens is small, in comparision with the diameter of the entire duct, as its walls are composed of dense and thick muscular layers. Hence, in order to enable the lower end to be drawn into the slit in the upper portion of the tube, the muscular walls had to be trimmed off to a tapering point, exactly as one would sharpen a leadpencil. This having been accomplished by the careful use of fine scissors, an incision one-eighth of an inch long was made in the sharpened end of the tube simply to insure a patent opening.

FIG. 1.



A. Testicular extremity of divided vas deferens. B. Proximal extremity. The distal portion, A, has been "sharpened," the opening has been enlarged by a longitudinal slit and the traction-suture has been introduced. The proximal fragment, B, has been ligated and a slit made in the side.

Two fine needles, armed with a single thread, were then passed from within outward through the wall of this portion of the vas deferens, thus securing it in the grasp of a loop of thread. The needles

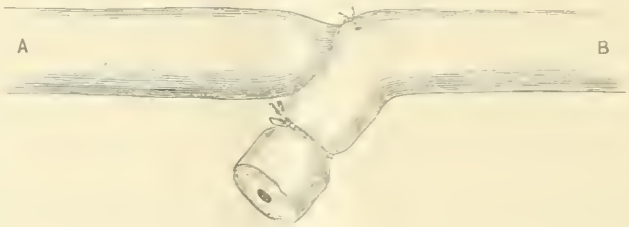
FIG. 2.

The needles of the traction-suture in the act of being passed through the wall of the proximal fragment from within outward.

FIG. 3.



The distal fragment has been drawn into the proximal segment by means of the traction-suture, which has been tied.

were then passed into the slit in the upper part of the duct, and their points being carried carefully upward within the tube for one-half an inch, the needles were pushed through the wall from within outward, emerging, of course, side by side. It is now easy to see that the *sharpened* lower fragment could be drawn into the upper fragment by the traction-suture. This being accomplished, the ends of the suture were tied together, and, the vas deferens being carefully returned, the wound was closed.

The autopsy upon this dog (killed with chloroform six weeks later) showed (1) a normal testicle upon the side subjected to experiment; (2) no accumulation of testicular secretion below the site of operation; (3) perfect patency of the duct at the point of reunion, as shown by the passage of a small probe; (4) complete continuity of the mucosa throughout; (5) firm union of the muscular walls, with a minimum of scar-tissue.

This simple means of reuniting the vas deferens after transverse injury commends itself, especially in the human subject, as the vas deferens in man is large enough to be fairly easy of manipulation, and it is long enough to admit of considerable shortening without detriment.

As to opportunities for the application of the method, one easily thinks of the possible, although of course rare, wounds due to missiles and cutting instruments; of wounds accidentally inflicted during surgical operations, especially in herniotomies and the open operation for varicocele, and of operations in which it might be desirable to remove a portion of this duct, as in tumors of the cord and, probably more frequently, in cicatricial contractions involving the vas deferens or in accidental and at first unrecognized ligations made during the subcutaneous operation for varicocele.

103 STATE STREET.

CLINICAL MEMORANDA.

SARCOMA OF THE NOSE—EPITHELIOMA OF THE LARYNX IN A WOMAN.[1]

BY HORACE CLARK, M.D.,
OF BUFFALO, N. Y.

THE cases that I have to report are:

1. A case of sarcoma of the nose, defined as a mixed sarcoma, containing melanotic pigment, and

2. A case of epithelioma of the larynx in a woman.

The sarcoma occurred in a woman, seventy-nine years old, whose family history is entirely negative. She has never had any serious illness, and is the mother of a large family. I saw the patient for the first time on October 23, 1893, and made the following memoranda:

About a year and a half ago a peculiar sensation was noticed in the nose. Six months later, during the course of an acute coryza, inability to breathe easily was referred especially to the left nostril. The finger came at once upon a lump, of the size of a small cherry, which was hard, scarcely sensitive, and bled when touched. From this time on, the lump rapidly increased in size and filled out like a little bladder, causing deformity of the ala. Three weeks previous to the date of this note there had been profuse nose-bleed in consequence of a fall. During a period corresponding with the patient's observation of the tumor the eye on this side had readily inflamed, and the lid had been puffy at times. There was an entire absence of pain, but a fulness in the head had been noticed all along.

Upon examination, the left nostril was found to be occluded just within the entrance by a round, bluish-gray mass, showing a superficial loss of tissue equal to about one quarter of the size of the presenting surface. With a probe, this mass was found to be hard, slightly movable, and apparently attached to the inferior turbinated body. It was immersed in a sero-sanguinolent fluid and bled readily.

Posterior rhinoscopy, not being readily practised, was

[1] Cases reported to the Section on Laryngology and Rhinology, New York Academy of Medicine, December 27, 1893.

not persisted in, because the patient had already been subjected to somewhat harsh examination at other hands.

A probable diagnosis of sarcoma was made.

That portion of the growth which presented was removed with the platinum wire. A dull-red heat was turned on until the wire had thoroughly caught. The cautery-loop was then used alternately as a hot and cold snare. The premaxillary fossa was curetted and such parts of the inferior turbinated body as were involved were removed with the cold snare and curet. Except for the larger portions, the curet worked best, for the tumor was very friable. There was very little bleeding at the time of the operation; nor had any occurred five hours later when a dressing was applied.

I had the opportunity of watching the case for six weeks. There is little question but recurrence will take place pretty rapidly.[1] It is worth noting that there was a suspicious-looking area upon the cartilaginous septum in the other nostril, which passed for a simple erosion.

Dr. Elmer Starr, of Buffalo, kindly had this case referred to me.

Epithelioma of the larynx was the diagnosis made in the case of a woman, thirty-eight years old, whom I saw in October, 1893. The notes upon the case in general were supplied by the family physician, Dr. Wilcox, for whom the operation was performed. They are essentially as follows:

The patient's father died of carcinoma. She herself did not present the marked cachexia of this disease. There had never been nausea or vomiting. Curetting had been done for hyperplastic endometritis, but no microscopic examination was made of the scrapings.

My own information relates to difficult swallowing, first noticed in February, 1893, but not until July did this become distressing. Food had often been refused after the latter date, never because of pain, but from inability to complete the act of swallowing. Also, since July, small quantities of yellowish matter had been evacuated by the mouth.

I shall not enter upon the details of the examination further than to say that the growth was found to be attached to the ary-epiglottic ligament on the left side, upon its extra-laryngeal surface, and did not rise above the level of that ligament. With inspiration the larynx presented the appearance of a recurrent paralysis. The bands came together in the median line in phonation, and the growth was carried in that direction. Aside from a general pallor the interior of the larynx presented nothing remarkable. Upon the neck there was a swelling which looked and felt very much like a bronchocele.

It was hoped that the evulsion of as much of the new growth as could be seen would make deglutition easier by giving freer movement to the larynx. The only result from operation was the substitution of a normal for a distorted position. The swelling in the neck had entirely disappeared on the following day. A constriction had probably been removed from the principal outlet for an extensive purulent infiltration of the bronchial glands and surrounding parts. The temperature was normal.

[1] On March 7th, a report from the case states that plugging is necessary to prevent hemorrhage. The tumor has extended into the face, which, with the nose, is enlarged a good deal.

There is nothing of interest in the subsequent care of the case, which was assumed by the family physician.

The autopsy, made ten days after the operation, revealed stenosis of the esophagus, due to an epithelioma extending some four inches downward from the level already mentioned at which the tumor appeared above. There were also two or three carcinomatous nodules upon the wall of the pharynx, showing that metastatic formation must have been very rapid.

The diagnosis in both cases was verified by Dr. Krauss, of Buffalo, whom I also have to thank for some beautifully stained sections from the growths.

Report of the microscopic examination by Dr. William C. Krauss, Professor of Pathology in the Medical Department of Niagara University, Buffalo, N. Y.:

Sarcoma. The tumor, composed of three separate pieces, was delivered to me by Dr. Clark, immersed in a 50 per cent. alcoholic solution, on October 24, 1893. The largest of these masses was as large as a chestnut, the other pieces the size of a bean. The largest piece was covered with a dense fibrous coat, except at its cut surface, and here it appeared mottled, pigmented, somewhat resembling the color of a bronchial gland. Its consistency was soft, friable, and highly vascularized.

Preliminary examination. Several small particles were taken from the large mass, carefully teased, and mounted temporarily in glycerin. Under a one-fifth-inch objective the mass appeared cellular, the bulk of the cells being of the small-spindle variety. Alongside of these spindle-cells were other cells, some resembling small, round cells, others round pigment-cells of a blackish-brown color. As these three varieties of cells composed the bulk of the tumor, I made the diagnosis of mixed sarcoma, probably melanotic.

The particles of tumor-tissue were further hardened in alcohol, imbedded in celloidin, and sections cut with a Schanze microtome. These were stained with picro-carmin and ammonio-carmin, cleared in clove-oil, and mounted in balsam. Examined with a one-fifth-inch objective the cellular structure appeared no less prominent than at the first examination. The spindle-cells, however, did not present the same general outline, because of their grouping and the necessary transverse sectioning through them. The pigment-cells appeared as in the fresh examination, in some sections exceedingly numerous, in others less so. Considerable connective tissue was present, forming a stroma for the support of the cells. The diagnosis made at the preliminary examination was thus further corroborated by the final examination.

Epithelioma. The tumor, composed of seven or eight irregularly shaped masses, was delivered to me, immersed in a 50 per cent. alcoholic solution, on October 21, 1893. In size these separate particles ranged from a chestnut to a small pea. The color was pinkish-red; the consistency soft, compressible. The macroscopic appearance resembled a highly cellular, vascularized tissue.

Preliminary examination. As an immediate examination and diagnosis were demanded, several minute particles were cut from different masses, carefully teased, and then, unstained, mounted temporarily in a normal salt-solution. The tissue was composed entirely of cellular elements, the connective-tissue stroma being sparsely present. The cells were of the flattened,

squamous variety, nucleated and closely packed together. The epithelial pearls were not well marked, and were small. After examining several slides, and finding the same general characteristics, I made the diagnosis of carcinoma, of the flat-celled variety, or, as these are commonly designated, epithelioma.

With a view of making permanent mounts, the tumor-particles were hardened by the alcohol method, imbedded in celloidin, and sections cut with a Schanze microtome. These were stained with ammonio-carmin and picro-carmin, and mounted in balsam. Examined with a Zeiss C objective, the same general characteristics were found that were present at the first examination. The nucleated squamous cells comprised the bulk of the tumor. Occasionally small aggregations of cells arranged concentrically (epithelial pearls) were found, but were not sharply defined. The first diagnosis was unchanged by this examination, the same features being present in both.

My opinion, then, is that the tumor in question must be an epithelioma, the diagnosis being subsequently fortified by the death of the patient.

A CASE OF ACUTE DELIRIUM, WITH AUTOPSY AND BACTERIOLOGIC EXAMINATION OF CEREBRO-SPINAL FLUID.[1]

BY CHARLES S. POTTS, M.D.,
OF PHILADELPHIA,
INSTRUCTOR IN NERVOUS DISEASES IN THE UNIVERSITY OF PENNSYLVANIA, ASSISTANT NEUROLOGIST TO THE UNIVERSITY HOSPITAL.

A DISEASE in which the symptoms are so severe, and the pathologic findings so meager, as is the case with acute delirium, would certainly seem to be due to a violent toxemia of some sort, and should, therefore, be a fruitful field for the bacteriologist.

Bacteriologic investigations in cases of this condition have, however, not been frequent, as, after a hurried search through the literature of the past few years, I have been able to find only one case, that reported by Dr. Carlo Rasori in the *Centralblatt für Bakteriologie und Parasitenkunde*, of October 20, 1893, and who isolated what he describes as small bacilli with rounded ends, three times as long as wide, which appeared generally separate, but were also seen in groups of two or three joined together by their ends. At times a few longer ones, both straight and curved, were seen, which did not take the stain so well. The germs stained darker at their ends than at the center. In a great many ways this description answers to that of the pneumonia-coccus, but Rasori evidently thinks he has found a new germ, whether correctly or not time will determine. As so little work has been done in this direction, the report of the following case of acute delirium may not be without interest.

A. G., thirty-three years old, a member of the medical profession, had, so far as I know, always enjoyed good health. He was, however, of a sensitive nature, and at times subject to fits of depression. His habits were good, excepting during periods of illness, when he took whiskey in excess. There was no history of syphilis. Just previous to the commencement of his last illness he had had considerable family trouble, and he was evidently under a severe mental strain. He first began to complain in the early part of June, when he was attacked with urticaria, which lasted until August, and did not improve under any plan of medication. During this period also he complained at times of lassitude and feelings of chilliness. In the early part of August a carbuncle made its appearance upon his upper lip, which was operated upon by Dr. J. B. Deaver about ten days later, and after which he appeared to be in good spirits, his temperature being normal and his appetite good, even ravenous. After being opened and curetted, the carbuncle healed rapidly, and everything appeared to be doing well until nine days later, when the patient became suddenly highly delirious at about 10 P.M., attempting to jump out of the windows, saying that the people in the house, who were Catholics, wanted to murder him because he was a Protestant.

Drs. J. F. Berlet and Klemm were summoned, and they naturally attributed his condition to the large quantities of whiskey (about one pint daily) and morphin, which he had been taking from the time of the appearance of the carbuncle until a few days before he came under their care. Bromids and chloral were administered, and the next morning the man appeared perfectly rational. In the afternoon he again became highly delirious, ran to the window, screaming "murder," and endeavored to jump out; he said "devils were chasing" him, etc. His nurse reported that during the previous morning he had had several irrational intervals, of which he seemed to be aware, as he inquired if he was going crazy, and told them not to tell Dr. Berlet, as he would think he was crazy.

On the same evening, August 23d, I saw him in consultation with Drs. Berlet and Klemm. As I entered the house I could hear the shouts of the patient; as I came into his room he recognized me and inquired after some members of my family whom he knew were ill, but he immediately entered upon a long harangue about going to Europe to study singing, that he was the finest tenor in the world, etc., and then abruptly asked my protection, as the people in the house wanted to kill him. He would take no medicine or nourishment unless I first tasted it, as he said they wanted to poison him. His temperature was then normal. Hyoscin was administered, and he slept several hours, but awoke in the same delirious condition. He continued in this state, his temperature being normal, until the evening of August 24th, when it was 101° F. The delirium became more violent, and it was necessary to restrain him mechanically. He saw "devils" and had other hallucinations, but he still recognized those about him, and when his housekeeper entered the room he tried to choke her, as she was one of those whom he thought wanted to kill him. He would ask for the vessel when he wished to urinate, and took his nourishment when assured by myself or Dr. Berlet that it contained no poison. On the next day, August 25th, Dr. C. K. Mills was called in consultation, and concurred in the diagnosis of acute delirium. At the time of his visit the rectal temperature was 104.1° F., the delirium still continuing, except for short intervals when the man was under the influence of hyoscin. The temperature gradually rose in spite of repeated antipyretic measures until 12.45 A. M., when it was 106° F.; at 4 A.M, it was 104.2° F. When I saw him, about 11 A. M. on August 26th, he did not recognize me, and refused his nourishment, but was still violently delirious, singing one minute and shrieking for protection the

[1] Read before the Phila. Neurological Society, Feb. 26, 1894.

next. His temperature continually rose, and at 5.30 P.M. it was 107.1°, being reduced to 105.2° by sponging; at 8.45 it was 108.2°. His breathing became irregular and of Cheyne-Stokes type; his pulse weak and rapid; the delirium gradually gave place to coma, and at about 11 P. M., he died. At no time during his illness did he complain of headache.

The autopsy was made by Dr. J. W. McConnell about seventeen hours after death, in the presence of Drs. Berlet, Klemm, Mills and myself. The brain and meninges appeared to be normal, as did all the other organs of the body. Some of the cerebro-spinal fluid that had drained into the base of the skull was collected in a small bottle previously sterilized with boiling water, and from this cultures were made by Dr. D. Braden Kyle, with the result that the presence of a bacillus answering to the description of the so-called micrococcus lanceolatus, or pneumonia-coccus of Frænkel and Weichselbaum, was demonstrated. The staphylococcus pyogenes aureus and the staphylococcus pyogenes albus were also present.

Microscopic examination of the cerebral cortex showed the appearances described by Osler,[1] *i. e.*, perivascular dilatation and leukocytes in the lymph-sheaths and perigangliar spaces.

The possibility of contamination by the instruments used to make the autopsy may be urged, and has occurred to me, as it must be admitted that they had not been sterilized, but if this were the case why is it that only the two forms of bacteria named were present and not others that would much more likely have been present, in fact should, of necessity, have been present. It seems to me probable that if this patient had lived longer the signs of meningitis or meningo-encephalitis would have been present. It will be noted that the germs isolated in this case were the same as have been usually found in the exudate in cases of meningitis.

I would therefore advance as a possible explanation of the lack of macroscopic findings, in spite of the violent symptoms present in the condition of acute delirium, that the toxemia is so violent that the patient usually dies before appearances visible to the naked eye have had time to develop.

In reporting this case I do not claim that we have settled the causation of acute delirium, but I think it probable that in association with future investigations it may have some value.

FLEETING HEMIANOPSIA OF SYPHILITIC ORIGIN.

BY E. J. BERNSTEIN, M.D.,
OF BALTIMORE, MD.

W. C. N., thirty years old, a real-estate broker, came to me August 27, 1892, complaining of inability to read or write after a few hours' exertion. He presented slight marginal blepharitis, which had persisted, more or less constantly, from childhood. The eyelashes were sparse, those remaining being short and stubby. The lids were not stuck together in the morning. The tear-ducts and the rest of the lachrymal appendages were normal.

Reading at night had been uncomfortable for five years, but the asthenopia (?) had been much worse for three weeks.

[1] Practice of Medicine, p. 925.

V., R. E., 6/6? Sn. 0.5 from 18–33 cm.
V., L. E., 6/6? Sn. 0.5 from 12–27 cm.

There was no vertical hyperphoria, but there was an exophoria of 1° in each eye. Distant vision:

R. E., + 0.50 D., cyl., axis vertical, 6/6 full.
L. E., — 0.75 D., cyl., axis vertical, 6/6 full.

I ordered simple cylinders in accordance with this finding. On September 21st the man returned, saying that while vision lasted he could see better with the lenses than without them, but after working till 11 A.M. his vision became worthless, and he could only see to get about by closing one eye and tilting his head to one side. He had also discovered that if he could cast his eyes down and hold a book above their level he could still distinguish large letters. It was only then that I suspected more profound trouble.

Accordingly, the field of vision was taken, when it was found that he could only distinguish large, bright objects in the entire superior portion of each field, while the inferior portion was still normal, so that the scotomata covered a part corresponding to a line drawn 15° *above* the horizontal diameter on the nasal over the whole superior field to within about 15° *below* the horizontal on the temporal.

As I could not complete my examination at this visit, I requested him to come again early the following morning, when I found the field of vision normal in both eyes. The color-sense was found to be good on both occasions.

The patient then told me again that this was the usual course, viz., that he saw well until about 11 A.M., when his sight "gave out."

On further examination I found numerous enlarged glands in the cervical region and above the elbows, and also several large, characteristic syphilitic scars on different parts of the body. The patient then acknowledged having contracted syphilis in November, 1890, for which he had been actively treated and had been told that he was cured.

He smoked some twelve cigars and drank three or four glasses of whiskey daily.

I examined him at various times, and always found the same condition, that is, early in the morning both fields were normal, but after a few hours' work the scotomata made their appearance, the field being preserved in the lower nasal portion, but the unnatural position of the eyes necessary to see with this portion of the field prevented further work.

The ophthalmoscope showed perfectly normal fundi. The retinal veins seemed more engorged and tortuous in the temporal portions of the fundi in the latter part of the day than in the morning. As the patient was considerably run down in health and the weather was very warm, I deferred the use of mercury and ordered syrupus ferri iodidi in large doses and rest in the mountains, with abstinence from all attempts at reading or writing. On October 15th the patient returned, much improved in health and sight. The field of vision had increased so much that the temporal scotomata were only as large as the previously nasal good portion, and would not be thus complete till afternoon. As it was now quite cool, I instituted mercurial inunctions according to the plan of Finger, of Vienna.

By December 1st the man had taken thirty inunctions, and the syrup of the iodid of iron was again given. From this time on his sight improved steadily until he was able to read almost all day, although compelled to rest at night. During January, 1893, the patient took neither mercury nor iodid.

By February 1st vision was normal. The man was again given mercury (not on account of vision, but to combat the old syphilis), which he took for thirty days. Then he took potassium iodid in large doses for thirty days; followed by a rest of like period; and then going on with the treatment according to the plan of Finger.

The point of interest to me was the peculiar recurrence of the scotomata and the portion of the visual field affected.

800 MADISON AVENUE.

MEDICAL PROGRESS.

Myotonia Congenita.—SÜSSKAND (*Zeitschrift für klinische Medicin*, B. xxv, H. 1, 2, p. 91) reports a case of the affection known as myotonia congenita, or Thomsen's disease, and formulates the conclusion that the disorder is a congenital functional abnormality of the voluntary muscular system, consisting in an undue muscular irritability. This manifests itself in that an extra effort of the will is necessary to overcome the tetanus induced in innervated muscles, and which subsides but slowly. The first movement is easily possible; the second, antagonistic movement, only after the cessation of the tetanic condition. If the volitional impulse is affected by a psychic influence (such as a sudden and unexpected command), the conception of the antagonistic movement is aroused and the antagonists are also made tetanic, so that no movement at all is possible. A sudden, unexpected stimulation, psychic or somatic, is capable of setting all muscles into a condition of tetanus (reflex tetanus), so that the patient may be caused to fall. The derangement of function depends upon an increase in number, a diminution in size, and a condensation of the muscular elements within the primitive fibrillæ, together with loss of cohesion among the individual fibrillæ themselves. In the increase in number and diminution in size of the muscular elements resides the cause of the greater susceptibility and irritability of the muscles, whether there be an increased area of contractile surface or a change in the transverse section of the muscle-elements, resulting in turn in a greater difference in the tension of the contained electric force.

A Premonitory Symptom of Pulmonary Tuberculosis.—DESTRÉE (*Wiener medizin. Presse*, 1894, No. 14, p. 593) has observed that in the course of pulmonary tuberculosis the pupil upon the affected side may be dilated without appreciable cause, if only one lung be affected; or either pupil, if both lungs are involved. The manifestation acquires diagnostic significance from its absence in apical pneumonia and chronic bronchitis, with emphysema, though it may be observed in the sequence of attacks of pleurisy. Experiments upon dogs and rabbits showed that inequality of the pupils could be induced by irritation of the dorsal sympathetic nerve. Mechanical or electric irritation of the sympathetic plexus in the neighborhood of the hilus of the lung was followed by dilatation of the pupil on the irritated side, the irritation being transmitted through the first thoracic and last cervical ganglia to the ophthalmic ganglion. An interesting substantiation of these observations is found in the results of post-mortem examinations, which show that in the course of pulmonary tuberculosis the fibers of the pulmonary plexus of the sympathetic nervous system may be subjected to mechanical irritation from the presence of enlarged bronchial glands. As these glands sometimes undergo enlargement before the pulmonary structures are invaded by the tuberculous process, inequality of the pupils may prove to be an important diagnostic sign.

The Radical Cure of Fistula in Ano.—GOELET (*American Medico-Surgical Bulletin*, June 1, 1894) describes an improved operation for fistula in ano which does away with the usual, troublesome, after-treatment in these cases, by securing primary union, and affords complete retentive power, even if there are two fistulæ, and the sphincters must be divided in two places. This result is obtained by carefully uniting the raw surfaces by means of sutures, introducing first continuous buried catgut sutures for the deeper structures, including the muscles, and separate, interrupted sutures of chromicized gut for the mucous membrane and perineum. Emphasis is placed upon the importance of previous divulsion of the sphincter, strict asepsis, thorough curettage of all fistulous tracks, the use of buried sutures for uniting the deeper structures, and separate superficial sutures for the mucous membrane only, with inactivity of the bowels, for five days following the operation.

In favor of this method of suturing, as against the introduction of sutures through the mucous membrane of the rectum, to include the deeper structures, is the avoidance of the danger of infection by leakage along the track of the suture, as well as obstruction to the circulation, and consequent edema that would interfere with primary union.

THERAPEUTIC NOTES.

For Nocturnal Enuresis, MACALISTER (*Practitioner*, vol. lii, No. 5, p. 331) recommends the administration of atropin to the point of tolerance, in conjunction with medicinal doses of strychnin. Thus, he begins with gr. $\frac{1}{100}$ of atropin at night, and gradually increases the dose every third night to gr. $\frac{1}{10}$ and more. When conditions requiring surgical interference are present these receive attention. It is further directed that no drink be taken after 6 P.M., that the medicine be taken at 9 P.M., and that after emptying the bladder the child should go to bed at 10, and that it should be awakened to urinate at 12 and again at 6 A.M.

Philadelphia.

SATURDAY, JUNE 30, 1894.

THE URINE OF WHOOPING-COUGH.

Although whooping-cough is one of the most familiar diseases and one of the most universally distributed, its etiology is yet undetermined, unless the observations of Ritter (see The News, January 28, 1893, p. 104) shall receive confirmation. This observer found in the bronchial secretions of cases of whooping-cough a diplococcus which he believed to be specific, and by the inoculation of which upon the air-passages of a tracheotomized dog he induced cough and fatal broncho-pneumonia. Independently of this evidence there is strong reason to believe that whooping-cough is an infectious disease, dependent upon some cause, of animal or vegetable origin, capable of indefinite multiplication in the body of its host. The strongest collateral evidence in support of this view is the transmissibility of the disease. Upon the basis of this assumption it is reasonable to go a step further and ascribe the symptoms of the disease primarily to a local action of the causative agent at its seat of lodgment in the air-passages, and secondarily to an influence exerted upon the nervous system by toxic matters generated as a result of the presence and activity of the invading parasite. This hypothesis would afford an explanation of the characteristic catarrhal and spasmodic symptoms of the disease. In the absence of a demonstrable pathology, we are without adequate data for a scientific therapeusis, so that the methods of treatment in vogue are largely, if not entirely, empiric.

The semeiology of whooping-cough has been fairly fully written, but a recent study of the urine in forty cases of the disease by a Russian observer, Blumenthal, of Moscow, and a report of which appears in the *St. Petersburger medicinische Wochenschrift*, 1894, No. 17, p. 155, has developed a number of interesting facts. The cases occurred in children of varying age, and were observed in private practice and at all stages of the disease. The examinations were made mostly with the morning urine alone, but in a few instances with the total twenty-four-hours' secretion. Briefly stated, it was found that the urine was characterized by a pale-yellow color, a strongly acid reaction, a notably high specific gravity (from 1022 to 1032 and higher) and the deposit of a yellowish sediment of varying amount soon after having been passed. This sediment, on microscopic examination, was found to consist of uric acid; occasionally, amorphous urates were also present. Neither calcium oxalate nor albumin was found. Some specimens exerted a reducing action upon Fehling's solution of copper and with Nylander's modification of Boettger's bismuth-test, but it was not believed that this was due to the presence of glucose. It was thought possible that this reaction might be due to the excess of uric acid present or of combinations of glycuronic acid. Some of the specimens had further an excessive levo-rotatory action, which was also perhaps due to glycuronic acid. The assumption of an excess of uric acid, based upon the specific gravity and the deposition of a sediment, was verified by quantitative analysis.

An interesting fact developed by comparative observations, and which may prove to have practical value from a diagnostic standpoint, at least, was that the peculiar pale-yellow color, the increase in specific gravity, and the excess of urates were evident in the catarrhal stage of the disease, before the paroxysmal cough had made its appearance. These variations appeared to be entirely independent of the pyrexia, and were appreciably modified by the administration of quinin and antipyrin, the specific gravity being lower, the uric acid not being in excess, and the pale and acid urine becoming turbid and alkaline. A milk-diet and febrile complications, especially pneumonia, brought about a

similar result. The opinion is expressed that the changes in the urine, and in particular the increased elimination of uric acid, are due to an abnormal leukocytosis, which makes its appearance early in the course of the disease, but this conclusion was not substantiated by examination of the blood.

These observations require extension and confirmation in order to yield practical and applicable results. They point out the possibility of diagnosis early or in doubtful cases, perhaps before the characteristic cough and whoop have made their appearance, and they suggest that under certain conditions, such as the administration of quinin and of antipyrin, and when certain complications are present, a neutralizing influence is exerted upon the products of the primary disease.

EDITORIAL COMMENTS.

The Formation of a New Epiglottis.—DR. W. S. HUSELTON, of Allegheny Pa., in the *Pittsburg Medical Review*, for May, 1894, describes a most remarkable formation of a new epiglottis after entire destruction of the original organ. His account is as follows:

"The original epiglottis was severed from its connection with the larynx and at once turned upward, where it quietly reposed—obstinately refusing to take any interest or part in the acts of respiration or deglutition. This left the opening into the larynx uncovered and open, and when the patient swallowed drink or food it was simply chance whether it entered the stomach or lungs or both. The manner in which Nature met and overcame this difficulty is perhaps the most interesting as well as remarkable feature of the case, and the one most worthy of note and report. It was not possible for a surgeon to make, in whole or in part, a substitute for the useless epiglottis. There was no material in front of the larynx from which it could be made; it was not possible to operate behind the larynx. Where was this necessary *valve* to come from? I did not know. Nature's resources, however, were not exhausted. In a short time a new formation was seen to be growing from behind the partially reconstructed larynx. Gradually it increased in size, and shaping itself somewhat like the normal epiglottis, soon began to demonstrate that it had a purpose, and that was to take the place of, or to perform the function of the normal, but useless, epiglottis. As I stated, this new formation grew from behind the larynx, consequently when in the act of swallowing, it, in order to close the glottis, had to move *forward* and downward, whereas, as you know, the normal epiglottis in performing this function moves *backward* and downward, thus completely reversing the natural movement. It completely closed the glottis, and he swallows with but little difficulty."

One rises from the perusal of such a report as this with a sense of profound reverence for the wisdom and ingenuity silently working within cellular and organic structures. In a final analysis, of course, the re-creation of a new organ (after destruction of the original one) is but little more wonderful than the first formation in the embryonic structure. The specialization of function, however, always lessens the plasticity of the material, and renders more striking the intelligence that lives in and utilizes living tissues as instruments of purpose.

The Work of the American Medical Association at San Francisco—On the whole the American Medical Association is to be congratulated on the outcome of the meeting at San Francisco. The report of the majority of the Revision Committee both as to the Constitution and the Code was overwhelmingly defeated, and while the Association refused to adopt an amendment to the report of the Trustees disapproving their conduct in the matter of the advertisement of nostrums, it also refused to table a resolution directly bearing on the subject and referred the matter to the Judicial Council. With the Judicial Council therefore the responsibility now rests. While we are not yet informed of the decision of the Council, we are glad to know that they excluded an attempt to drag personalities into the discussion. We trust that the Code-question will now be allowed to drop. The sentiment of the State societies and of the Association's members in general is against revision and against agitation. There is nothing useful to be accomplished by further discussion. The question of the conduct of the *Journal* is not yet decided, and it will depend upon the course pursued by the Editor and Trustees during the coming year, whether or not that subject will again be heard of at Baltimore. For the present, discussion may well be suspended.

Anglicise Titles of Articles.—What nonsense to use Latin titles when addressing an audience, of whom all know English and few know Latin. What an absurdity to Latinize the names of diseases, etc., and write about them in English. What barbarism to make part of the title in Latin and the rest in English. If the Latinization of titles, etc., is worth anything, it is of value only if carried out by all writers, so that readers who do not understand English, and who, perhaps, do understand Latin, may in the catalogues see that a paper has been written on a certain subject. But, will it help him much? Will it help him to see *Otitis media suppurativa chronica*, instead of *Chronic suppurative otitis of the middle ear?* If so, will not his satisfaction be marred by the rest of the title, *Removal of the malleus, intermittent fever, recovery*, in the non-understood English? And then, how about the one hundred or two hundred thousand English and American physicians who do not know Latin?

Why not sometime make an end of sloughing the useless remains of the old medieval Latin snake-skin?

Medical Fees in France.—It is related that a well-known French physician sued a notary, whose wife he had treated, to recover an honorarium of 1500 francs. The lawyer, who had already tendered 700 francs, pleaded that this sum was sufficient. Having heard the advocates on both sides, the civil tribunal delivered judgment, basing its decision on the following grounds: As in a question of medical fees the points to be regarded are the pecuniary situation of the patient and the repute which the physician may have acquired through his labors and his discoveries; and considering in the present case the position of the patient's husband and

the medical eminence of the physician, the sum demanded is not excessive. The tribunal accordingly condemned the attorney to pay the fee of 1500 francs in full.

REVIEWS.

ANTISEPTIC THERAPEUTICS. By E. TROUESSART, M.D. Translated by E. P. HURD, M.D. The Physician's Leisure Library. 2 vols., pp. 316. Detroit: Geo. S. Davis, 1893.

IN the introduction to this work therapeutic agents are divided into three great classes: (1) eusthetic medicaments, or such as act directly on the organism, modifying altered function in such a manner as to favor a return to the normal; in this class are included the alkaloids; (2) hypnotics, or medicaments designed to prevent the constitutional effects resulting from organic alterations; (3) antiseptics, or medicaments which do not act on the organism itself, but upon noxious products of the bodily metabolism or of agents introduced from without. Even if anything were to be gained by such a classification, we are not sure that this one is better than the established one, according to which drugs are used from a prophylactic, curative, or palliative point of view, while, of course, no such classification can be rigidly and arbitrarily adhered to. The body of the book is divided into three parts, the first of which deals with groups of antiseptics from a chemic, pharmaceutic, and physiologic standpoint; the second discusses the clinical applications of antiseptics, the various systems of organs and the affections to which they are liable being considered serially; the third part deals with the antisepsis of hygiene, particularly the hygiene of the sick. The work contains considerable interesting information and should prove useful to those for whom it is intended. The text suffers a little in the translation, which has a tendency to be literal.

STUDIES FROM THE DEPARTMENT OF PATHOLOGY OF THE COLLEGE OF PHYSICIANS, COLUMBIA COLLEGE, N. Y. Vol. III. For the Collegiate Year 1892–1893.

THIS brochure contains reprints of the more important studies published by the workers in the department of pathology in various journals during the collegiate year 1892–1893, and is a praiseworthy exhibition of practical and scientific work accomplished, reflecting credit upon both the director of the deparment, Dr. Prudden, and the individual workers. This collection is the third of its kind, and contains the following papers: "On the Importance of Vibration to Cell-life," by S. J. Meltzer; "Diphtheria and Other Pseudo-membranous Inflammations," by W. H. Park; "Report of a Recent Sanitary Inspection of One of the Sources of the Croton Water-supply," and "A Consideration of Artesian Well and Surface Waters, from the Standpoint of Bacteriology and Public Health," by T. M. Cheesman; "Observations on a Case of Recurrent Amebic Dysentery, with Successive Large Hepatic Abscesses," by J. W. Brannan; "A Contribution to the Pathology of Traumatic Epilepsy," by Ira van Gieson; "Sterilization of Milk at 75° C. (Pasteurization) and its Efficiency in Destroying Pathogenic Organisms," by R. G. Freeman; "A Study on the Etiology of Exudative Pleuritis," by T. M. Prudden; "A Study of the Leukocytosis of Lobar Pneumonia," by James Ewing; "On the Etiology of Appendicitis," by Eugene Hodenpyl.

TEXT-BOOK OF NORMAL HISTOLOGY: INCLUDING AN ACCOUNT OF THE DEVELOPMENT OF THE TISSUES AND OF THE ORGANS. By GEORGE A. PIERSOL, M.D. Philadelphia: J. B. Lippincott Company, 1893.

DR. PIERSOL is so well known as a teacher of histology that a book from his pen will at once receive a cordial reception. The work before us leaves little to desire. In clearness and at the same time conciseness of expression it is a model; and the illustrations, so important in a work of this kind, are most excellent. Nearly all of them were drawn by the author himself from microphotographs or with the aid of a camera lucida. It is needless to call attention to the separate portions of the book, excepting to point out one or two novel features. The plan of including a short account of the development of the tissues and the organs at the end of the various chapters will meet with general approval. The description of the cell and of the structure of tissues in general is especially clear and interesting. Of the chapters devoted to special tissues we are particularly attracted to those concerning the nervous system. This book is undoubtedly the most useful smaller work on histology in our language.

THE POST MAGAZINE ALMANACK, THE INSURANCE DIRECTORY, REFERENCE, AND YEAR-BOOK: Containing Statistics and Facts of Ordinary Life, Industrial Life, Fire and Accident Insurance. London: T. J. W. Buckley, 1894.

THIS volume of one hundred and ninety-one pages will prove of special interest to insurance men in England and on the Continent, as is evidenced by the table of contents. In this we note, among others, the following subjects: Foreign Offices Opened in London; British Companies Ceased to Exist; British Life Business in 1892; Registration Fees, Licenses, and Taxes; House of Lords; House of Commons; Actuarial Institutions; New Companies; Directory of British Insurance Offices; Statutes relating to Life Insurance; Rates of Premium; Synopses of Ordinary Life, Industrial, Fire, and Accident Accounts; Synopsis of Accounts of Continental Insurance Companies; British Insurance Companies in Canada and America. There is also a complete Calendar for 1894, with Historical Memoranda. The book must fully answer the purpose for which it was published.

OUTLINE OF PHYSICAL DIAGNOSIS OF THE THORAX. By ARTHUR M. CORWIN, A.M., M.D., Demonstrator of Physical Diagnosis in Rush Medical College, etc. Pp. 111. Chicago: W. T. Keener Company, 1893.

THIS little book may find a limited usefulness in the ward-class or recitation-room as a stimulus to a flagging memory It teaches nothing that the student should not be familiar with from other sources, although it groups in concise and convenient form the method, the course, and the results of physical examination of the chest. Failing to possess the knowledge that the use of this

book presupposes, the student can scarcely do worse than to hope to profit by memorizing its contents.

THE PHYSICIAN'S WIFE AND THE THINGS THAT PERTAIN TO HER LIFE. By ELLEN M. FIREBAUGH. 8vo, pp. xi, 186. Philadelphia: The F. A. Davis Company. London: F. J. Rebman, 1894.

THIS neatly printed little volume details many of the experiences that are wont to happen in the domestic life of the country doctor. The delineation is faithful, the narrative interesting, the illustrations appropriate. The book is perhaps best adapted for those to whom it is dedicated, physicians' wives, but it should prove instructive and entertaining to all intelligent persons.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Fifth Session, held at West Point, N. Y., May 24, 25, and 26, 1893. Edited by FLOYD M. CRANDALL, M.D. Vol. V. Printed by Bailey & Fairchild, 1893.

THIS volume contains twenty-eight papers by representative pediatrists of this country, and does not call for extended comment here, inasmuch as a *rêsumê* of the proceedings of the meeting was presented in THE NEWS for June 10, 1893, p. 637. It remains but to state the work does credit to the body from which it emanates.

BRAITHWAITE'S RETROSPECT OF MEDICINE, for the six months ending December, 1893, is out promptly. Vol. CVIII maintains the distinctive features of its predecessors. The selections have been carefully made, the synopsis is good, and the index full. The preservation of the exact words of authors, while it diminishes the number of articles referred to, increases in many cases the value of the reference. We are gratified to note the number of citations from THE MEDICAL NEWS and *The American Journal of the Medical Sciences*.

CORRESPONDENCE.

PALATE-HOOK.

To the Editor of THE MEDICAL NEWS,

SIR: The palate-hook, or retractor, figured in THE MEDICAL NEWS of May 26, 1894, p. 574, and described by Dr. A. H. Cleveland, was invented in 1889, by Dr. F. Sohon, of this city, while a student under the late Professor Schnitzler, of Vienna. It was described and recommended by Professor Schnitzler in his *Klinischer Atlas der Laryngologie und Rhinologie*, p. 29 (Wien, 1891).

Very respectfully,

W. H. COFFRON.

5 TENNESSEE AVE., N. E., WASHINGTON, D. C.

NEWS ITEMS.

Changes at the Medico Chirurgical Hospital.—At a recent meeting of the Board of Trustees of the Medico-Chirurgical College the following appointments were made: Dr. Isaac Ott, of Easton, Pa., Professor of Physiology; Dr. William E. Hughes, Professor of Clinical Medicine; Dr. Albert E. Roussel, Assistant Professor of Clinical Medcine, and of Practice of Medicine; Dr. Charles W. Burr, Clinical Professor of Nervous Diseases; Dr. William C. Hollopeter, Clinical Professor of Diseases of Children; Dr. Arthur H. Cleveland, Clinical Professor of Laryngology; Dr. Edward B. Gleason, Clinical Professor of Otology, and Dr. William Blair Stewart, Lecturer in Therapeutics.

Professor Edwin J. Houston and Dr. Henry Fisher were elected members of the Board of Trustees.

Cholera in Europe.—A dispatch from Paris states that sixty cases and fifteen deaths from cholera have occurred at Jemmapes, near Liége, Belgium.

Jemmapes is a town in the province of Hainaut, on the Haine River and on the canal from Mons to Conde. Mons is the nearest large city. It is fifty miles distant from Antwerp and close to the French frontier. The place has a population of 13,000 engaged in brewing, tanning, and coal-mining.

The Railway Surgeon is a new bi-weekly publication, issued from Chicago as the official organ of the National Association of Railway Surgeons, and edited by Dr. R. Harvey Reed.

Dr. A. P. Ohlmacher has been elected Professor of Pathology and Bacteriology in the Medical Department of the University of Wooster.

Dr. John S. Billings has been made Lieutenant-Colonel and Deputy Surgeon-General of the United States Army.

Chloroform and morphin in the treatment of chorea, 494
Chlorphenols and bromphenols, treatment of erysipelas with, 150
Cholera, epidemics of, occurrence of definite types of, 329
Chorea, chloroform and morphin in the treatment of, 494
during pregnancy, 431
Cigars, infection through, 303
Circulation, mode of controlling, through the abdominal aorta, 103
Clamp, new, for repairing intestinal injuries, 666
Clark, sarcoma of the nose; epithelioma of the larynx in a woman, 716
Cleveland, A. H., a new form of palate-hook, 574
epithelioma of the soft palate, 458
Medical Society, 221
Ohio, medical progress in, 335
Climatology of New Mexico and Arizona, 166
Club-foot, congenital, spontaneous recovery from, 430
Coagulation-necrosis, diffuse, in the spleen, following thrombosis in typhoid fever and pneumonia, 325
Cocain-anesthesia, to render it safe, 104
Code-revision, Dr. N. S. Davis, on, 435
Coffman, malarial insanity, 391
Coffron, palate-hook, 724
Cohen, J. Solis-, sarcoma of tonsil, evulsion through the mouth, 99
S. Solis-, pulmonary tuberculosis, 486
Colchicum-poisoning, 457
Colic, appendicular, 494
Colleges, American medical, statistics of the attendance of, 417
medical, teaching of chemistry in, 697
Collodion, salicylated, for lupus, 298
Colostrum and milk of nursing women, changes in, induced by disease, 635
Communications, privileged, 191
Compression of the spinal cord by echinococci, 131
Congelation in diagnosis and treatment, 576
Congress, third triennial, of American Physicians and Surgeons, 604
Constipation, toxins in the urine during, 520
Consultation-fees, attending physicians and, 668
Contagious, infectious and, 222, 277
Convalescent-homes, 416
Coplin, the element of malignancy in tumors, 482
Copyrights on books and patents on instruments, difference between, 669
Cornett, a case of paroxysmal tachycardia of long standing relieved by the use of beechwood creosote, 239
Coronary arteries, effects of ligature of, 298
Coroner, to abolish the office of, 135
Correspondence, London, 249, 278, 500
Coryza, for, 150
for acute, 216
Cover-glasses, slides, soiled, to clean, 576
Cramming in our medical schools, 661
Craniectomy, circular, 48
Craniotomy, Cesarean section, and symphysiotomy fairly considered as obstetric expedients, 495
Cremation, argument for, 54
Creosote, fatal intoxication with medicinal doses of, 635
Crile, fracture of the base of the skull; recovery, 12
Criminality, hereditary, how to stop, 525
Cryer, a spiral osteotome for opening the skull in brain-surgery, 12
Cumston, multiple deviations of both legs in a rachitic child; osteotomy of five bones in one seance; recovery, 100
Cunningham, the morbidity and mortality of negro convicts, 113
Current, interrupted high-voltage, primary or mixed, 120
Curvature, lateral, of the spine, treatment of, 274
Cystinuria, in four members of one family, 635
Cystotomy, suprapubic, 124
in an infant two years old, 575

DABNEY, the administration of a glycerin solution of mercuric chlorid as a prophylactic measure against diphtheria, 183
Da Costa, J. Chalmers, the identification of the large and small intestine, 634
J. M., acute appendicitis, 566
clinical remarks on the external use of guaiacol in reducing high temperature in typhoid fever and other febrile diseases, 85
the treatment of nephritis, 425
Dandridge, report of two cases of amputation at the hip-joint in which hemorrhage was controlled by transfixion-pins and elastic compression, 72
Danforth, the prognostic significance of tube-casts, 176
Darnall, the treatment of ptomaïn-poisoning by means of subcutaneous injections of blood-serum, 46
Davis, A. M., extravasation of urine; external perineal urethrotomy without a guide; death from uremia, 492
E. P., cesarean section and symphysiotomy for the relative indications, with a report of cases, 401
fatal nausea and vomiting of pregnancy, with report of cases, 597
G. G., operations for the correction of inveterate pes varus, 141
J. D. S., the management of the epicystic fistula in prostatic enlargement, 70
T. C., chorea during pregnancy, 431
Death-rates, city, comparison of, 81
sudden, due to ascending neuritis, 1
Deaver, acute appendicitis, 533, 566
chronic appendicitis, 655
hallux valgus, 39
Delirium, acute, with autopsy and bacteriologic examination of cerebro-spinal fluid, 718
Dentistry, old-time and modern, 334
Depravity, moral, does not legally establish mental insanity, 18
Development, arrested, 503
Deviations, multiple, of both legs in a rachitic child, 100
Diabetes, guaiacol in, 412
mellitus, knee-jerk in, 271
sudden blindness in the course of, in young persons, 216
Diabetics, a bread for, 391
Diachylon ointment, poisoning by, 242
Dietaries, study of, 303
Di-iodoform, 14
Diphtheria, 67
allocheiria in the sequence of, 298
cultures, detailed directions for a simplified method of preparing Loeffler's blood-serum medium for, 352
glycerin solution of mercuric chlorid as a prophylactic against, 183
of the external auditory canal, 242
prophylactic and germicidal treatment of, 270
some practical points in the treatment of, by calomel-fumigations, 505
Dispensary, legal, 108
Dodge, intestinal anastomosis, 694
six cases of appendicitis, 508
Downes, a portable tray instrument-sterilizer, 459
Drinking-water, bacteriologic examination of, 217
Drunkenness and insanity, difference of presumptions as to, 416
Dulles, report on hydrophobia, 653
Duncan, shall the term auto-infection be retained, 313
Dysphagia of laryngeal tuberculosis, for, 328
Dysentery, for, 384
Dysmenorrhea, 355

EAR-SCREW, for the removal of foreign bodies, 101
Eastman, address of the chairman of the section of obstetrics and diseases of women, American Medical Association, 629
Echinococcus of the liver, injections of mercuric chlorid in the treatment of, 520
Eclampsia, puerperal, induced labor as related to, 258
Eczema, etiology of, 35
seborrheic, 298
vesicular, internal remedies for, 186
Editor blesses the advertisers, 80
Education, for higher medical, 699
higher medical, a proposal in the interests of, 316
physical, 173
Elbow-joint, ankylosis of, with dislocation of the radius, 291
Elephantiasis, 712
Elevate to a pure and ethical plane, 434
Emmenagogue, oxalic acid as, 12
Emphysema, non-traumatic subcutaneous, 519
Empyema, dressing of, after Estlander's operation, 234
treatment of, in childhood, 272
Engelmann, the interrupted high-voltage, primary or mixed, current, 120
Enteric fever, perforation, peritonitis; recovery, 271
Enteritis, membranous, in young child, 215
Enterprise, journalistic and professional, 81
Enuresis, quinin for, 550
Epiglottis, new, formation of, 722
Epilepsy, for, 132
or hysteria, 390
traumatic, trephining as a cure for, 204
Epileptics, New York colony for, 554
Epiplocele, 374
Epithelioma of the face, sulphuric-acid paste in the treatment of, 573

Erck, a case of purpura rheumatica, with edema of genitalia in a mulatto girl, 352
Error, great medical, of the day, 19
Erysipelas, guaiacol in the treatment of, 567
scrotal, 306
treatment of, with chlorphenols and bromphenols, 150
Erythromelalgia, 356
Eshner, congenital absence of the gall-bladder, 548
influenza followed by pleuritis and endocarditis, 148
Eskridge, bilateral cerebral thrombosis due to syphilitic arteritis, with incontinence of the vesical and anal sphincters, 7
tumor of brain simulating a vascular lesion, with an account of the autopsy, and remarks, 261
Esophagotomy for the removal of a buckeye-nut, 98
Esophagus, esophagotomy, and gastrotomy for removal of denture from, 493
rupture of, 516
Estes, gold-foil in the shape of a conical cup introduced into a lacerated cavity of the cerebrum for the purpose of permanently stopping the outflow of cerebral tissue and closing a hole in the membranes, 267
Examiners, medical, 138
medical, State Board of, 108
Extracts, organic, therapeutic uses of, 76
Extravasation of urine, 492

FARIES, physical education, 173
Favus, for, 636
Fees, medical, in France, 722
Feld, a case of tetanus, 473
Femoral vein, common, results and treatment of wounds of, at Poupart's ligament, 185
Ferguson, five cases of sudden death due to ascending neuritis, 1
Ferratin, 387
Fetation, simultaneous intra-uterine and extra-uterine, 416
Fetus, hydrocephalic; rupture of the uterus; removal; recovery, 383
Fibroid processes, relative frequency of, in the dark-skinned races, 29
uterine, 454
Fibro-lipoma, 234
Fingers, congenital hypertrophy of, 294
Fistula, epicystic, management of, in prostatic enlargement, 70
in ano, 291
in ano, radical cure of, 720
Flick, the transmissibility of tuberculosis, 701
Food, useless and expensive adulterations of, 415
Foot, congenital hypertrophy of, 296
Football at West Point, 250, 366
perils of, 415
reform, promised, 53
Forbes, the removal of stone in the bladder, 681
Fowler, a case of fibro-cystic myoma removed at the third celiotomy, 98
Fracture-box, improved, for the repair of injuries of the lower extremities requiring extension and counter-extension, 664
compound, of the leg, 543
comminuted, of the frontal and ethmoid bones; injury to the meninges; laceration and protrusion of brain substance, 456
simple, of the thigh, 543
Fractures of the lower end of the radius, new method for reduction of, 695
Frictions of the feet as a resuscitating measure, 696

GALL-BLADDER, congenital absence of, 548
Galvano-puncture for hypertrophied tonsils, 419
Gangrene of the foot, 44
Gastric affections, various, potassium bichromate in the treatment of, 550
juice and intestinal putrefaction, relation between, 636
Gastroplication, 636
Genu valgum, 291
Glycosuria during infancy, 14
of nasal origin, 550
Goiter, 291
Gold-cure, mental derangement with extreme prostration following, 408
foil introduced into a lacerated cavity of the cerebrum for the purpose of permanently stopping the outflow of cerebral tissue and closing a hole in the membrane, 267
Gordinier, injury to the cauda equina, probably due to intra-meningeal hemorrhage, with recovery, 405
Gould, an arrangement of prisms for testing adduction, abduction, exophoria, and esophoria, 130
Gout, English and German views of, 187
Gradle, the causes and treatment of migraine, 230
Graham, the vectis in vertex-posterior positions of the fetus, 382
Grayson, carcinoma of the larynx, with consecutive epithelioma of the lip, 378
Greene, death in the Nile, 201
Gregg and Moreland, practical applications of potassium permanganate as an antidote to laudanum, 491
Guaiacol, applications of, in the treatment of orchitis, 550
external application of, to reduce febrile temperature, 216
external use of, in reducing high temperature in typhoid fever and other febrile diseases, 85
in diabetes, 412
in the treatment of erysipelas, 576
value of, applied externally as an antipyretic, 343

HALLUX valgus, 39
Hamilton, A. McL., insanity characterized by dominant concepts, with presentation of cases of an unusual form, 57
C. H., prophylactic and germicidal treatment of diphtheria, 270
J. B., osteitis: fistula in ano: goiter; hygroma; carcinoma of the stomach; sebaceous cyst; rachitis; genu valgum; congenital torticollis; ankylosis of the elbow-joint with dislocation of the radius, 201
W. D., esophagotomy for the removal of a buckeye-nut, 98
Hammond, three cases of attic suppuration in which operation was followed by facial paralysis (Bell's palsy), 572
Hancock, a case of quinin-idiosyncrasy, 271
Hand, changes in, fifteen years after division of the median nerve, 382
Hand, A., acetanilid as a surgical dressing, 269
Hansell, two cases of functional nervous disease treated by tenotomy of the superior and inferior rectus muscles, 237
Hart, Mrs. Ernest, 136
Hay-fever, new and successful treatment of, 197
Haynes, a uterine irrigating-tube, 518
orchectomy for hypertrophy of the prostate, 224
Heagey, hydatidiform mole, report of a case, 381
Health, authority of boards of, to suppress nuisances, 79
national bureau of, 109
Health-ordinances, administration of, 139
public, popular beverages and, 385
public, proposed national bureau of, 359
Heart, disease of, chronic valvular, 709
-disease, the relation of, to menstruation, 460
-exhaustion, cardiac asthenia or, 497
Hektoen, diffuse coagulation-necrosis in the spleen following thrombosis in typhoid fever and pneumonia, 325
Hemeralopia, 328
Hemianopsia, fleeting, of syphilitic origin, 719
Hemorrhage, extra-dural, trephining for, 44
fatal secondary, following removal of faucial and pharyngeal tonsils, 411
gastro-intestinal in the newborn, 424
spinal, 374
Hemorrhoids, for, 636
Hernia, radical cure of, 104
Herpes zoster, showing erythematous, papular, and vesicular stages, 428
Herrick, laminectomy, 362
Hibberd, president's address, 625
Hill, elephantiasis, 712
Hingston, stone in the bladder; choice of operation, 663
Hirst, a coincident intra-uterine and extra-uterine pregnancy; two cases of obliquely contracted pelvis; the primary repair of a lacerated perineum; stricture of the rectum following a Whitehead operation for hemorrhoids, 347
two recent additions to the teratologic collection in the Wistar and Horner Museum of the University of Pennsylvania; specimens of acephalus and of micromelus, 184
Histology or obstetrics, 529
Historic case, 251
History of medicine, plea for chairs of, in medical colleges, 503
Holmes, a proposal in the interest of higher medical education, 316
Home Missionary Society, 434
Homeopathy, preposterous claims of, 335
Hospitals and the profession, 19
medical profession and, 54
Hudnut, galvano-puncture for hypertrophied tonsils, 419
Humerus, suspected fracture of, 234
Hurd, the physician in literature, 41
Hydrocephalus, chronic, basal drainage for, 103
Hydrogen arsenid, fatal intoxication with, 13
dioxid, commercial forms of, 288
Hydronephrosis, congenital, cured by nephrectomy, 328
intermittent, cured by simple puncture, 216
Hydrophobia, report on, 653
Hygiene, physiology and, teaching of, in the public schools, 357
Hygroma, 291
Hyperemesis gravidarum, 47
Hypnotism and suggestion in practice, 433
Hysterectomy for other conditions than fibroid and malignant tumors, 289
vaginal, for carcinoma of the uterus performed by enucleation without hemorrhage, 146
in a woman sixty-six years old, 695
operation of, by enucleation, due to Langenbeck, 223
Hysteria, diagnosis of, 521
epilepsy or, 350
the visual fields in cases of, 149
toxic, 331

IDIOCY, study of, at Elwyn, 301
Inch-and-a-half incision and week-and-a-half confinement in appendicitis, 375
Incus, removal of, chronic tinnitus aurum and tympanic vertigo relieved by, 452

Inebriety, American quack-cures for, 417
as a disease analytically studied, 690
Infancy, migraine in, 554
Infectious and contagious, 222, 277
Influenza, 49
followed by pleuritis and endocarditis, 148
for, 48, 216, 412
Ingrowing hairs, 271
Injury, exciting cause of, viewed legally, 80
Insane, care of, 299
reforms in care and treatment of, 578
reforms in the treatment of, 275
training of nurses for care of, 669
Insanities characterized by dominant concepts, 57
Insanity cured by quinin, 270
drunkenness and, difference of presumptions as to, 416
malarial, 391
Inscription, an, 525
Instrument-sterilizer, portable tray, 459
International sanitary conference, 219
Intestinal anastomosis, 694
injuries, new clamp for repairing, 666
putrefaction, gastric juice and, relation between, 636
Intestine, identification of the large and small, 634
Intoxicants, medicinal preparations as, 18
Intoxication, effect of, on testamentary capacity, 18
Iodo-caffein, iodo-thein, iodo-theobromin, 76
Irrigation of the urethra and bladder without a catheter, 659

JOHNSON, suicides, 540
Johnston, puerperal fever, the contagion of, 111
Jones, puerperal fever, complicated with embolic pneumonia and phlegmasia dolens; recovery, 351
Journal of the American Medical Association, conduct of, 463
personalties in, 389
Journalism, English and American, compared, 137
Judicial council, now the, 577

KATATONIA, 253
Keen, football at West Point, 250, 336
Keller, two cases of traumatic intestinal perforation, with recovery, 46
Kerr, a case of rupture of the lung, unassociated with fracture of the ribs, with early subsequent recovery, 214
Kidney, new method of examining, especially for stone, 214
King, Clarence, Bright's disease in children, 421
E. H., an unusual accident after celiotomy, 409
Knee-jerks, return of, in posterior spinal sclerosis, 519
Knowles, acetanilid as a surgical dressing in veterinary practice, 419
Koehler, a bread for diabetics, 391
Konkle, gastro-intestinal hemorrhage in the newborn, 424
Kuh, E. J., galvano-puncture for hypertrophied tonsils, 307
Sydney, the pathology of locomotor ataxy, 227
Kyle, the etiology, pathology, and treatment of ozena, 484

LABOR, induced, as related to puerperal eclampsia, 258
ordinary, conduct of, through external examinations solely, 297
Lactophenin, treatment of typhoid fever with, 461
Laminectomy, 362
Laminectomy, cases of, for spinal fracture, 265
for fracture of dorsal vertebra, 633
Laryngeal tuberculosis, for the dysphagia of, 328
Laryngismus stridulus, for, 507
Larynx, carcinoma of, with consecutive epithelioma of the lip, 378
epithelioma of, in a woman, 716
extirpation of, 302
hyoid bone, and five rings of trachea, excision of, for malignant disease, 326
pulsation of, due to arterial anomalies, 131
Laudanum, potassium permanganate as an antidote to, 491
Lautenbach, a new tongue-depressor and an ear-screw for the removal of foreign bodies, 101
Laws of Alabama, 304
State licensing, a desirable amendment to, 579
Lawyers, when they disagree, who shall decide, 667
Laxative, agreeable, 48
carbonated, 104
Lead-poisoning from tea, 14
Leffmann, the commercial forms of hydrogen dioxid, 288
Leidy, multiple thrombosis of the circle of Willis, 129
Lepra, erythema of, containing giant-cell-like structures, simulating somewhat the giant-cells found in tuberculosis, 406
Leprosy, contagiousness of, 151
national control of, 657
Leuf, the effect of athletics in the Philadelphia preparatory schools as to mental and moral character, 368
Leukopathia unguium, 212
Liability for injuries when death follows surgical operations, 220
of railroad corporations for negligence of physicians, 135
of the husband for medical attendance upon the wife, 221
Libraries, public medical, need of, 52
Ligature, effects of, of the coronary arteries, 298
Lithemia, pathology of, 300
Liver, acute yellow atrophy of, in a child, 355
and spleen, relative weight of, in mammals, 519
Locomotor ataxia, pathology of, 227
Lung, rupture of, unassociated with fracture of the ribs, with early subsequent recovery, 214
abscess, three cases of, 61
Lupus, salicylated collodion for, 298

MAGNESIUM sulphate hypodermatically as a purgative, 104
Malignancy in tumors, 482
Mammals, relative weight of liver and spleen in, 520
Mann, cyst of the broad ligament from a patient sixty years old; carcinoma of the body of the uterus; uterine fibroid, 454
Mastoid disease, diagnostic symptom of, 412
Mattice, pneumonia followed by mania, 624
Maxilla, superior, tumors of, 233
McDowell, Dr. Ephraim, memorial address in honor of, 179
McFarland, the etiology of carcinoma, 371
McLoughlin, compound comminuted fracture of the frontal and ethmoid bones, with injury to the meninges, and laceration and protrusion of the brain-substance; recovery, 456
McMurtry, memorial address in honor of Dr. Ephraim McDowell, 179
McPhedran, a case of gold-cure; mental derangement with extreme prostration following, 408
Meat-extracts, 54
supply, milk-supply and, municipal supervision of, 54
Medicine, an opprobium of, 194
Medicines, patent, use of, as evidence of legal want of care, 80
proprietary, taxing, 136
Melæna neonatorum, etiology of, 132
Meningitis, tuberculous, successful treatment of, by trephining and drainage of the sub-arachnoid space, 410
Menopause or presbyopia, 152
some neuroses associated with, 75
Menstruation and ovulation, 432
the relation of heart-disease to, 460
Mercuric chlorid, injections of, in the treatment of echinococcus of the liver, 520
Mercurials, treatment of syphilis by hypodermatic injections of, 636
Merycism, 494
Methylene-blue in beri-beri, 48
Micromelus, specimen of, 184
Microphotograph, 108
Micturition, normal, function of the muscular coat of the bladder in, 550
Migraine, causes and treatment of, 230
for, 132
in infancy, 554
Milk, colostrum and, of nursing women, changes in, induced by disease, 635
-control, rational, 637
-supply and meat-supply, municipal supervision of, 54
Mind, unsoundness of, and incapacity for business are co-relative, 334
Minority report, 524
rule in a democratic form of government, 153
Mitchell, concerning the history of the discovery of reflex ocular neuroses, and the extent to which these reflexes obtain, 449
notes on surface-temperatures as affected by posture of limbs, 6
Mole, hydatidiform, 381
Monstrosity, 503
Montgomery, atheroma, 178
an erythema of lepra containing giant-cell-like structures, simulating somewhat the giant-cells found in tuberculosis, 406
Morality and English are much alike, 277
Morphin, elimination through the saliva of, subcutaneously injected, 76
potassium permanganate as an antidote to, 699
recovery from toxic doses of, 70
sulphate of, attempted suicide by, treated by permanganate of potassium, 380
Morphology as a factor in the study of disease, 589
Morris, the inch-and-a-half incision and week-and-a-half confinement in appendicitis, 375
Morrison, extra-uterine pregnancy simulated by small tumor of the ovary; operation; recovery, 571
Morton, two cases of congenital hypertrophy of the fingers, 294
Moyer, a case of colchicum-poisoning, 457
congenital ptosis; traumatic paralysis of the leg; neuritis following influenza; spasm of the muscles of the forearm, with trophic changes, 207
Mundé, enucleation of the uterus, 502
Munn, phimosis and the conditions that it complicates in the adult, 322
Mydriatic, necessity of, in prescribing glasses, 361
Myoma, fibro-cystic, removed at the third celiotomy, 98

NAUSEA and vomiting of pregnancy, fatal, with report of cases, 597
Negro convicts, morbidity and mortality of, 113
mortality of, 389
Nephrectomy, congenital hydronephrosis cured by, 328
Nephritis, non-albuminous, a form of, other than typical fibroid kidney, 393
treatment of, 425
without albuminuria, 111
Nervous disease, functional, treated by tenotomy of the superior and inferior rectus muscles, 237
Neuralgia, for, 14
Neuritis, arsenical peripheral, 14
ascending, five cases of sudden death due to, 1
following influenza, 207
sciatic, pathogeny and treatment of, 576
Neuroses, 413
reflex ocular, concerning the history of the discovery of, and the extent to which these reflexes obtain, 449
some, associated with menopause, 75
Neurosis, stonemason's, 272
Newborn, gastro-intestinal hemorrhage in, 424
Nile, death in, 201
Nitrogen, amount of, contained in the red blood-corpuscles in health and disease, 696
Nomenclature of chemic terms, 77
Nose, sarcoma of, 716
Nostrums, Carolina physicians and, 524
Nurses, training of, for care of insane, 669

OBSTETRICS, histology of, 529
Obstruction, intestinal, by a biliary calculus, celiotomy for, 460
Ohlmacher, detailed directions for a simplified method of preparing Löffler's blood-serum medium for diphtheria-cultures, 352
Oil, injection and congelation of, for the control of muscular spasm, 520
Operations, two well-known, new ideas with reference to, 169
Ophthalmia, blennorrhagic, quinin locally in the treatment of, 696
Opium and its alkaloids, potassium permanganate as an antidote to, 186
and its derivatives, recovery from toxic doses of, 669
poisoning, four cases of, in which potassium permanganate was administered, 514
Orchectomy for hypertrophy of the prostate, 224
Orchitis, applications of guaiacol in the treatment of, 550
Organic matters, various, influence of, upon the bodily temperature, 603
Osler, the army surgeon, 318
Osteitis, 291
Osteomyelitic process, latent circumscribed, virulent staphylococci in, after many years, 411
Osteotome, spiral, for opening the skull in brain-surgery, 12
Ostrich, human, 665
Ott, fifteen years' observation among beer-drinkers, 4
Outhouses, school, 136
Ovary, dermoid cyst of, simulating appendicitis, 324
small tumor of, extra-uterine pregnancy simulated by, 571
Overcrowding in the medical profession, 246
Oversight, singular, 247
Ovulation, menstruation and, 432
Oxalic acid as an emmenagogue, 12
Ozena, etiology, pathology, and treatment of, 484

PACKARD, pistolshot wound of the neck; gangrene of the foot; vesical calculus in the female; trephining for extradural hemorrhage, 44
Palate-hook, 724
a new form of, 574
soft, epithelioma of, 458
Palsy, inferior maxillary, with loss of taste, 384
Pancreas, large suppurating cyst of, 377
traumatic cyst of, 356
Paralysis agitans, pathology of, 388
facial, three cases of attic suppuration in which operation was followed by, 572
of diaphragm, 411
of the leg, 207
partial, of the ocular muscles from injury to the head, 130
peripheral facial, 309
pseudo-hypertrophic, five cases of, in one family, 356
Paraplegia due to Pott's disease, 543
Paraxanthin as a factor in the etiology of certain obscure nervous conditions, 561
Paretic dementia at puberty, 131
Paris, quinin-idiosyncrasy, 419
Park, extra-articular abscess near the hip; compound fracture of the leg; simple fracture of the thigh; paraplegia due to Pott's disease, 543
spinal hemorrhage; epiplocele; resection of leg for compound fracture of tibia; ununited after a month, 374
talipes planus; suspected fracture of humerus; fibro-lipoma; dressing of empyema after Estlander's operation, 234
two further suggestions for the relief of ingrowing toe-nail, 110
Patek, two cases of rupture of the esophagus, 516
typhoid fever complicated by twin abortion, recovery, 325
and Hand, two attacks of typhoid fever in the same person, 409
Patella, treatment of fracture of, by arthrotomy and metallic suture, 494
Patents on instruments, copyrights on books and, difference between, 669
Pelvis, obliquely contracted, two cases of, 347
Pen and holder swallowed, 272
Penis, tuberculosis of, 186
Pennell, a monstrosity, 503
Penrose, a case of primary carcinoma of the body of a divided uterus, 238
hysterectomy for other conditions than fibroid and malignant tumors, 289
Pepper, Dr., resignation of of the office of provost of the University of Pennsylvania, 463
Peptonuria, 519
Perforation from gastric ulcer, surgical treatment of, 387
traumatic intestinal, 46
Perineum, lacerated, primary repair of, 347
Pershing, epilepsy or hysteria, 390
Pes varus, inveterate, operations for the correction of, 141
Pharmacy act declared unconstitutional, 247
Phelps, inebriety as a disease analytically studied, 690
Phenol-elimination in disease, 432
Phimosis and the conditions that it complicates in the adult, 322
Phlebitis, advanced, with calcareous degeneration, 404
Photomicrograph, 108
Physician, a royal, 213
as a sociologic factor, 78
country, one of the difficulties of, 333
in literature, 41
Physicians, attending and consultation fees, 668
Physicians of Ohio, 81
should they charge each other for medical services, 154
Physiology and hygiene, teaching of, in the public schools, 357
Pigmentation of the whole surface of the body occurring suddenly during the treatment of a case of psoriasis, 127
Pistolshot wound of the neck, 44
Pityriasis auris, treatment of, 150
Pleurisy, atrophy of shoulder-muscles in the sequence of, 327
Pneumonia, differential diagnosis of, from bronchitis, safranin-reaction as an aid to, 462
followed by mania, 236, 624
transient aphasia in the course of, 190
Policy, right, and the right principle, 220
Post-mortem injury, duplication of the spinal cord as a result of, 545
Potassium bichromate in the treatment of various gastric affections, 550
permanganate as an antidote to laudanum, 491
as an antidote to morphin, 699
as an antidote to opium and its alkaloids, 186
attempted suicide by sulphate of morphin treated by, 380
Potts, a case of acute delirium, with autopsy and bacteriologic examination of cerebro-spinal fluid, 718
disease, paraplegia due to, 543
Pregnancy, chorea during, 431
coincident intra-uterine and extra-uterine, 347
extra-uterine, simulated by small tumor of the ovary, 571
fatal nausea and vomiting of, with report of cases, 597
pernicious anemia following, 701
Presbyopia, menopause or, 152
President's address, 625
Press, quacks, and public, 221
Price, the incision in abdominal section, how to close it, and its post-operative complications, 64
Prisms, arrangement of, for testing adduction, abduction, exophoria, and esophoria, 130
Profession, medical, and the Pension Bureau, 415
medical, its own worst enemy, 462
Prolapse of the iris, to prevent, in simple extraction of the lens, 666
Prostate, hypertrophy of, a summary of the history and present position of the operation of castration for, 601
Prostatic enlargement, management of epicystic fistula in, 70
Prostatitis, for, 132
Pruritus, for, 104
vulvæ, for, 132
Psoriasis, pigmentation of the whole surface of the body occurring suddenly during treatment of, 127
syphilitic, thyroid extract in the treatment of, 186
Ptomaïn-poisoning, treatment of, by means of subcutaneous injections of blood-serum, 46
Ptosis, congenital, 207
Puerperal fever, complicated with embolic pneumonia and phlegmasia dolens, 351
fever, the contagion of, 111
Pulmonary second sound, accentuation of, in typhlitis, 451
Purpura rheumatica, with edema of the genitalia in a mulatto child, 352
Pyle, four cases of opium-poisoning in which potassium permanganate was administered, 514
Pyloroplasty, successful, 410
Pylorus, constricted, successful dilatation of, 242

Pylorus, resection of, functional activity of the stomach after, 603

QUACK medical advertisements refused, 233
Quackery, attenuated, 498
sectarianism and, affinity between, 97
Quacks, illegally practising, professional tolerance of, 463
Quinin for enuresis, 550
-idiosyncrasy, 271, 419, 529
locally in the treatment of blennorrhagic ophthalmia, 696

RACHFORD, paraxanthin as a factor in the etiology of certain obscure nervous conditions, 561
Rachitis, 291
Radius, dislocation of, ankylosis of the elbow-joint with, 291
fractures of lower end of, new method of reduction of, 695
fractures of the lower end of, with forward displacement of the carpal fragment, 391
Raia, three cases of partial paralysis of ocular muscles from injury to head, 130
Ramsey, a case of scrotal erysipelas, 306
Ravogli, the etiology of eczema, 35
Reading-notice evil, way to stop it, 81
Rectum, stricture of, following a Whitehead operation for hemorrhoids, 347
Reed, a fatal case of hyperemesis gravidarum, 47
Refractionist, 464
Reports, untrustworthy, of medical facts, 304
Resection of leg for compound fracture of tibia, ununited after a month, 374
Resuscitating measure, frictions of the feet as, 696
Retort courteous, 302
Reyburn, enucleation of the uterus, 529
operation of vaginal hysterectomy by enucleation due to Langenbeck, 223
vaginal hysterectomy for carcinoma of the uterus performed by enucleation without hemorrhage, 146

Symphysiotomy, 504
Cesarean section and, for the relative indications, 401
craniotomy, Cesarean section and, fairly considered as obstetric expedients, 495
in America, 191
Syphilis, reinfection with, 72
treatment of, by hypodermatic injections of mercurials, 636
Syphilitic origin, fleeting hemianopsia of, 719
tumors of the spinal cord, symptoms of syringomyelia from, 75
Syphilitics, changes in the blood of, 356
Syringomyelia, symptomatology of, 550
symptoms of, from syphilitic tumors of the spinal cord, 75

TACHYCARDIA, paroxysmal, of long standing, relieved by the use of beechwood creosote, 239
Talipes planus, 234
Talley, a note as to the use of oxalic acid as an emmenagogue, 12
Tartar emetic, large dose of, recovery from, 696
Taste, loss of, inferior maxillary palsy with, 384
Taylor, supra-pubic cystotomy, 124
Temperature, bodily, influence of the various organic matters upon, 603
febrile, external application of guaiacol to reduce, 216
high, external use of guaiacol, in reducing, in typhoid fever and other febrile diseases, 85
Tenotomy of the superior and inferior rectus muscles, functional nervous disease treated by, 237
Testimony, privileged, of physicians which cannot be stricken out, 334
Tetanus, 473
ammonium bromid for, 298
complicating vaccinia, 209
Texas, good news from, 524
Thallin periodid, treatment of carcinoma with, 432
Thayer, note on the value of guaiacol applied externally as an antipyretic, 343
Therapeutic enthusiasms, source of some, 53
Thompson, some remarks on the practical treatment of hepatic abscess, 117
Thorington, an axonometer, 240
Thrombosis, bilateral cerebral, due to syphilitic arteritis, with incontinence of the vesical and anal sphincters, 7
multiple, of the circle of Willis, 129
Thyroid extract in the treatment of syphilitic psoriasis, 186
tic douloureux, for, 666
therapy, possibilities of, 554
Tinea tricophytina, for, 132
Tinnitus aurium and tympanic vertigo, chronic, relieved by removal of incus, 452
Toe-nails, ingrowing, two further suggestions for the relief of, 110
Toms, tetanus complicating vaccinia, 209
Tongue-depressor, new, 101
Tonsil, sarcoma of, 99
Tonsillitis, acute, guaiacol topically in, 461
Tonsils, hypertrophied, galvano-puncture for, 307
Torticollis, congenital, 291
Tracy, a brief splint-technology for surgeons, 284
Tube-casts, prognostic significance of, 176
Tubercle-bacilli in house-dust, 150
-bacillus, two portals of entry for, 304
Tuberculosis of the bladder, 412
of the penis, 185
practical method of registration of, 307
prevention of, 524, 699
to prevent the spread of, 133, 224
transmissibility of, 701
treatment of, in the country, 328
pulmonary, 486
pulmonary, ammonium sulphichthyolate in the treatment of, 550
for, 14, 150, 432
infectiousness of, 105
the Falkenstein treatment of, 388
Tuberculous patients, seminal fluid of, 276
Tumors, element of malignancy in, 482
Typhlitis, accentuation of the pulmonary second sound in, 451
Typhoid fever, alpha naphthol in, 384
and other febrile diseases, external use of guaiacol in reducing high temperature in, 85
and pneumonia, thrombosis in, diffuse coagulation-necrosis in the spleen following, 325
complicated by diphtheria; tracheotomy; recovery, 666
by twin abortion, 325
mortality from, 575
relapses in, 432
relation of phlegmasia alba dolens in, to typhoid-bacilli, 432
the pathogenesis of the laryngeal complications of, 575
treatment of, by the ingestion of large quantities of water, 494
with lactophenin, 461
two attacks, of in same person, 409
without intestinal lesions, 192
Tyson, terms infectious and contagious, 222

ULCER, for gastric, 150
gastric, etiology of, 154
Understandings, insular, 463
Updegrove, the medical examiners, 136
Uretero-ureterostomy, 47
Urine, extravasation of, 492
of whooping cough, 721
toxins in, during constipation, 520
Urticaria, for, 696
Uteri, two distinct, a woman with, 241
Uterine irrigating-tube, 518
Uterus, carcinoma of the body of, 454
enucleation of 502, 529
primary carcinoma of the body of a divided, 238
rupture of, with recovery, 431
treatment of rupture of, 150
vaginal hysterectomy for carcinoma of, performed by enucleation without hemorrhage, 146

VACCINIA, tetanus complicating, 209
Valvular disease of the heart, chronic, 709
Van Hook, experimental reunion of the transversely divided vas deferens, 715
Vario a, confluent, treatment of, 583
Variolin, 192
Vas deferens, transversely divided, experimental reunion of, 715
Vectis in vertex-posterior positions of the fetus, 382
Vertigo, tympanic, and tinnitus aurium, chronic, relieved by removal of the incus, 452
Vinton, peripheral facial paralysis, 309

WALKER, case of attempted suicide by sulphate of morphin treated by permanganate of potassium; recovery, 380

Ward, new ideas with reference to two well-known operations, 169
Water, treatment of typhoid fever by ingestion of large quantities of, 494
Wharton, successful triple amputation, 350
White, a summary of the history and present position of the operation of castration for hypertrophy of the prostate, 601
Whooping-cough, urine of, 721
Wire-pullers, disgusting, 578
Wisdom, medico-legal, 525
Woman's work, proper sphere of, 498
Wotherspoon, a symphysiotomy, 504
Wounds, a physician can testify as to the effect of, merely described to him, 155
Wrongs, two, do not make one right, 551
Wroth, the climatology of New Mexico and Arizona, 166
Wyman, national control of leprosy, 657

YOUNG, spontaneous recovery from congenital club-foot, 430.
